

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### **Usage guidelines**

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

### **About Google Book Search**

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

The Publishers and the Editor-in-Chief will be grateful to reader this volume who will kindly call attention to any errors of omission or commission therein. It is intended to make our publications stand as works of study and reference, and, to that end, the greatest accuracy is sought. It rarely happens that the early editions of books are free from errors; but it is the endeavor of the Publishers to have them removed and it is therefore desired that the Editor-in-Chief may be aided in his task of revision, from time to time, by the kindly criticism of readers.

## PREFACE TO SECOND EDITION

The steady demand for this book since its first appearance in 1914 has shown conclusively that an encyclopedic handbook of Electrical Engineering is an indispensable tool to the engineer. Its use in a number of large universities has also shown that the encyclopedic arrangement is well adapted to the purposes of the class room.

Although in many respects electrical engineering practice to-day is much the same as it was in 1914, there have nevertheless been noteworthy developments in several branches of the industry, for example, in radio-communication, electric welding, electric ship propulsion, etc. Electrical science has also made considerable progress, especially in the development of the electron theory and its application to engineering.

In order to keep this Handbook abreast of the times, the publishers requested the editor in 1920 to undertake a thorough revision of the book. In line with this request, each article was submitted to the original contributor or other qualified person with the request that he go over it carefully, add new matter where the development of the art warranted, and bring the article up to date.

The result of this review was that nearly every article in the book has been revised, the amount of revision varying from a few lines to the entire article, according to the desires of the authors. While the greater part of the revisions appear in paragraphs interspersed throughout the book, new articles have been added on the following subjects:

Frequency Changers.

Ignition, Electric.

Phase Converters and Balancers.

Ships, Electric Propulsion of.

Starting and Lighting Systems for Automobiles.

Welding, Electric.

The following articles have been completely rewritten:

Ammeters.

Ampere-hour Meters.

Corona, Electric.

Dams.

Demand Meters.

Depreciation.

Electron Theory.

Heating and Cooking by Electricity.

Hydraulics.

Hydrology.

Insulating Materials.

Lighting of Trains by Electricity.

Oil, transformer.

Radio Communication (replacing the articles on Detectors, Electric Wave; Waves, Electromagnetic; Wave meters; Wireless Telegraphy and Wireless Telephony).

Standardization Rules and Standard Specifications.

Water Wheels and their Settings.

Water Wheels, Speed regulation of.

In addition to the above, extensive changes have been made in the following articles:

Alloys.

Buildings, Allowable Unit Stresses in.

Cross-Arms.

Electrolysis.  
 Frequency Indicators.  
 Generators, Alternating Current.  
 Grounding for Electric Circuits.  
 Heat and Thermal Properties.  
 Insulators, Overhead.  
 Lamps and Illumination.  
 Motors, Alternating-current Commutator.  
 Oscillographs.  
 Power Factor Indicators and Reactive Volt-ampere Indicators.  
 Resistance and Conductance.  
 Rubber.  
 Signalling, Railway.  
 Synchronizers and Synchrosopes.  
 Transformers, Instrument.  
 Voltmeters.  
 Watt-hour Meters.  
 Wattmeters.  
 Wires and Cables, Bare.  
 Wires and Cables, Insulated.  
 Wiring of Buildings.

The Standards of the American Institute of Electrical Engineers (formerly known as the Standardization Rules) are given in full at the end of the book. These standards are a verbatim copy of the 1922 edition and are reproduced with the permission of the Board of Directors of the Institute. It is the plan of the publishers to revise these Standards whenever a new edition is published by the Institute, which in the past has been about every two years.

While the encyclopedic arrangement of the book especially commends it for reference purposes, no difficulty attends its use for consecutive study, if the order given in the *Topical List of Articles* is followed. This list is arranged in the order usually followed in the course of class studies. Some teachers may prefer to vary the order of reading, and will find it easier to do so by the aid of such a list, than where the text itself is arranged in some arbitrary order.

Care has been taken to make each article a readable compendium on its subject and not merely a series of disconnected paragraphs containing miscellaneous data, a too common fault in books of this class.

In the preparation of the Second Edition, the editor has been fortunate in having associated with him, as Associate Editor-in-Chief, Mr. William A. Del Mar. Mr. Del Mar has supervised all articles dealing with Electric Railways, Wires and Cables, Transmission and Distribution, Switch Gear and Control Apparatus, Electric Meters and Instruments for commercial use, Mathematics, and Mathematical Tables. These articles make up about one-third of the entire book.

A glance at the make-up of the "Editorial Staff" will show the care with which experts in each line have been selected. In several cases men were selected because of notable investigations or researches which they were conducting at the time along the lines of the articles assigned to them.

The editor takes this opportunity to express his sincere appreciation of the earnest effort of all members of the Editorial Staff to make this new edition of the Handbook thoroughly representative of modern engineering practice.

HAROLD PENDER

## FROM THE PREFACE TO THE FIRST EDITION

1. This Handbook has been prepared primarily for the practicing engineer. With this end in view the matter has been so arranged as to be most readily found, and all *theoretical discussions have been segregated into separate articles*. Fundamental or "theoretical" principles are fully but concisely treated in articles dealing with such matters and nothing else, e.g., such article as *Electricity and Magnetism, Principles of; Alternating Currents; Electrochemistry, Principles of; Mechanics, Principles of; Hydraulics; etc.* Therefore, in articles dealing with practical matters only enough is said of theory to indicate the general principle of which the matter in hand may be a specific application.

2. This book is primarily for Electrical Engineers, but the general arrangement of the subject matter and the method of treatment adopted will make the book a useful reference book for mechanical, civil, mining and other engineers who have occasion to utilize any of the numerous applications of electricity in their special fields. Considerable space has been devoted to those matters pertaining to the applications of motors in all branches of modern industry; see the article on *Motors, Industrial Applications of*, and the numerous cross references there given.

3. Although this book deals primarily with electrotechnical matters, a large amount of space has been devoted to those mechanical and civil engineering subjects which are closely related to electrical engineering practice.

4. Numerous mathematical tables and relations are given. Among these may be mentioned the articles on *Logarithms, Trigonometric Functions, Hyperbolic Functions, Exponential Functions, Derivatives, Integrals, Indeterminate Forms, Equations, etc.*

5. In spite of the fact that this book contains upwards of 2000 pages, many of the articles have been greatly condensed. However, it has been the consistent endeavor of the editorial staff to make each article sufficiently complete so that the information given therein should be of the greatest practical value.

6. Although this book has been prepared primarily for the practicing engineer, it is believed that the method of treatment adopted will render many of the articles suitable as the bases for courses of lectures in technical schools. A teacher usually has his own method of presenting a subject, and sometimes a textbook proves more of a handicap than a help; yet every teacher recognizes the desirability of putting in the hands of his students some sort of synopsis or syllabus which will serve as a general guide.

7. Experience has shown that the alphabetical arrangement is eminently fitted for an encyclopedia of general information; a like arrangement is equally applicable to a reference book dealing only with engineering topics. The subject matter of this book has therefore been disposed in 266 articles alphabetically arranged. The user of the book will undoubtedly find it more convenient at first to refer directly to this detailed index, but as soon as he becomes acquainted with the main article headings, he will be able to turn directly to the article containing the information he may be seeking without referring to the index.

8. One feature of this Handbook which should prove particularly helpful is that the same plan of treatment has been consistently followed in all the articles, at least wherever possible. This applies particularly to articles dealing with apparatus or machinery, the plan of treatment being:

- a. General Description and Definitions.
- b. Brief Statement of Application.
- c. Principle of Operation.
- d. Design.
- e. Testing.
- f. Performance.
- g. Specifications.
- h. Installation.
- i. Operation.
- j. Dimensions, Weights and Costs.
- k. Bibliography.

In some instances it was found advisable to vary this scheme more or less, but the general sequence of topics was adhered to as closely as possible. At the beginning of each article occupying more than fifteen pages is given a brief table of contents.

9. It is believed that the cost data given in the various articles will prove particularly valuable when properly used. These data in most instances are given as unit costs, and usually the ordinary *range* of cost is given. It has been the experience of the writer that students and recent technical graduates are sadly lacking in even the roughest idea of the cost of apparatus and structures. It is primarily to supply a rough idea of such costs that the cost curves and figures are given in the various articles. The cost data given will also be found suitable for preliminary estimates; but for close estimating, current prices should of course be obtained from the makers of the apparatus, or, in the case of construction work, some one having personal experience in similar work should be consulted.

10. The bibliography given at the end of each article is intended to direct the reader to more extended information in treatises and current periodicals. The space available for these bibliographies has made it necessary to omit many important works and technical articles. The references are usually those in which the writer of the article in question is most familiar and which he has found most useful. They are therefore in no sense complete, but will be found a very useful guide in the search for additional information. In many instances a blank space of a half page or more is left after the bibliography; this space may be advantageously utilized by the insertion of references to new books and articles as they appear.

11. The articles in this Handbook have been prepared by an editorial staff of experts; this staff is given on pp. iii and iv.

The Editor-in-Chief wishes to take this opportunity of expressing his sincere appreciation of the hearty coöperation of the entire editorial staff and of the spirit of coöperation and generosity shown by the publishers throughout the preparation of this book.

HAROLD PENDER.

EAST BLUEHILL, ME.,

September 5, 1914.

## TOPICAL LIST OF ARTICLES

The articles listed under each main heading, except those of a statistical nature, are in an order appropriate for consecutive reading or assignment for class-room instruction.

### General and Miscellaneous

Associate Editors: W. A. Del Mar (a)  
                           H. M. Goodwin (b)  
                           R. G. Hudson (c)  
                           P. G. Agnew (d)

	PAGE
Shock, Electric (c).....	1402-1403
Standardization Rules and Standard Specifications (d).....	1446-1451
Standards of the A.I.E.E.....	2083-2183
Specifications and Contracts (a).....	1442-1445
Depreciation (a).....	351-358
Interest, Annuities and Sinking Fund (a).....	881-882
Elements, Chemical (b).....	526

### Units, Abbreviations and Symbols

Associate Editors: Harold Pender (a)  
                           R. G. Hudson (b)

Abbreviations and Symbols (a).....	5
Units, Practical Electric (a).....	1876-1877
Units and Conversion Factors (a) and (b).....	1853-1875

### Mathematics

Associate Editor: W. A. Del Mar

Greek Alphabet.....	710
Decimal Equivalents.....	343
Pi ( $\pi$ ), Value of.....	1129
Interest, Annuities and Sinking Fund.....	881
Roots and Powers.....	1372

**ABBREVIATIONS AND SYMBOLS.**—(See also *Units and Conversion Factors*.) At the meeting of the International Electrotechnical Commission in Berlin, in 1913, a list of abbreviations for electrotechnical and related quantities was adopted. The American Institute of Electrical Engineers has also adopted (1918) a list of such symbols, which for the most part is in agreement with the list of the I.E.C., but contains certain additional symbols not included in the I.E.C. list. In the following table both lists are given, see the *Standardization Rules of the A.I.E.E.* for symbols for photometric quantities.

## STANDARD SYMBOLS AND ABBREVIATIONS

Name of quantity	Symbol for the quantity		Name of Unit, adopted by A.I.E.E.	Abbreviation for the unit to be used only after numerical values	
	Adopted by I.E.C. (See Note 1)	Adopted by A.I.E.E.		Adopted by I.E.C.	Adopted by A.I.E.E.
Acceleration due to gravity.....	$g$	$g$	{ centimeter per second per second }	—	cm. per sec. per sec.
Acceleration due to gravity, Standard (=980.665 cm. per sec. per sec.) (Note 5)	—	$g_0$	{ centimeter per second per second }	—	cm. per sec. per sec.
Admittance.....	—	$Y, y$	mho	—	—
Angles.....	$\alpha, \beta, \gamma$ , etc.	—	—	—	—
Angular velocity ( $\omega$ ).....	$\omega$	$\omega$	{ radian per second }	—	—
Capacity (Capacitance).....	$C$	$C$	farad	<b>F</b>	—
Conductance.....	$G$	$g$	mho	—	—
Conductivity (Note 6)	—	$\gamma$	{ mho per centimeter }	—	{ mho per cm. }
Current.....	$I$	$I, i$	ampere	<b>A</b>	—
Dielectric constant	$\epsilon$	$\epsilon$ or $k$	—	—	—
Dielectric field intensity or electric force	—	$F$	—	—	—
Dielectric flux.....	—	$\psi$	—	—	—
Dielectric flux density	$D$	$D$	—	—	—
Efficiency.....	$\eta$	$\eta$	per cent	—	(Note 7)
Electromotive force (e.m.f.).....	$E$	$E, e$	volt	<b>V</b>	—
Energy.....	$W (U)$	$U$ or $W$	{ joule or watt-hour }	—	—
Frequency.....	$f(\nu)$	$f$	{ cycle per second }	—	$\sim$
Impedance.....	$Z (\mathcal{Z})$	$Z, z$	ohm	(Note 2)	—
Inductance (or coefficient of self-induction).....	$L (\mathcal{L})$	$L$	henry	<b>H</b>	—

## STANDARD SYMBOLS AND ABBREVIATIONS (Continued)

Name of quantity	Symbol for the quantity		Name of unit adopted by A.I.E.E.	Abbreviations for the unit to be used only after numerical values	
	Adopted by I.E.C. (See Note 1)	Adopted by A.I.E.E.		Adopted by I.E.C.	Adopted by A.I.E.E.
Inductance, mutual (or coefficient of mutual induction)	$M$ ( $\mathcal{M}$ )	$M$	henry	<b>H</b>	—
Length	$l$ (Note 3)	$l$	centimeter	cm.	cm.
Magnetic flux (Note 4)	$\Phi$ ( $\mathcal{F}$ )	$\Phi, \phi$	maxwell	—	—
Magnetic flux density	$B$ ( $\mathcal{B}$ )	$B, \mathcal{B}$	{ gauss (Note 4)	—	—
Magnetization, intensity of	$J$ ( $\mathcal{J}$ )	$J$	—	—	—
Magnetizing force or magnetic field intensity	$H$ ( $\mathcal{H}$ )	$H, \mathcal{H}$	{ gilbert per centimeter or gauss	—	{ gilbert per cm.
Magnetomotive force (m.m.f.)	—	$\mathcal{F}$	{ gilbert (Note 4)	—	—
Mass	$m$ (Note 3)	$m$	gram	—	g.
Period	$T$	—	—	—	—
Permeability	$\mu$	$\mu$	—	—	—
Phase displacement (or phase angle)	$\phi$	$\theta, \phi$	{ degree or radian	—	(Note 5)
Potential difference (p.d.)	—	$V, v$ or $E, e$	volt	<b>V</b>	—
Power	$P$	$P, p$	watt	<b>W</b>	—
Quantity of electricity	$Q$	$Q, q$	{ coulomb or ampere-hour	<b>C</b>	—
Reactance	$X$ ( $\mathcal{X}$ )	$X, x$	ohm	(Note 2)	—
Reluctance	$S$ ( $\mathcal{R}$ )	$\mathcal{R}$	—	—	—
Resistance	$R$	$R, r$	ohm	(Note 3)	—
Resistivity (Note 6)	$\rho$	$\rho$	{ ohm-centimeter	—	ohm-cm.
Revolutions per unit time	$n$	$n$	{ revolution per second	—	{ rev. per sec.
Susceptance	—	$b$	mho	—	—
Susceptibility	$\kappa$	$\kappa$	—	—	—
Temperature, absolute	$T, \Theta$	—	{ degree centigrade	—	—
Temperature, centigrade	$t$ ( $\theta, \delta$ )	$T, t, \theta$	{ degree centigrade	—	{ deg. cent. (Note 8)
Time	$t$ (Note 3)	$t$	second	—	sec.
Turns or number of conductors	—	$N$	{ convolution or turn	—	—
Voltage	—	$E, e$ or $V, v$	volt	<b>V</b>	—
Work, mechanical	$A$ ( $\mathcal{W}$ )	$\mathcal{W}$ or $A$	{ joule or watt-hour	—	—

**NOTES.** — (1) The symbols in brackets are recommended in case the principal symbol is unobtainable; instead of the script letters heavy-faced or other special type may be used. (2) One or other of the symbols  $\Omega$  and  $\Omega$  is recommended provisionally to represent the ohm. The symbol  $\Omega$  should no longer be employed for the megohm. (3) In dimensional equations the capital letters  $L$ ,  $M$  and  $T$  for length, mass and time respectively are to be employed. (4) An additional unit for m.m.f. is the "ampere-turn", for flux the "line", and for magnetic flux density "maxwell per sq. in." (5) This has been the accepted standard value for many years and was formerly considered to correspond accurately to 45° latitude and sea level. Later researches, however, have shown that the most reliable value for 45° and sea-level is slightly different; but this does not affect the standard value given above. (6) The numerical values of these quantities are *ohms resistance* and *mhos conductance* between two opposite faces of a cm. cube of the material in question, but the correct names are as given, not ohms and mhos per cm. cube as commonly stated. (7) The symbol % is commonly used for per cent, but is not recommended by the A.I.E.E. (8) The symbol ° is commonly used for degree, ° C. for degree centigrade and ° F. for degree Fahrenheit; these symbols are not recommended by the A.I.E.E.

In addition to the symbols for the units given in the above table, the I.E.C. adopted (1913) the following signs to be used only after numerical values.

Volt-coulomb .....	VC	Kilovolt-ampere .....	kVA
Watt-hour .....	Wh	Kilowatt-hour .....	kWh
Volt-ampere .....	VA	Sign for milli- .....	m
Ampere-hour .....	Ah	Sign for kilo- .....	k
Milliamperes .....	mA	Sign for micro- or micr- .....	$\mu$
Kilowatt .....	kW	Sign for mega- or meg- .....	M

**SPECIAL RULES IN REGARD TO SYMBOLS.** — The following rules were also adopted at the Berlin meeting (1913) of I.E.C., and are concurred in by the Standards Committee of the A.I.E.E. The latter committee also recommends that vector quantities be printed in bold-face capitals.

Instantaneous values of electrical quantities which vary with the time to be represented by small letters. In case of ambiguity they may be followed by the subscript "t."

Virtual (*i.e.*, *effective* or *r.m.s.*) or constant values of electrical quantities to be represented by capital letters.

Maximum values of periodic electrical and magnetic quantities to be represented by capital letters followed by the subscript "m."

In cases where it is desirable to distinguish magnetic quantities from electric quantities, magnetic quantities should be represented by capital letters of either script, heavy-faced or other special type. Script letters should not be used except for magnetic quantities.

Angles should be represented by small Greek letters.

Dimensionless and specific quantities should be represented wherever possible by small Greek letters.

Ordinary numerals as exponentials shall exclusively be employed to represent powers. (In consequence, it is desirable that the expression  $\sin^{-1}x$ ,  $\tan^{-1}x$ , employed in certain countries, be expressed by arc  $\sin x$ , arc  $\tan x$ .)

The comma and the full-stop shall be employed for separating decimals according to the custom of the country, but the separation between any three digits constituting a whole number shall be indicated by a space and not by a full-stop or a comma (1 000 000).

For the multiplication of numbers and geometric quantities indicated by two letters, it is recommended to use the sign  $\times$  and the full-stop only when there is no possible ambiguity.

To indicate division in a formula it is recommended that the horizontal bar and the colon be employed. Nevertheless the oblique line may be used when

## 4 Abbreviations and Symbols

there is no possibility of ambiguity; when necessary, ordinary brackets ( ), square brackets [ ], and braces { } may be employed to obtain clearness.

**INSTITUTE (A.I.E.E.) STYLE.**—The Editing Committee of the American Institute of Electrical Engineers issues a little pamphlet called "Suggestions to Authors," in which are given the rules of the Institute in regard to manuscript submitted for publication. The following list of abbreviations is taken from the last edition (1919) of these rules.

Name	A.I.E.E. style	Name	A.I.E.E. style
Alternating current...	spell out, or a.c. as adjective.	Kilowatts.....	kw.
Amperes.....		Kilowatt-hours.....	kw-hr.
Brake horse power.....	spell out	Magnetomotive force.....	m.m.f.
Boiler horse power.....	b.h.p.	Mean effective pressure.....	spell out
British thermal units.....	boiler h.p.	Miles.....	mi.
Candle power.....	B.t.u.	Miles per hour per second.....	mi. per hr. per sec.
Centigrade.....	c.p.	Millimeters.....	mm.
Centimeters.....	cent.	Milligrams.....	mg.
Circular mils.....	cm.	Minutes.....	min.
Counter electromotive force.....	cir. mils	Meters.....	m.
Cubic.....	counter e.m.f.	Meter-kilograms.....	m-kg.
Diameter.....	cu.	Microfarad.....	spell out
Direct current.....	spell out	Ohms.....	spell out
	spell out, or d.c. as adjective.	Per.....	spell out
Electric horse power.....	e.h.p.	Percentage.....	per cent. or % in tabu- lar matter.
Electromotive force.....	e.m.f.	Pounds.....	lb.
Fahrenheit.....	fahr.	Power-factor.....	spell out
Feet.....	ft.	Revolutions per minute.....	rev. per min., or r. p. m. in tabular mat- ter.
Foot-pounds.....	ft-lb.		Seconds.....
Gallons.....	gal.	Square.....	sq.
Grains.....	gr.	Square-root-of-mean- square.....	effective, or r.m.s.
Grams.....	g.	Ton-mile.....	spell out
Gram-calories.....	g-cal.	Tons.....	spell out
High-pressure cylinder.....	spell out	Volts.....	spell out
Hours.....	hr.	Volt-amperes.....	spell out
Inches.....	in.	Watts.....	spell out
Indicated horse power.....	i.h.p.	Watt-hours.....	watt-hr.
Kilogram.....	kg.	Watts per candle power.....	watts per c.p.
Kilogram-meters.....	kg-m.	Yards.....	yd.
Kilogram-calories.....	kg-cal.		
Kilometers.....	km.		
Kilovolts.....	kv.		
Kilovolt-amperes.....	kv-a.		

1. Use "Fig.," not "Figure." Example: "Fig. 3" and not "Figure 3."

2. In all decimal numbers having no units, a cipher should be placed before the decimal point. Example: "0.32 lb." not ".32 lb."

3. Use the word "by" instead of "x" in giving dimensions. Example: "8 by 12 in." not "8x12 in."

4. Never use the characters (') and (") to indicate either feet and inches, or minutes and seconds as period of time.

5. Do not use the expression "rotary" or "rotary converter"; use "converter" or "synchronous converter."

6. Do not use a descriptive adjective as a synonym for the noun described. Example: a "spare transformer," not a "spare"; a "portable instrument," not a "portable"; "automatic apparatus," not "automatics"; a "short circuit," not a "short."

7. Do not use the words "primary" and "secondary" in connection with transformer windings. Use instead "high-tension" and "low-tension."

8. Avoid dividing mathematical expressions into two or more parts if possible. If division is necessary, divide *after* a plus, minus or equality sign.

9. Use the English plural where there is a choice. For example: abscissas, not abscissae; formulas, not formulae.

10. Data is the plural form and takes plural verb, etc.

11. Make compounds of two-word adjectives, as direct-current motor, three-phase circuit, etc.

**ACIDS.**—The properties of some of the more important acids used in the arts are given in the following paragraphs.

**Aqua Regia** is a mixture of one part of nitric acid and three parts of hydrochloric acid. It obtains its name from the fact that it will dissolve gold. It is used as an oxidizing agent and for dissolving metals, such as platinum, gold, etc., which are insoluble in other acids. It should be used as soon as possible after being prepared since it loses its characteristic properties after standing a short time. It is distinguished by its reddish yellow color and its chlorine-like odor.

**Hydrochloric Acid or Muriatic Acid (HCl)** is an aqueous solution of hydrogen chloride, a colorless, pungent gas. While the pure acid is colorless, the commercial acid is a yellowish liquid, the color being due to impurities. The concentrated acid has a specific gravity of 1.16 and contains 32 per cent of HCl. The dilute acid has a specific gravity of 1.09 and contains 18.4 per cent of HCl. Hydrochloric acid is used extensively in the manufacture of chlorine, hydrogen and bleaching powder and is prepared as a by-product of the soda manufacture. The acid is recognized by its odor and by the dense fumes it makes with ammonia.

**Hydrofluoric Acid (HF)** is an aqueous solution of anhydrous hydrogen fluoride, a colorless, fuming liquid. The acid, when saturated, has a specific gravity of 1.25. Its gas is poisonous if inhaled and causes swellings and pain if applied to the skin. It readily dissolves glass and must be kept in platinum, lead, rubber or wax vessels. The acid is most commonly used for etching glass.

**Nitric Acid (HNO<sub>3</sub>)** is a colorless fuming liquid with a specific gravity of 1.55 at 0° C. Commercial nitric acid has a specific gravity of 1.414 at 15° C. and contains 68 per cent of the pure acid. The commercial acid is yellowish in color and the pure acid becomes yellow if exposed to the light. Nitric acid is a powerful oxidizing agent and decomposes organic substances. The acid is used in the manufacture of many chemical substances. Concentrated nitric acid is best recognized by the red fumes, which are given off when the acid is acting upon a metal.

**Sulphuric Acid or Oil of Vitriol (H<sub>2</sub>SO<sub>4</sub>)** is a colorless oily liquid. The concentrated acid has a specific gravity of 1.854 at 0° C. and contains 1.5 per cent of water. Commercial sulphuric acid, sometimes known as "brown acid," has a specific gravity of 1.720 and usually contains arsenic as an impurity. Sulphuric acid boils at 290° C., the temperature increasing to 338° C. as the boiling continues. The acid has a strong affinity for water and is frequently used as a drying agent. When diluted with water, the mixing should be performed gradually as great heat is evolved. The acid should be added to the water as the addition of water to the acid may produce violent explosions due to the ebullition of the water.

Sulphuric acid is used in the manufacture of many chemical substances, in dyeing and in refining petroleum. It is a fairly good conductor of electricity and is used in the lead type of storage batteries (q.v.). The acid is recognized by its weight, by its carbonizing action upon organic bodies and by the white precipitate formed by the addition of barium chloride.

**ALLOYS** — (See also *Wires, Resistor*.) In this article is given a brief description of some of the more common alloys used in engineering work, together with specific data on some of their more important properties. It should be noted that there may be a considerable departure from the quantitative values given. Traces are not included in the chemical compositions given. The various alloys are listed alphabetically. Additional data on their various physical properties will be found in the articles on *Heat and Thermal Properties; Resistance and Conductance; Strength and Elasticity; Weight of Materials, etc.*

**Acid-resisting Alloys.** — Alloys of iron and chromium and of iron and silicon are used for containers, partly replacing stoneware, in the manufacture of acids. Ferro-chrome is not attacked by sulphuric or nitric acid, but is readily attacked by hydrochloric acid. Silicon-iron containing 14 to 15 per cent silicon (with a small amount of Mn) is likewise not attacked by sulphuric or nitric acid. Such an alloy has a specific gravity of about 7, a melting point of about 2500° F., a tensile strength of about 15,000 pounds per square inch, and a compressive strength of about 70,000 pounds per square inch. Acid-resisting silicon irons are sold under various trade names, such as "duriron," "tantiron," etc. (W. C. Carnell, *Chem. News*, 116, p. 92, Aug. 23, 1917.)

**Aluminum Brass** (70.5 Cu, 26.4 Zn, 3.1 Al). — The tensile strength is about 21 tons per square inch, the elastic limit 8.5 tons per square inch and the elongation 50 per cent. Aluminum brass is used when very accurate castings are desired, e.g., for pumps, valves, pinions and propellers. It can be rolled and forged while hot but is not easily worked when the aluminum content exceeds 4 per cent.

**Aluminum Bronze** (95 Cu, 5 Al). — The tensile strength is about 28 tons per square inch, the elastic limit 12 tons per square inch and the elongation 75 per cent. Aluminum bronze containing less than 7.5 per cent Al is very ductile. With more than 7.5 per cent Al the alloy becomes brittle but increases in tensile strength. Tubes, propellers and propeller shafts are sometimes made of aluminum bronze. It has not been found to withstand intense heat for any length of time without fracturing. It is sometimes drawn into wire for use as an electrical resistance.

**Amalgams** are alloys of mercury and other metals. When newly made amalgams are plastic but harden in a short time without appreciable expansion or contraction. The common metals combined with mercury to form amalgams are tin, copper, cadmium, bismuth, silver and gold. Amalgams are used for silvering glass and as a cement for metals and porcelain.

**Anti-friction Metals** are alloys of copper, tin, zinc, lead and antimony in various combinations. These alloys are commonly used in bearings for revolving shafts and for valve packings. See *Babbitt and Bearing Metals* below.

**Babbitt Metal** (4 Cu, 69 Zn, 19 Sn, 5 Pb, 3 Sb) is used extensively for bearings, the composition stated being that used for car bearings of the Pennsylvania Railroad. See also the article on *Bearings*.

**Bearing Metals** for use in specific cases are illustrated by the following examples: Locomotive (82 Cu, 8 Zn, 10 Sn), railway car (90 Cu, 10 Sn), low-speed bearing (16 Sn, 84 Pb). There are a large number of anti-friction metals in use, the object in the composition of each of them being to procure a metal which is as hard as possible but plastic enough to be moulded by the shaft into a shape offering a minimum friction.

**Brass** is an alloy of copper and zinc and often contains small percentages of lead, tin, arsenic, antimony, bismuth and iron. Cast brass usually consists of 66 per cent of copper and 34 per cent of zinc. *Low brasses*, suitable for hot

rolling contain from 55 per cent to 63 per cent of copper. *High brasses*, suitable for cold rolling and drawing, contain from 60 per cent to 70 per cent of copper. In drawing brass it must be annealed and cleaned in acid at frequent intervals to prevent fracture. The ductility of brass is impaired if the lead content exceeds 0.1 per cent, but in the case of brasses intended for turning about 2 per cent of lead is often added so that the brass may be turned at higher speed and possess a better finish. Brass is made harder by the addition of about 1 per cent of tin and is found to better withstand corrosion due to salt water. The presence of small quantities of arsenic, antimony or bismuth in brass is liable to cause it to crack when rolled. The addition of 1 per cent to 3 per cent of iron to brass produces a harder and stronger alloy. The tensile strength of commercial brass ranges from 15 to 40 tons per square inch and the elongation varies from 10 per cent to 40 per cent depending upon the composition.

**Bronze** is a name used to designate various alloys of copper and tin with other metals. Ordinary bronze is an alloy of copper, tin, and zinc, and melts about 980° C. See also *Aluminum Bronze*, *Manganese Bronze*, and *Phosphor Bronze* in this article.

**Duralumin** is an alloy whose composition varies between the limits Cu, 1 to 4.5 per cent; Mg, 0.4 to 1.0 per cent; Mn, 0 to 0.7 per cent; Fe, 0.4 to 1.0 per cent; Si, 0.3 to 0.6 per cent; and the balance aluminum. It has a specific gravity of 2.85 and possesses the remarkable property of being appreciably hardened by quenching from temperatures below its melting point and subsequent ageing. (*Amer. Inst. Min. Eng., Bull. No. 150, 1919.*)

**Ferro-Alloys.**— See above under *Acid-resisting Alloys* and the article on *Steel*.

**Fusible (Low Melting Point) Metals** consist of various alloys of bismuth, lead, tin and cadmium. The chemical composition of the common fusible metals and their melting points are given in the following table:

Alloy	Composition				Melting point °C.
	Bi	Pb	Sa	Cd	
Newton's alloy.....	50.0	31.25	18.75	.....	95
Rose's alloy.....	50.0	26.00	24.00	.....	100
Darcet's alloy.....	50.0	25.00	25.00	.....	93
Wood's alloy.....	50.0	24.00	14.00	12.00	66-71
Lipowitz's alloy.....	50.0	27.00	13.00	10.00	60

Lower melting points are obtained by the addition of mercury.

**German Silver** is an alloy of copper, nickel and zinc in various combinations. It is sometimes called nickel silver, argentan, packfong, silveroid, silverite or electrum. German silver is extensively used because of its ductility; it can be readily rolled, hammered and drawn. It is hard, tough and not easily corroded. Its composition varies from (50 Cu, 30 Ni, 20 Zn) to (57 Cu, 7 Ni, 36 Zn), the nickel content decreasing as the zinc increases. The usual impurities found in German silver are iron, lead and tin. The presence of iron in the alloy makes it stronger, harder and more elastic. Tin makes the alloy brittle. Lead is sometimes added to render the alloy more workable but should not be added when the alloy is to be rolled. German silver is drawn into wires for use as a

ectrical resistance and has been drawn into tubes for use in locomotive boilers.  
*Wire, Resistor.*

**Gun Metal** is a bronze consisting of about 90 per cent of copper and 10 per cent of tin. The tensile strength varies from 12 to 16 tons per square inch, depending upon the method of working. Melting point 980 to 995° C. It is mechanically strong and elastic and withstands severe shocks without fracture. A small amount of lead is added to gun metal, the alloy is more easily turned and filed. Better castings are made by the addition of a small amount of zinc and the alloy is made harder by adding a small percentage of iron.

**Manganese Bronze** is an alloy containing copper, tin, zinc, lead, iron and manganese in various combinations. Alloys containing from 4 per cent to 6 per cent of manganese possess high tensile strength at high temperatures and are therefore used for fire-box stays. High tensile strength at ordinary temperatures is obtained, however, by the addition of very small quantities of manganese. The composition of manganese bronze for certain specific uses is as follows: For hydraulic machinery (82 Cu, 8 Sn, 5 Zn, 3Pb, 2Mn); for forging (82 Cu, 38.4 Zn, 1.6 Fe, 0.02 Mn). The tensile strength ranges from 27 to 30 tons per square inch but if the alloy is cold-rolled, a tensile strength of 50 tons per square inch may be obtained. Manganese bronze is often used in place of steel or copper, when a higher tensile strength is required. It is not easily turned and may be bent when hot or cold.

**Magnetic Alloys.**—See the article on *Magnetic Properties of Iron and its Alloys.*

**Monel Metal** is described in the article on *Wires, Resistance.* It has a tensile strength of 40 tons per square inch at air temperature and 29 tons per square inch at 500° C. It is used for pump rods and valves as well as for resistor wires. (*J. Arnott, Engineering, 106, p. 451, Oct. 25, 1918.*)

**Non-expansive Alloys** are composed of iron, nickel and carbon. *Platinite* contains 46 per cent of nickel and 0.15 per cent of carbon. *Invar* contains 36 per cent of nickel and 0.2 per cent of carbon. Its coefficient of expansion ranges from  $5 \times 10^{-7}$  to  $25 \times 10^{-7}$  per degree centigrade. These alloys are used extensively in scientific instruments for standard measures of length and in incandescent lamps where the wire connections fused into the glass must not expand enough to fracture the glass.

**Phosphor Bronze** consists of copper, tin and phosphorus in various proportions, the phosphorus content rarely exceeding 2 per cent. The most useful property of phosphor bronze is its hardness and resistance to wear. Phosphor bronzes containing (A) 8 to 10 per cent of tin and 0.5 to 0.7 per cent of phosphorus are used for valves, pumps, propellers and boiler fittings, (B) 10 to 12 per cent of tin and 0.7 to 1 per cent of phosphorus are used for worms and gears and (C) 10 to 12 per cent of tin and 1 to 1.5 per cent of phosphorus are used for gears, gears and bearings where the wear is excessive. The tensile strength ranges from 10 to 15 tons per square inch, the elastic limit from 5 to 7 tons per square inch and the percentage elongation from 2 to 6 per cent.

**Platinum Substitutes.**—Alloys of gold and silver with palladium have recently developed as a substitute for platinum for contacts and sparking points in magnetos.

**Pyrophoric Alloys** are certain alloys of rare earths, especially ferrotitanium, which give a shower of sparks when filed or struck. Sb and Bi are added (1 per cent) to harden the alloy and copper (5 per cent) to produce a low melting point and a smooth casting product. (*Engineering and Mining Journ., p. 212, 1917.*)

**Resistance Alloys.** — See article on *Wires, Resistor*.

**Solder** is an alloy of tin and lead. Cadmium may be used as a substitute for part of the tin, 80 Pb, 10 Sn, 10 Cd being a satisfactory solder. *Hard* or *tin* solder contains 50 per cent of tin and 50 per cent of lead and melts at 370° F. *Soft* or *plumber's solder* contains 33.3 per cent of tin and 66.6 per cent of lead and melts at 441° F.

**ALTERNATING CURRENTS.**—(See also *Electricity and Magnetism, Principles of; Generators, Alternating-current; Motors, Alternating-current; Resistance and Conductance, Electric; Skin Effect; Transformers; Wave Analysis, &c.*).

**GENERAL DEFINITIONS.**—(See also *Standardisation Rules of the I.J.E.E.*). To avoid repetition the following definitions are given in terms of electric current; they also apply to electromotive forces, potential differences or to any other functions of time.

An alternating current is defined as a current which varies continuously with time from a constant maximum value in one direction to an equal maximum value in the opposite direction and back again to the same maximum in the first direction, repeating this cycle of values over and over again in equal intervals of time.

**Period, Frequency and Alternations.**—The period of an alternating current is the time taken for the current to pass through a complete cycle of positive and negative values.

The frequency or number of cycles per second is the number of periods per second.

The number of alternations per minute is the total number of times per minute that the current changes in direction, from positive to negative and from negative to positive. In engineering practice the number of cycles is usually referred to the second as the unit of time and the number of alternations is referred to the minute as the unit of time.

Let  $T$  be the period,  $f$  the frequency or number of cycles per second and  $a$  the number of alternations per minute, then

$$f = \frac{1}{T} \quad \text{and} \quad a = 120f = \frac{120}{T}. \quad (1)$$

The constant  $\omega = 2\pi f = \frac{2\pi}{T}$  (1a)

is sometimes called the angular velocity or angular frequency of the current. The name periodicity for this quantity is not recommended.

**Instantaneous, Maximum and Average Values.**—The instantaneous value of an alternating current is the value of the current at any instant. Instantaneous values of current, potential difference and electromotive force will be designated by small letters throughout this article, viz.,  $i$ ,  $v$  and  $e$ .

The maximum value of an alternating current is the numerical value of its maximum instantaneous value. Maximum values will be designated by capital letters with the subscript "m."

The average value of an alternating current for which the positive and negative half cycles are equal, which is usually the case, is defined as the numerical value of the average of its instantaneous values for a half cycle; the average over a complete cycle is of course zero. The general expression for the average value of a symmetrical current wave over a half cycle is

$$I_{\text{aver.}} = \frac{2}{T} \int_0^{T/2} i \, dt, \quad (2)$$

where  $t$  is a value of  $t$  at which  $i = 0$ ; similarly for a voltage wave.

**R.M.S. or Effective Values.**—The square root of the mean of the squares of the instantaneous values of an alternating current over a complete period is called the r.m.s., or effective, value of the alternating current. In specifying the value of an alternating current as so many amperes this r.m.s. value is always meant unless specifically stated otherwise. In the same manner the square root of the mean of the squares of the instantaneous values of an alternating

potential difference over a complete period is called the r.m.s. value of the alternating potential difference. When the value of an alternating potential difference is specified as so many volts, this r.m.s. value is always meant unless specially stated otherwise.

The reason for selecting this particular function of the instantaneous values of an alternating current or potential difference as the measure of the current or potential difference is that the deflection of all instruments used in alternating current measurements is a function of this r.m.s. value. See *Ammeters, Electrodynamometers, Voltmeters, etc.* Moreover, the average power dissipated as heat in a resistance,  $r$ , when an alternating current of r.m.s. value  $I$  flows through it, is  $rI^2$ .

R.m.s. values will be designated throughout this article by capital letters without subscripts.

The general expression for the r.m.s. value of an alternating current is]

$$I = \sqrt{\frac{1}{T} \int_0^T i^2 dt}, \quad (3)$$

and similarly for an alternating potential difference.

**Form Factor.** — The form factor of an alternating current is defined as the ratio of its r.m.s. to its average value, viz.,

$$\text{Form factor} = \frac{I}{I_{\text{aver}}}, \quad (4)$$

and similarly for an alternating potential difference.

**Crest or Peak Factor.** — The crest factor, also called the peak factor or amplitude factor, of an alternating current is defined as the ratio of its maximum to its r.m.s. value, viz.,

$$\text{Crest factor} = \frac{I_m}{I}. \quad (5)$$

**Instantaneous and Average Power.** — Let  $v$  be the value at any instant of the potential drop from any point 1 to any other point 2, and let  $i$  be the instantaneous value of the current from 1 to 2 at this same instant; then the power input at this instant is

$$p = vi. \quad (6)$$

When  $v$  and  $i$  are both positive (i.e., in the direction from 1 to 2, say) or when they are both negative, the power input is positive, but when  $v$  is positive and  $i$  negative or vice versa, the power input is negative, i.e., there is an actual power output.

The average value of the product  $vi$  over a complete period for both  $v$  and  $i$  (or over any whole number of periods) is the average power input or output, usually called simply the power input or output (input when the average of  $vi$  is positive, output when the average of  $vi$  is negative), the word average being understood. That is, the average power input is

$$P = \frac{1}{T} \int_0^T p dt = \frac{1}{T} \int_0^T vi dt, \quad (7)$$

$T$  being a complete period. For the actual measurement of alternating-current power see *Wattmeters*.

**Power Factor.** — Only in certain special cases (see below) is the average power input  $P$  equal to the product of the r.m.s. value  $V$  of the potential difference by the r.m.s. value  $I$  of the current; it can never be greater and as a rule is less. The ratio of the average power  $P$  to the product of the r.m.s. value  $V$  of the

potential difference by the r.m.s. value  $I$  of the current is called the power factor of the circuit between the terminals considered, i.e.,

$$\text{Power factor} = \frac{P}{VI} \quad (8)$$

When  $V$  is expressed in volts and  $I$  in amperes then  $P$  must be in watts; when  $V$  is expressed in kilovolts and  $I$  in amperes  $P$  must be in kilowatts.

**Volt-Amperes, Kilovolt-Amperes (kv-a.)** — The product of the r.m.s. volts across the terminals of a circuit by the r.m.s. amperes through it is called the volt-amperes taken by the circuit; this product divided by 1000 is called the kilovolt-ampere input. Or, when  $V$  is in volts and  $I$  in amperes

$$\text{volt-amperes} = VI, \quad (9)$$

$$\text{kilovolt-amperes} = \frac{VI}{1000} \quad (9a)$$

Kilovolt-amperes are usually abbreviated kv-a. or K.V.A., the former abbreviation being that recommended by the American Institute of Electrical Engineers and used in this book.

**Effective Resistance ( $r$ ) and Conductance ( $g$ ).** — The effective resistance of any portion of a circuit to an alternating current is the quotient of the average rate  $P_h$  at which heat is developed by this current, either directly in the substance through which it passes or indirectly as a consequence of the hysteresis and eddy-current losses produced by its magnetic field (see *Magnetic Properties of Iron*), divided by the square of the r.m.s. value  $I$  of the total current (conduction plus displacement or charging current) through this portion of the circuit, viz.,

$$r = \frac{P_h}{I^2} \quad (10)$$

Similarly, calling  $V$  the r.m.s. value of the potential difference across the given portion of the circuit the effective conductance  $g$  of this portion of the circuit is defined by the relation

$$g = \frac{P_h}{V^2} \quad (11)$$

In general, both  $r$  and  $g$  depend upon both the frequency and the wave-shape (see below) of the current and voltage but in many instances they may be considered as practically constant irrespective of the frequency or wave-shape. See the articles on *Resistance and Conductance* and *Skin Effect* for further discussion.

**Impedance ( $z$ ) and Admittance ( $y$ ).** — Let  $V$  be the r.m.s. value of the potential drop through any portion of a circuit due to its effective resistance, self-inductance and capacity (see *Electricity and Magnetism, Principles of*), i.e., if there is any other source of e.m.f. in the given portion of circuit (e.g., a generator or motor)  $V$  is the r.m.s. value of the potential drop which the same current would produce through this portion of circuit were this external source of e.m.f. removed. Then the quotient of the potential drop  $V$  by the r.m.s. value of the current  $I$  in this portion of the circuit, viz.,

$$z = \frac{V}{I} \quad (12)$$

is defined as the impedance of this portion of the circuit.

The reciprocal of the impedance, viz.,

$$y = \frac{1}{z} = \frac{I}{V}, \quad (13)$$

is defined as the admittance of the given portion of the circuit.

Impedance and admittance, as thus defined, both depend upon the frequency and wave-shape. Impedance is expressed in the same units as resistance (e.g. ohms), and admittance in the same units as conductance (e.g. mhos); see *Units and Conversion Factors*.

**Reactance ( $x$ ) and Susceptance ( $b$ ).** — The square root of the difference between the square of the impedance and the square of the effective resistance of a given portion of an electric circuit is defined as the reactance  $x$  of this portion of the circuit, viz.,

$$x = \sqrt{z^2 - r^2}. \quad (14)$$

The reactance of a coil of inductance  $L$  to a sine-wave current of frequency  $f$  is

$$x = 2\pi fL. \quad (14a)$$

Similarly, the susceptance  $b$  of the given portion of the circuit is defined by the relation

$$b = \sqrt{y^2 - g^2}. \quad (15)$$

The susceptance of a condenser of capacity  $C$  to a sine-wave voltage of frequency  $f$  is

$$b = 2\pi fC. \quad (15a)$$

The simple relations expressed by (14a) and (15a) hold only for sine-wave currents and voltages; see Pender, H., *Electricity and Magnetism for Engineers, Part II*, N. Y., 1919. See also the articles in this book on *Capacity and Charging Current* and *Inductance and Inductive Reactance*.

**Inductive and Condensive (or Capacity) Reactance and Susceptance.** — The reactance of a circuit may be due either to the back e.m.f. set up as a consequence of the varying magnetic field of the current or to a back e.m.f. set up by a condenser or its equivalent, or to both. In the first case the reactance and susceptance are said to be "inductive" and in the second case "condensive." A condensive reactance or susceptance is equivalent to a negative inductive reactance or susceptance; e.g., the inductive susceptance of a condenser to a sine-wave voltage is  $-2\pi fC$ .

**Equivalent\* Resistance, Impedance and Reactance.** — Sometimes in calculating alternating-current circuits it is convenient to consider a motor or other load developing a back e.m.f. as equivalent to a single resistance and reactance. Let  $P$  be the total power taken by the load,  $V$  the voltage between its terminals,  $I$  the current; then the equivalent resistance is defined as

$$R = \frac{P}{I^2}, \quad (16)$$

the equivalent impedance as

$$Z = \frac{V}{I} \quad (16a)$$

and the equivalent reactance as

$$X = \sqrt{Z^2 - R^2}. \quad (16b)$$

The difference between the *effective* resistance and the *equivalent\** resistance is

\* The distinction here made between equivalent and effective is not always observed; the term equivalent resistance is frequently used in the same sense as effective resistance.

that the first takes into account only the power dissipated as heat, whereas the latter takes into account the total power, of which only a part is heat, the rest being converted into some other form, e.g. mechanical power.

**SIMPLE HARMONIC OR SINE-WAVE CURRENTS AND VOLTAGES.** — A simple harmonic or sine-wave current is one which varies with time according to the sine formula

$$i = I_m \sin (\omega t + \theta),$$

where  $t$  represents time in seconds, measured from any arbitrarily chosen instant,  $I_m$  the maximum value of the current,  $\omega = 2\pi f = \frac{2\pi}{T}$ , where  $f$  is the frequency in cycles per second and  $T$  the period as a fraction of a second, and  $\theta$  a constant, called the "phase angle," which depends upon the instant chosen as the zero of time. See the section on *Harmonic Motion* in the article on *Mechanics, Principles of*, for a full discussion of this equation and its physical significance.

**Difference in Phase Between a Sine-wave Current and a Sine-wave Voltage of the Same Frequency.** — In general, when a sine-wave electromotive force is impressed on a circuit the resulting current is likewise a sine function of time (after a very brief interval, see *Transient Electric Phenomena and Oscillations*) having the same frequency, but the e.m.f. and current do not reach their maximum values simultaneously. Let the current and the potential drop in the direction of the current be represented respectively by the two equations

$$i = I_m \sin \omega t,$$

$$v = V_m \sin (\omega t + \theta),$$

where  $t$  is the time measured from the instant when  $i = 0$  and is increasing in the positive direction. The current reaches its maximum value when  $t = \frac{\pi}{2\omega}$ ,

while the potential drop reaches its maximum value when  $t = \frac{\pi}{2\omega} - \frac{\theta}{\omega}$ .

Hence when  $\theta$  is positive the potential drop reaches its maximum value  $\frac{\theta}{\omega}$  seconds before the current reaches its maximum, or the current reaches its maximum value  $\frac{\theta}{\omega}$  seconds after the potential drop reaches its maximum; when

$\theta$  is negative the current reaches its maximum value  $\frac{\theta}{\omega}$  seconds before the potential drop reaches its maximum. In the first case the current is said to "lag" the potential drop, and in the second case the current is said to "lead" the potential drop. The angle  $\theta$  is called the "difference in phase," or simply the phase angle, between the current and potential drop.

In general, when  $i$  and  $v$  are expressed by the formulas

$$i = I_m \sin (\omega t + \theta_i),$$

$$v = V_m \sin (\omega t + \theta_v),$$

$i$  reaches its first maximum at an interval of time  $\frac{1}{\omega} (\theta_i - \theta_v)$  ahead of  $v$ , and therefore  $i$  leads  $v$  by the angle  $\theta_i - \theta_v$ . Note the order of the subscripts:  $i$  leads  $v$  by the angle  $\theta_i - \theta_v$ ; or  $v$  leads  $i$  by  $\theta_v - \theta_i$ . A negative lead is of course equivalent to an actual lag, and a negative lag is equivalent to an actual lead.

**Currents and Voltages in Phase, in Quadrature and in Opposition.** — When the phase difference is zero the current and potential drop are said to be "in phase"; when the phase difference is  $\frac{\pi}{2}$  radians or  $90^\circ$  the current and potential drop are said to be "in quadrature"; when the phase difference is  $\pi$  radians or  $180^\circ$  the current and potential drop are said to be "in opposition."

**R.M.S. and Average Values, Form Factor and Crest Factor.** — For a sine wave:

$$\text{R.m.s. value} = \frac{\text{Maximum value}}{\sqrt{2}}; \quad (17)$$

$$\text{Average value} = \frac{2}{\pi} \times (\text{maximum value}); \quad (17a)$$

$$\text{Form factor} = \frac{\pi}{2\sqrt{2}} = 1.11; \quad (17b)$$

$$\text{Crest factor} = \sqrt{2} = 1.414. \quad (17c)$$

For any other relation between the instantaneous values of the current or voltage and time, i.e., for any other shape of current or voltage wave, these relations do not hold. The form factor of a rectangle is 1.00; of an isosceles triangle, 1.15; of a semi-circle or semi-ellipse, 1.04. The corresponding crest factors are 1.00, 1.73 and 1.22. See also article on *Wave Analysis*.

**Power and Power Factor for Sine-wave Current and Voltage.** — Let the voltage drop from terminal No. 1 to terminal No. 2 through any piece of apparatus be  $v = \sqrt{2} V \sin(\omega t + \theta_v)$  and the current from terminal No. 1 to terminal No. 2 be  $i = \sqrt{2} I \sin(\omega t + \theta_i)$ , where  $V$  and  $I$  are the r.m.s. values and therefore  $\sqrt{2} V$  and  $\sqrt{2} I$  are the maximum values. Then the instantaneous power input is

$$p = vi = VI [\cos(\theta_v - \theta_i) - \cos(2\omega t + \theta_v + \theta_i)]. \quad (18)$$

A study of Fig. 1 will show the physical meaning of this expression. The average power input is

$$P = VI \cos(\theta_v - \theta_i), \quad (18a)$$

where  $(\theta_v - \theta_i)$  is the difference in phase between the current and voltage. Putting  $\theta$  for this difference in phase, viz.,  $\theta = \theta_v - \theta_i$ , equation (18a) may be written

$$P = VI \cos \theta. \quad (18b)$$

Whence the power factor of the load supplied to the apparatus is, from equation (8),

$$\cos \theta = \frac{P}{VI}. \quad (19)$$

**Power-factor Angle.** — Since in the case of sine-wave currents and voltages the power factor is equal to the cosine of the angle which expresses the difference in phase between them, this difference in phase is frequently called the "power-factor angle." When the wave shape is not a pure sine

Fig. 1.

curve, the power factor cannot be interpreted as the cosine of the phase difference, for phase difference has no definite meaning except in reference to sine waves; see definitions above. A non-sinusoidal voltage and current may both reach their zero values at the same instant, as in the case of an arc (*see Arc, Electric*), and in a sense may be said to be "in phase," but the power factor as defined by equation (8) may be far from unity.

**Leading and Lagging Power Factor.** — The power factor is always a positive quantity, but the power-factor angle may be either positive or negative, i.e., the current may lag or lead the voltage drop by any angle between  $0^\circ$  and  $90^\circ$ , or lag or lead the potential drop by any angle between  $0^\circ$  and  $90^\circ$ .<sup>\*</sup> When the current lags the reference voltage by an angle between  $0^\circ$  and  $90^\circ$  the power factor is stated as such a fraction or percentage, *lagging*, e.g., a power factor of 60% lagging, and when the current leads the power factor is stated as such a fraction or per cent, *leading*. In the first case the power-factor angle is taken as positive, and in the second case negative.

**Equivalent Sine-wave Currents and Voltages.** — In very few instances are the actual currents and voltages in a circuit pure sine-waves, but many of the ordinary calculations of alternating-current circuits may be made with sufficient accuracy by assuming them as sine-waves of the same r.m.s. values as the actual waves, and differing in phase by the angle whose cosine is equal to the actual power factor, i.e., by the angle

$$\theta = \cos^{-1} \frac{P}{VI}, \quad (19a)$$

where  $P$  is the average power,  $V$  the r.m.s. value of the actual voltage and  $I$  the r.m.s. value of the actual current.

**Vector Representation of Sine-wave Currents and Voltages.** — Consider any sine function

$$i = I_m \sin \omega t.$$

The value of  $i$  at any instant may be represented graphically, see Fig. 2, by the vertical projection (i.e., the vertical distance from  $P_1$  to  $OX$ ) of a point  $P_1$  at the end of a radius  $OP_1 = I_m$  which revolves† at an angular speed  $\omega$  about a fixed point  $O$ , the angle  $\omega t$  being measured from the horizontal fixed line  $OX$ . Similarly, any other sine function

$$e = V_m \sin (\omega t + \theta)$$

may be represented by the vertical projection of the point  $P_2$  at the end of a radius  $OP_2 = V_m$  also revolving about  $O$  with an angular speed  $\omega$ , the angle between  $OP_1$  and  $OP_2$ , when the frequency of both  $i$  and

Fig. 2.

<sup>\*</sup> When there is an actual power input into a portion of a circuit (e.g., a motor) it is most convenient to refer the current to the voltage *drop* through this portion of circuit in the direction of the current; when there is an actual power output (e.g., a generator) it is most convenient to refer the current to the voltage *rise* through this portion of the circuit, i.e., to the electromotive force in this portion of the circuit, in the direction of the current. When the potential *rise* is used as the reference, then for a power-factor angle between  $-90^\circ$  and  $0^\circ$  and between  $0^\circ$  and  $+90^\circ$ , the apparatus gives out power, and for a power-factor angle between  $-90^\circ$  and  $-180^\circ$  and between  $+90^\circ$  and  $+180^\circ$  the apparatus absorbs power.

† Counter-clockwise rotation has been adopted (1911) as standard by the International Electrotechnical Commission.

$v$  is the same, remaining fixed in value and equal to the difference in phase  $\theta$  between  $v$  and  $i$ . That is,  $v$  and  $i$  may be represented by rotating vectors (see article on Vectors) and when of the same frequency the relative position of the two vectors remains fixed. Similarly any number of currents and voltages of the same frequency may be represented by rotating vectors which remain fixed with respect to one another.

Instead of referring the various rotating vectors to a fixed line  $OX$ , this line of reference may also be considered as rotating with the same speed  $\omega$  as the various vectors, or any one of the vectors may be chosen as the line of reference, for example, the vector  $OP_1$  in Fig. 2. The rotating vectors referred to this rotating line of reference are then fixed with respect to this line of reference, and the entire diagram may be considered as fixed, as in Fig. 3, the originally chosen fixed line of reference  $OX$  rotating in the opposite direction with an angular speed  $\omega$ .

Instead of making the vectors equal in length to the maximum values of the sine functions they may be chosen equal in length to their r.m.s. values. This merely introduces a factor  $\sqrt{2}$  so that when any vector is considered as rotating the instantaneous value of the quantity which it represents is equal to  $\sqrt{2}$  times the perpendicular distance from its end to the fixed line of reference.

**Addition of Sine-wave Currents or of Sine-wave Voltages.** — Since the r.m.s. values and phase relations of sine-wave currents and voltages may be represented by vectors, sine-wave currents are added in exactly the same manner as vectors, or forces, are added, and similarly for sine-wave voltages. The addition of vectors is fully treated in the article on Vectors, q.v. To add any two sine-wave currents or voltages not only must their effective values be known but also their phase relation; *the resultant of two alternating voltages of r.m.s. values  $V_1$  and  $V_2$  is never the arithmetical sum of  $V_1$  and  $V_2$ , except when the two voltages are exactly in phase, and similarly for alternating currents.*

**In-phase and Quadrature Components.** — In Fig. 3, considering  $OP_1$  as equal to the r.m.s. value  $I$  of the current and  $OP_2$  as representing the r.m.s. value  $V$  of the voltage, the voltage  $V$  may be considered as made up of two components, viz.:

$$V_1 = V \cos \theta \quad \text{in phase with } I,$$

$$V_2 = V \sin \theta \quad \text{in quadrature with } I.$$

The average power corresponding to the component  $V_1 = V \cos \theta$  is, from equation (18b),  $IV_1 = IV \cos \theta$ , and is equal to the total power corresponding to  $V$  and  $I$ . The average power corresponding to the component  $V_2 = V \sin \theta$ , since the angle between the current and this component of the voltage is  $90^\circ$ , is equal to zero. The voltage component  $V_1 = V \cos \theta$  is therefore frequently called the "power" component of the voltage, and the component  $V_2 = V \sin \theta$  is frequently called the "wattless" component of the voltage. These terms, however, are not recommended. It is preferable to refer to these two components as the in-phase and quadrature components respectively. The terms active and reactive components are also used.

Similarly, the current  $I$  may be considered as made up of two components, viz.:

$$I_1 = I \cos \theta \quad \text{in phase with } V,$$

$$I_2 = I \sin \theta \quad \text{in quadrature with } V.$$

Fig. 3.

The first component is called the in-phase component of the current and the second the quadrature component of the current.

**Resistance Drop and Reactance Drop.** — When a sine-wave current of r.m.s. value  $I$  is established in a coil which has an effective\* resistance  $r$  and inductance  $L$ , the drop of voltage  $V$  through the coil is represented by the vector diagram shown in Fig. 4. The reactance of such a coil, from the definition given by equation (14a), is then  $x = 2\pi fL$ . The voltage drop  $rI$ , due to the resistance of the coil, is in phase with the current  $I$ , whereas the voltage drop  $2\pi fLI = xI$ , due to the reactance of the coil, is  $90^\circ$  ahead of the current. A "resistance drop" i.e., the drop of potential due to a current through a resistance, is always in phase with the current which causes it, and an inductive reactance drop is always  $90^\circ$  ahead of the current which produces it. (A condensive reactive drop is always  $90^\circ$  behind the current which causes it, and is therefore directly opposite in phase to an inductive reactance drop produced by the same current.)

Fig. 4.

**Impedance of a Coil to a Sine-wave Current.** — From Fig. 4 and the definition of impedance, equation (12), it is evident that the impedance of a coil of resistance  $r$  and inductance  $L$  is

$$z = \sqrt{r^2 + (2\pi fL)^2} \tag{20}$$

**Leakage Current and Charging Current of a Condenser.** — When a sine-wave voltage of r.m.s. value  $V$  is established across a condenser which has an effective† conductance  $g$  and capacity  $C$ , the total current  $I$  through it is represented by the vector diagram shown in Fig. 5. The condensive susceptance of a condenser from the definition given in equation (15a) is then  $b = 2\pi fC$ , or the inductive susceptance is  $b' = -b = -2\pi fC$ . The conduction or leakage current  $gV$  is in phase with the voltage drop through the condenser, whereas the charging or capacity current (or displacement current)  $2\pi fCV = bV$  is  $90^\circ$  ahead of the voltage.

Fig. 5.

**Admittance, Impedance, Effective Resistance and Reactance of a Condenser.** — From Fig. 5 and the definitions given by equations (12) to (15) it follows that the admittance of a condenser to a sine-wave voltage is

$$y = \sqrt{g^2 + (2\pi fC)^2} \tag{21}$$

the impedance is

$$z = \frac{1}{y} = \frac{1}{\sqrt{g^2 + (2\pi fC)^2}} \tag{21a}$$

\* When the coil has a non-magnetic core and the frequency is low, say 60 cycles or less, the effective resistance is practically equal to its ohmic or d-c. resistance; see article on *Skin Effect*.

† Even for moderate frequencies, 25 cycles or more, the effective conductance of a condenser is in general many times its ohmic conductance; see article on *Condensers, Electric*.

the effective resistance is

$$r = \frac{g}{g^2 + (2\pi fC)^2}; \quad (21b)$$

and the effective *condensive* reactance is

$$x_c = \frac{2\pi fC}{g^2 + (2\pi fC)^2}; \quad (21c)$$

which is equivalent to an *inductive* reactance of

$$x = -x_c = \frac{-2\pi fC}{g^2 + (2\pi fC)^2}. \quad (21d)$$

Only when the effective conductance  $g$  is zero is the reactance of a condenser equal to  $-\frac{1}{2\pi fC}$ , but in many instances the value of  $g$  is so small compared with  $2\pi fC$  that the inductive reactance may be taken as  $-\frac{1}{2\pi fC}$ ; the error in this approximate expression is less than 1 per cent for  $g$  less than 10 per cent of  $2\pi fC$ .

**Relations between Effective Resistance, Reactance and Impedance and Effective Conductance, Susceptance and Admittance for Sine-wave Currents and Voltages.** — From the definitions given above, equations (12) to (15), it may be shown that for sine-wave currents and voltages of a given frequency the following relations hold for any portion of a circuit:

$$\left. \begin{aligned} z &= \sqrt{r^2 + x^2}, & y &= \sqrt{g^2 + b^2}, \\ z &= \frac{1}{y}, & y &= \frac{1}{z}, \\ r &= \frac{g}{y^2}, & g &= \frac{r}{z^2}, \\ x &= \frac{b}{y^2}, & b &= \frac{x}{z^2} \end{aligned} \right\} \quad (22)$$

where  $r$  = effective resistance,  $x$  = reactance (taken positive when inductive),  $z$  = impedance,  $g$  = effective conductance,  $b$  = susceptance (taken positive when inductive) and  $y$  = admittance, all for the given portion of circuit. Equations (20) to (21d) are special cases of equation (22).

**Impedances in Series.** — Let  $z_1, z_2, z_3$ , etc., be the impedances of the several portions of a circuit all connected in series (same current through each). Then the resultant impedance is

$$\left. \begin{aligned} Z &= \sqrt{R^2 + X^2}, \\ \text{where} \quad R &= r_1 + r_2 + r_3 + \text{etc.}, \\ \text{and} \quad X &= x_1 + x_2 + x_3 + \text{etc.}, \end{aligned} \right\} \quad (23)$$

where  $r_1, r_2, r_3$ , etc., are the effective resistances and  $x_1, x_2, x_3$ , etc., the reactances (condensive reactances to be considered as negative) of the several impedances. When there is no external source of e.m.f. in any portion of the circuit, then the resultant power factor is  $\cos \theta$  where

$$\tan \theta = \frac{x_1 + x_2 + x_3 + \text{etc.}}{r_1 + r_2 + r_3 + \text{etc.}} \quad (23a)$$

**Example.** — An alternating current of 100 amperes is to be supplied to a receiver which has an equivalent resistance  $r_1$  of 2 ohms and an equivalent

reactance  $x_2$  of 0.5 ohms. The line has a resistance  $r_1$  of 0.1 ohms and an inductive reactance  $x_1$  of 1.5 ohms. The equivalent resistance of the line and receiver is then  $R = r_1 + 0.1 = 2.1$  ohms and the equivalent reactance of the line and receiver is  $X = 0.5 + 1.5 = 2.0$  ohms. Hence the equivalent impedance of the line and receiver is  $Z = \sqrt{(2.1)^2 + (2.0)^2} = 2.90$  ohms. The impedance of the receiver alone is  $z_2 = \sqrt{(2)^2 + (0.5)^2} = 2.06$  ohms and the impedance of the line alone is  $z_1 = \sqrt{(0.1)^2 + (1.5)^2} = 1.50$  ohms. The arithmetical sum of  $z_1$  and  $z_2$  is 3.56, which is 23 per cent greater than the true impedance of the line and receiver.

When the current supplied to the receiver is 100 amperes, the voltage at the receiver is  $V = 100 \times z_2 = 100 \times 2.06 = 206$  volts and the voltage at the generator is  $V_g = 100 \times Z = 100 \times 2.90 = 290$  volts, see Fig. 6, that is, the voltage at the receiver is  $290 - 206 = 84$  volts less than at the generator. The total potential drop in the two wires forming the line, however, is  $100 \times z_1 = 100 \times 1.50 = 150$  volts, which is 79 per cent greater than the true difference between the potential drops across the generator and across the receiver terminals.

Fig. 6.

Fig. 7.

**Resonance of a Coil and Condenser in Series.**—Consider the circuit shown in Fig. 7. When a sine-wave current of effective value  $I$  is established in such a circuit the voltage drop across the resistance is  $V_r = rI$  and is in phase with  $I$ . The voltage drop across the inductance is  $V_L = (2\pi fL) I$  and leads  $I$  by  $90^\circ$ . The voltage drop across the capacity (a condenser with negligible conductance) is  $V_c = \frac{I}{2\pi fC}$  and lags  $I$  by  $90^\circ$ . Hence the resultant voltage across the entire circuit is

$$V = \sqrt{V_r^2 + (V_L - V_c)^2} = I \sqrt{r^2 + \left(2\pi fL - \frac{1}{2\pi fC}\right)^2} \quad (24)$$

The reactance is therefore

$$x = \sqrt{s^2 - r^2} = \left(2\pi fL - \frac{1}{2\pi fC}\right)$$

When the inductance  $L$ , capacity  $C$  and frequency  $f$  are so related that

$$f = \frac{1}{2\pi \sqrt{LC}} \quad (25)$$

the reactance of the circuit is zero, the impedance is equal to the resistance, the power factor is unity and the current corresponding to a given voltage  $V$  is  $I = \frac{V}{r}$ ; that is, the current is a maximum and depends only upon the resistance

of the circuit. The frequency corresponding to this condition is the same as the frequency with which the current and p.d. would oscillate were the condenser short-circuited by the inductance; i.e., this frequency corresponds\* to the free period of such a circuit (see *Transient Electric Phenomena and Oscillations*). In general, a condenser and coil in series are said to be in resonance with the impressed frequency when the current for a given impressed voltage is a maximum, and the power factor therefore unity. When the conductance of the condenser is negligible the resonant frequency is given by equation (25).

When resonance obtains in a series circuit the voltage across the coil and that across the condenser may be many times the impressed voltage. For example, when the inductance  $L$  is 1 henry, the capacity  $C$  is 7.04 microfarads, and the frequency is 60 cycles, the inductive reactance is  $x_L = 2\pi \times 60 \times 1 = 377$  ohms, the condensive reactance is  $x_C = \frac{1}{2\pi \times 60 \times 7.04 \times 10^{-6}} = 377$  ohms, and the circuit is in resonance. For a resistance of 1 ohm in the coil and an impressed e.m.f. of 100 volts, the voltage across the coil is  $\sqrt{(100)^2 + (377 \times 100)^2} = 37,700$  volts and the voltage across the condenser is  $377 \times 100 = 37,700$  volts.

**Impedances in Parallel.**— Let  $z_1, z_2, z_3$ , etc., be the impedances of several branch circuits as shown in Fig. 8, and let the resistances and reactances constituting these impedances be  $r_1, r_2, r_3$ , etc., and  $x_1, x_2, x_3$ , etc., respectively.† First calculate the corresponding conductances  $g_1, g_2, g_3$ , etc., and susceptances  $b_1, b_2, b_3$ , etc., using equations (22). Then the resultant admittance, provided there are no external sources of e.m.f. in any of the branches, is

Fig. 8.

$$\text{where } \left. \begin{aligned} Y &= \sqrt{G^2 + B^2}, \\ G &= g_1 + g_2 + g_3 + \text{etc.}, \\ B &= b_1 + b_2 + b_3 + \text{etc.}, \end{aligned} \right\} \quad (26)$$

and the resultant power factor is  $\cos \theta$  where

$$\tan \theta = \frac{b_1 + b_2 + b_3 + \text{etc.}}{g_1 + g_2 + g_3 + \text{etc.}} \quad (26a)$$

**Resonance of a Coil and Condenser in Parallel.**— When a coil of negligible resistance and a condenser of negligible conductance are connected in parallel, the resultant current established through the circuit by a given impressed voltage will be zero (infinite impedance) when the inductance  $L$ , capacity  $C$  and frequency  $f$  bear the following relation:

$$f = \frac{1}{2\pi \sqrt{LC}} \quad (27)$$

Compare with equation (25). Under these conditions the coil and condenser are said to be in resonance with the impressed frequency. When the coil has an appreciable resistance and the condenser an appreciable conductance they are said to be in resonance when the resultant current is a minimum for a given impressed voltage, and the power factor therefore unity.

\* Approximately only when  $r$  is large; see *Transient Electric Phenomena and Oscillations*.

† Condensive reactances to be considered negative.

**NON-SINUSOIDAL CURRENTS AND VOLTAGES.** — The general expression for any alternating current, or in fact of any continuous periodic function, is

$$i = \sqrt{2} I_1 \sin (\omega t + \theta_1) + \sqrt{2} I_2 \sin (2 \omega t + \theta_2) + \sqrt{2} I_3 \sin (3 \omega t + \theta_3) + \dots,$$

where  $I_1, I_2, I_3$ , etc., represent the r.m.s. values of each of the terms. That is any current or voltage wave may be considered as made up of a "fundamental" sine-wave, having the same frequency as that of the actual wave, and "harmonic" sine-waves having frequencies which are integral multiples of the frequency of the fundamental. Alternating currents and voltages in practice usually contain one or more of the *odd* harmonics; *even* harmonics practically never occur in ordinary electric circuits supplied from commercial forms of generators. However, as noted above, it is permissible in most instances to assume sine-wave currents and voltages, since the harmonics present are usually relatively weak compared with the fundamental. In certain instances, however, it is necessary to analyze a wave into its fundamental and harmonics. For methods of experimentally determining the shape of current and voltage waves see the articles on *Oscillographs* and *Brown Tube*; for the analysis of the curves themselves see the article on *Wave Analysis*.

**R.M.S. Value of a Non-sinusoidal Wave.** — The r.m.s. value of such a wave can be obtained directly from equation (3), or if the r.m.s. values  $I_1, I_2, I_3$ , etc., of the harmonic and fundamentals are known the r.m.s. value of the resultant wave is

$$I = \sqrt{I_1^2 + I_2^2 + I_3^2 + \dots} \quad (28)$$

A like relation holds for the r.m.s. value of a voltage wave. Similarly, if for example a 25-cycle e.m.f., say  $E_{25}$ , and a direct e.m.f., say  $E_d$ , are acting in series in the same circuit, the resultant e.m.f. of the combination is

$$E = \sqrt{E_{25}^2 + E_d^2}.$$

**Power Corresponding to Non-sinusoidal Currents and Voltages.** — Let  $I_1$  be the r.m.s. value of the fundamental (first harmonic) of the current,  $V_1$  the r.m.s. value of the fundamental of the voltage and  $\theta_1$  the difference in phase between these two fundamentals, both being of the same frequency; let  $I_2, V_2$  and  $\theta_2$  be the corresponding quantities for the second harmonic; let  $I_3, V_3$  and  $\theta_3$  be the corresponding values for the third harmonic, etc. Then the average power is

$$P = V_1 I_1 \cos \theta_1 + V_2 I_2 \cos \theta_2 + V_3 I_3 \cos \theta_3 + \text{etc.}$$

That is, each harmonic contributes an amount to the total power equal to the power it would develop were the other harmonics not present. If, for example, the third harmonic is not present in the current wave, then this harmonic contributes nothing to the average power even though there may be a large third harmonic in the voltage wave. Again, when a 25-cycle alternating electromotive force  $E_{25}$  and a direct electromotive force  $E_d$  are acting in series on the same circuit the power developed is the sum of the powers which each would develop if they acted separately, but the resultant e.m.f. of the combination is not  $E_{25} + E_d$ , but, as noted above, is  $\sqrt{E_{25}^2 + E_d^2}$ .

**Calculation of Networks when the Currents and Voltages are Non-sinusoidal.** — See below under *Symbolic Notation*, equations (31) and (32), and the accompanying text.

**SYMBOLIC NOTATION FOR EXPRESSING SINE-WAVE CURRENTS AND VOLTAGES.** — Since sine-wave currents and voltages may be represented by vectors equal in length to the r.m.s. values of these quan-

titles and making definite constant angles with one another, two mutually perpendicular axes of references may be chosen, and each current and voltage resolved into two components, one along the X-axis or horizontal axis and one along the Y-axis or vertical axis. The component along the X-axis may be expressed as an ordinary algebraic quantity, and the component along the Y-axis may also be expressed as an algebraic quantity with the symbol " $j$ " written in front of it to indicate that it is perpendicular to the X-component. That is, any current may be written

$$I = I_1 + jI_2$$

where  $I_1$  is the horizontal or X-component of the current and  $I_2$  the vertical or Y-component. Until one gets familiar with this notation it is best to indicate the symbolic nature of the currents, voltages, impedances, etc., by writing dots under them; but these dots may be dispensed with in the actual solution of problems by this method when one keeps clearly in mind that in all operations the various quantities are to be treated as complex quantities throughout.

A voltage drop in symbolic notation is expressed in a similar manner, viz.,

$$V = V_1 + jV_2$$

and an electromotive force as

$$E = E_1 + jE_2$$

the same axis of reference being used for the currents, voltage drops and electromotive forces.

**Impedance and Admittance in Symbolic Notation.** — In this notation an impedance of resistance  $r$  and reactance\*  $x$  is represented by the complex quantity

$$z = r + jx, \quad (29)$$

and an admittance of conductance  $g$  and susceptance\*  $b$  by the complex quantity

$$y = g - jb. \quad (29a)$$

These expressions are independent of the axes of reference chosen.

**Currents, Voltages, Impedances and Admittances as Complex Numbers.** — In all operations involving the addition or subtraction of currents or voltages and in all operations involving products of currents and impedances or products of voltages and admittances, these quantities when written in symbolic notation may be treated as complex quantities (see article on *Complex Quantities*), provided all the currents and voltages are referred to the same axis of references. In all such operations the symbol " $j$ " may be considered as mathematically equivalent to  $\sqrt{-1}$ . Hence when a term of the form  $A_1 + jA_2$  occurs in the denominator of any fraction, the fraction may be "rationalized" by multiplying numerator and denominator by  $A_1 - jA_2$ , which gives

$$\frac{1}{A_1 + jA_2} = \frac{A_1 - jA_2}{A_1^2 + A_2^2}. \quad (30)$$

In any resulting expression for a current or voltage when thus rationalized the "real" part represents the actual component of the current or voltage in the direction of the X-axis and the " $j$ " part, i.e., the sum of the terms which are multiplied by  $j$ , represents the actual component of the current or voltage along the Y-axis.

\* Taken positive when inductive, negative when condensive, e.g., the admittance of a condenser is  $g + j(\omega/C)$ .

**Solution of Alternating-current Networks.**—When all the currents, voltages, impedances and admittances are expressed in symbolic notation, the following relations hold.\*

1. The sum of all the currents flowing to any point in any network of conductors is zero. That is, at any point

$$I + I' + I'' + \dots = 0, \quad (31)$$

where the currents are all expressed in symbolic notation and are all referred to the same line of reference.

2. The sum of all the impedance drops in a given direction around any closed loop in any network of conductors is equal to the sum of all the externally induced e.m.f.'s acting in this loop in this direction. That is, around any closed loop

$$\xi + \xi' + \xi'' + \dots = E + E' + E'' + \dots, \quad (32)$$

where the currents, impedances and electromotive forces are all expressed in symbolic notation, and the currents and e.m.f.'s are all referred to the same axis of reference. That is, the currents are to be expressed as  $I = I_1 + jI_2$ ,  $I' = I_1' + jI_2'$ , etc., and the e.m.f.'s as  $E = E_1 + jE_2$ ,  $E' = E_1' + jE_2'$ , etc., where all the components of the currents and e.m.f.'s with the subscript 1 are parallel to one another and all those with the subscript 2 are parallel to one another and lead the first set of components by 90 degrees.

The electromotive forces due to inductance and capacity are taken account of by the impedance; the electromotive forces represented by the  $E$ 's in equation (32) are the externally induced electromotive forces such as those due to generators or motors or to the mutual inductance of the two windings of a transformer.

In applying equations (31) and (32) to the calculation of the currents and potential drops in any network of circuits, care must be taken to designate clearly the sense of the vectors representing the currents and e.m.f.'s. This is most conveniently done by numbering all the junction points in the network, and designating each current and e.m.f. by a double subscript written in the order corresponding to the assumed direction of the current or e.m.f. vector. For example, in Fig. 9, the e.m.f. from 0 to 1 is represented by  $E_{01}$  while the e.m.f. from 1 to 0, which is equal to  $-E_{01}$ , is represented by  $E_{10}$ . In the figure, then, the net electromotive force from 1 to 2 is

Fig. 9.

$$E_{12} = E_{10} + E_{02},$$

$$E_{12} = -E_{01} + E_{02}.$$

Each equation of the form (31) or (32) is in reality equivalent to two equations, since the sum of all the "real" terms on one side must be equal to the sum of all the real terms on the other side, and similarly, the sum of all the "j" terms on one side must be equal to the sum of all the "j" terms on the other side, the denominators of all fractions having been cleared of "j" terms by the transformation given by equation (30). This is merely another way of stating the fact that the component in any direction of the resultant of any number of vectors

\* These relations are simply Kirchhoff's Laws (see *Electricity and Magnetism, Principles of*) expressed in a convenient form for alternating currents.

must be equal to the algebraic sum of the components in this direction of all the individual vectors. Applying these two laws to any network enables one, therefore, to calculate both components of every p.d. and every current, when the impedances and the electromotive forces are known.

These equations hold only when the currents and e.m.f.'s are all simple harmonic functions of the same frequency and the resistances and reactances are constant. When, however, the resistances, inductances and capacities are constant, a similar set of equations holds for each frequency that may be present. Since the equations are all linear in the  $I$ 's and  $E$ 's, the currents and e.m.f.'s of any given frequency will be uninfluenced by the presence of currents or e.m.f.'s of any other frequency. Hence, when the harmonics present in each e.m.f. are known, the harmonics present in each current may be calculated by solving the equations corresponding to the frequency of this particular harmonic, these equations being exactly the same as would hold were all the other harmonics absent.

Network problems can often be simplified by various expedients, see for example, *Analytical Solutions of Power-Circuit Network Problems*, by R. D. Evans, in the *Electric Journal*, Vol. 16, pp. 345-349, 1919.

**Difference in Phase between a Current and Voltage in Symbolic Notation.** — Let the current be represented by

$$I = I_1 + jI_2$$

and the voltage drop in the same sense as the current be represented by

$$V = V_1 + jV_2.$$

Then the current lags behind the voltage drop by the angle  $\theta$ , where

$$\tan \theta = \frac{V_2 I_1 - V_1 I_2}{V_1 I_1 + V_2 I_2}. \quad (33)$$

**Power Corresponding to a Current and Voltage in Symbolic Notation.** — Let the current and voltage drop be represented by the same expressions as in the preceding paragraphs. Then the average power is

$$P = V_1 I_1 + V_2 I_2. \quad (34)$$

Note that this expression is equal to the real part of the product of the complex numbers  $V_1 + jV_2$  and  $I_1 + jI_2$  with the sign between the two terms reversed.

**Example of the Use of the Symbolic Method.** — An impedance  $z_1$  has a resistance of 3 ohms and an inductive reactance of 4 ohms; a second impedance  $z_2$  has a resistance of 8 ohms and a condensive reactance of 6 ohms.  $z_1$  is then represented symbolically as  $z_1 = 3 + j4$  and  $z_2$  as  $z_2 = 8 - j6$ .

Let these two impedances be connected in series, and let an e.m.f. of 100 volts be impressed across them. Choosing the vector representing the over-all potential drop as the axis of reference, and calling the current  $I$ , then  $(3 + j4 + 8 - j6) I = 100 + j0$ , whence

$$I = \frac{100}{11 - j2} = \frac{1100 + j200}{121 + 4} = 8.8 + j1.6.$$

Hence the effective value of the current is

$$I = \sqrt{(8.8)^2 + (1.6)^2} = 8.94 \text{ amperes}$$

and the current leads the over-all potential drop by the angle

$$\tan^{-1} \frac{1.6}{8.8} = 10.3^\circ.$$

The potential drop across the first impedance is

$$V' = (3 + j4)(8.8 + j1.6) = 26.4 - 6.4 + j(35.2 + 4.8) = 20 + j40,$$

which has the effective value

$$V' = \sqrt{(20)^2 + (40)^2} = 44.7 \text{ volts,}$$

and leads the over-all potential drop  $V$  by the angle

$$\tan^{-1} \frac{40}{20} = 63.5^\circ.$$

The potential drop across the second impedance is

$$V'' = (8 - j6)(8.8 + j1.6) = 70.4 + 9.6 - j(52.8 - 12.8) = 80 - j40,$$

which has the effective value

$$V'' = \sqrt{(80)^2 + (40)^2} = 89.4 \text{ volts,}$$

and lags behind the over-all potential drop  $V$  by the angle

$$\tan^{-1} \frac{40}{80} = 26.5^\circ.$$

The power input into the first impedance is

$$W' = 8.8 \times 20 + 1.6 \times 40 = 240 \text{ watts.}$$

The power input into the second impedance is

$$W'' = 8.8 \times 80 - 1.6 \times 40 = 640 \text{ watts.}$$

The total power input is

$$W = 8.8 \times 100 + 1.6 \times 0 = 880 \text{ watts,}$$

which of course is the sum of  $W'$  and  $W''$ .

**POLYPHASE SYSTEMS.**—A polyphase alternating-current system is a network (i.e., combination of circuits) supplied from a generator or generators which develop two or more electromotive forces differing in phase from one another by a constant angle; see *Distribution of Electric Energy; Generators, Alternating-current; Transformers*. The two kinds of polyphase circuits commonly employed are the two-phase and three-phase circuits.

**Star and Mesh Connections.**—Consider  $n$  separate coils or windings, which may be mounted on a common armature or be entirely distinct, as for example  $n$  groups of lamps. When these  $n$  windings are connected end to end so that they are all in series, forming a closed chain, as in Fig. 10, and terminals

Fig. 10.

Fig. 11.

are brought out from the  $n$  junctions, they are said to be connected in "mesh." When one terminal of each of these windings is connected to a common junction point, as in Fig. 11, and terminals are brought out from the free ends, the windings are said to be connected in "star," and the common point is called the "neutral point."

**n-Phase System.** — When such a group of  $n$  windings, as shown in Fig. 10 or 11, is connected to a generator or other source of e.m.f., having  $n$  separate windings and therefore developing  $n$  different e.m.f.'s which differ in phase from one another, the system is called an  $n$ -phase system, each winding being called a "phase." For example, when there are three separate windings on the generator, three line wires and three windings constituting the load, the system is a three-phase system.

**Balanced Systems.** — When the e.m.f.'s, if any, in the  $n$ -phases of any system of connection are all equal in r.m.s. value and differ successively in phase by  $360/n$  degrees and if the currents in these windings are also equal in r.m.s. value and differ successively in phase by  $360/n$  degrees, the system is said to be a "balanced"  $n$ -phase system. When the e.m.f.'s in the various parts of a system are equal in r.m.s. value and differ successively in phase by  $360/n$  degrees, and the impedances in the various windings or phases are all equal, both as regards resistance and reactance, then the currents are necessarily equal in r.m.s. value and differ successively in phase by  $360/n$  degrees, and the system is balanced.

**Phase and Line Currents and Voltages.** — The current in any winding or phase of an  $n$ -phase system, see Figs. 10 and 11, is called the "phase current," and the drop (or rise) of potential *through* this winding is called the "phase voltage." The current in the line leaving any terminal of an  $n$ -phase system is called the "line current" and the voltage between *adjacent* line wires or terminals is called the "line voltage," except in the special case of a two-phase connection, see below, when the voltage between diametrically opposite terminals is called the line voltage. In the case of a star-connection the voltage between any terminal and the neutral point is called the "voltage to neutral"; in the case of a balanced mesh connection by voltage to neutral is meant the voltage which would exist between any terminal and the neutral of a star-connection connected to the terminals of the actual device, the impedance of all the legs of the star-connection forming this "artificial neutral" being equal and sufficiently large not to take an appreciable current.

The relations between these various currents and voltages for a balanced  $n$ -phase system are as follows:

	Mesh	Star
Number of phases.....	$n$	$n$
Line current.....	$I_l$	$I_l$
Line voltage.....	$V_l$	$V_l$
Phase current.....	$I_p = \frac{1}{2 \sin \frac{\pi}{n}} I_l$	$I_p = I_l$
Phase voltage.....	$V_p = V_l$	$V_p = \frac{1}{2 \sin \frac{\pi}{n}} V_l$
Voltage to neutral.....	$V_n = \frac{1}{2 \sin \frac{\pi}{n}} V_p$	$V_n = V_p$
Total volt-amperes.....	$n V_p I_p = \frac{n}{2 \sin \frac{\pi}{n}} V_l I_l$	$n I_p^2 = \frac{n}{2 \sin \frac{\pi}{n}} V_l I_l$

**Two-phase or Quarter-phase System.**—Strictly, the so-called single-phase system is a star-connected two-phase system, since the currents from the two terminals are in opposite directions at any instant, the current leaving by one and entering by the other. However, in practice the name two-phase system is used for a system supplied from a generator or other source of e.m.f. having two windings in which are developed two e.m.f.'s differing in phase by 90°; e., a two-phase system is in reality two distinct single-phase systems each with two terminals. Two of the four terminals may be connected to each other, in which case but three line wires are required. Or, the two single-phase systems may be connected at their middle points; in this case the two-phase system may be considered as a four-phase, or, as it is usually called, a "quarter-phase" system. See the articles on *Distribution of Electric Energy and Transformers*.

**Three-phase System.**—Delta and Y-Connections.—For a three-phase system the generators and motors are designed with three windings or phases which may be connected either in mesh, usually called a "delta-connection" in this case, since the diagram of the three windings forms a Greek delta, or the three windings may be connected in star, usually called a "Y-connection" in this case, since the diagram of the three windings forms a Y. The relations between line and coil currents and voltages for a *balanced* three-phase system are as follows:

	Delta	Y
Line current.....	$I_l$	$I_l$
Line voltage.....	$V_l$	$V_l$
Phase current.....	$I_p = \frac{I_l}{\sqrt{3}}$	$I_p = I_l$
Phase voltage.....	$V_p = V_l$	$V_p = \frac{V_l}{\sqrt{3}}$
Voltage to neutral.....	$V_n = \frac{V_l}{\sqrt{3}}$	$V_n = V_p$
Total volt-amperes.....	$3V_p I_p = \sqrt{3} V_l I_l$	$3V_p I_p = \sqrt{3} V_l I_l$

**Calculation of Balanced Three-phase Circuits.**—Any problem in regard to a balanced three-phase circuit may be solved by reducing all parts of the circuit to an equivalent Y-connection, provided the currents and e.m.f.'s are sine-waves. The transformations are made as follows:

Any  $\Delta$ -connected motor or generator is considered as equivalent to a Y-connected generator or motor in which

$$E_Y = \frac{E_{\Delta}}{\sqrt{3}}, \quad r_Y = \frac{r_{\Delta}}{3}, \quad x_Y = \frac{x_{\Delta}}{3},$$

where the quantities  $E_Y$ ,  $r_Y$  and  $x_Y$  are the e.m.f., resistance and reactance per phase of the Y-connected machine equivalent to the e.m.f., resistance and reactance per phase of the actual  $\Delta$ -connected machine.

Each of the line wires is in series with a corresponding phase of the equivalent Y-connected machine.

When all parts of the circuit have thus been reduced to equivalent Y's, each of the three-phases may be treated as a single-phase circuit, each circuit considered completed by a wire having zero impedance connecting all the neutrals together, since all the neutrals are at the same potential.

The voltages thus calculated are the voltages to neutral and the currents are line currents. To find the line voltage multiply the calculated voltage by  $\sqrt{3}$ ; similarly, to find the actual phase current in the  $\Delta$ -connected generator or load divide the calculated current by  $\sqrt{3}$ .

**Example of Three-phase Calculation.** — Energy is supplied from a generating station to a substation 50 miles away at a rate of 20,000 kilowatts. The system is a balanced three-phase system and operates at a frequency of 25 cycles. The transmission line consists of three No. 0000 B. & S. copper wires spaced six feet between centers. It is desired to find (1) the voltage between wires at the generating station when the voltage between wires at the substation is 60,000 volts, and the power factor at the substation is 80 per cent, with the current lagging, (2) how much power is lost in the transmission line and (3) what is the power factor at the generating station. The electrostatic capacity of the line may be neglected.

The current per wire is

$$I = \frac{20,000,000}{\sqrt{3} \times 60,000 \times 0.8} = 241 \text{ amperes.}$$

The voltage to neutral at the substation is

$$V_n = \frac{60,000}{\sqrt{3}} = 34,600$$

The component of this voltage in phase with the line current is  $0.8 \times 34,600 = 27,700$  volts and the component  $90^\circ$  ahead of the line current is  $0.6 \times 34,600 = 20,800$  volts, since  $\cos \theta = 0.8$  and  $\sin \theta = 0.6$ .

The resistance per mile of a No. 0000 wire is 0.258 ohm; its reactance per mile at 25 cycles is 0.303 ohm. Hence the total resistance of each wire is 12.9 ohms and the total reactance of each wire 15.2 ohms. The resistance drop in each wire is then  $12.9 \times 241 = 3110$  volts and is in phase with the line current and the inductive drop in each wire is  $15.2 \times 241 = 3660$  volts and is  $90^\circ$  ahead of the line current.

At the generator end the voltage to neutral in phase with the line current is then  $27,700 + 3110 = 30,810$  volts and the voltage to neutral  $90^\circ$  ahead of the current is  $20,800 + 3660 = 24,460$  volts. The resultant voltage to neutral at the generator end is then  $\sqrt{(30,810)^2 + (24,460)^2} = 39,300$  volts, and therefore the line voltage at the generating station is

$$V_l' = \sqrt{3} \times 39,300 = 68,000.$$

The power lost in the line is equal to  $3RI_l^2$ , where  $R$  is the total resistance of each wire and  $I_l$  the line current. Hence the power lost in the line is

$$3 \times 12.9 \times (241)^2 \text{ watts} = 2250 \text{ kilowatts.}$$

The total power delivered to the line and substation is then 22,250 kilowatts. Hence the power factor at the generating station is

$$\frac{22,250,000}{\sqrt{3} \times 68,000 \times 241} = 0.784 = 78.4 \text{ per cent.}$$

**Measurement of Power in Three-phase Circuits.** — See *Wattmeters*.

**Calculation of Unbalanced Three-phase Circuits.** — When a three-phase system is unbalanced, the currents and voltages can always be calculated by applying Kirchhoff's laws to the junctions and loops formed by the various parts of the system. For example, referring to Fig. 12, what will be the currents in each line wire and what will be the readings of the two watt-meters connected as shown when the three impedances forming the unbalanced star

Give the values  $s_1 = 1 + j2$ ,  $s_2 = 3 - j4$  and  $s_3 = 5 + j6$ , and the voltages between the terminals 1, 2 and 3 are balanced and numerically equal to 100 volts? What is the voltage from each terminal to the neutral?

Fig. 12.

The following relations then hold, taking  $V_{12}$  as the reference vector:

$$V_{12} = 100, \quad (a)$$

$$V_{23} = -50 + j86.6 \quad (b)$$

$$V_{31} = -50 - j86.6 \quad (c)$$

$$I_1 + I_2 + I_3 = 0 \quad (d)$$

$$100 = (1 + j2)I_1 - (3 - j4)I_2 \quad (e)$$

$$-50 + j86.6 = (3 - j4)I_2 - (5 + j6)I_3 \quad (f)$$

Substituting in (f) the value of  $I_2$  from (d) there results,

$$-50 + j86.6 = (8 + j2)I_3 + (5 + j6)I_1 \quad (g)$$

Substituting in (g) the value of  $I_3$  from (e) and solving for  $I_1$  there results,

$$I_1 = 25.36 + j5.90. \quad (h)$$

Substituting this value of  $I_1$  in (e) there results,

$$I_2 = -19.43 - j7.04 \quad (i)$$

Substituting (h) and (i) in (d) there results,

$$I_3 = -5.93 + j1.14 \quad (j)$$

The r.m.s. values of these three currents are respectively,

$$I_1 = 26.04; \quad I_2 = 20.64; \quad I_3 = 6.04.$$

Wattmeter  $A$  indicates the power  $P_A$  corresponding to the voltage  $V_{12}$  and the current  $I_1$ , and wattmeter  $B$  indicates the power  $P_B$  corresponding to the voltage  $V_{23}$  and the current  $I_2$ . Note that from (b) and (c) and (h) and (i),

$$V_{12} = 50 + j86.6, \quad V_{23} = -50 + j86.6,$$

$$I_1 = 25.36 + j5.90, \quad I_2 = -19.43 - j7.04.$$

Whence, from equation (34),

$$P_A = 1779 \text{ watts and } P_B = 362 \text{ watts.}$$

Note that  $(P_A + P_B)$  is equal to the total power input to the three phases, viz., to  $(e_1 I_1^2 + e_2 I_2^2 + e_3 I_3^2)$ , and compare with the article on *Wattmeters*.

The r.m.s. voltage from each terminal to the neutral is the product of the current in that particular phase of the  $Y$  by the impedance of that phase, viz.

$$V_{10} = 26.04 \times \sqrt{(1)^2 + (2)^2} = 58.23 \text{ volts,}$$

$$V_{20} = 20.64 \times \sqrt{(3)^2 + (4)^2} = 103.20 \text{ volts,}$$

$$V_{30} = 6.04 \times \sqrt{(5)^2 + (6)^2} = 47.17 \text{ volts.}$$

**Unbalanced Polyphase System Equivalent to Two Balanced Polyphase Systems of Opposite Phase-rotation.**—In many cases it is advantageous, for the purpose of calculation, to consider an unbalanced polyphase system as the superposition of two balanced polyphase systems of opposite phase rotation. The procedure and a number of applications are given by Fortescue in the *A.I.E.E. Proc.*, June 18, 1918, p. 629. See also Lyon, W. V. *Elec. World*, 75, p. 1304, June 5, 1920.

**BIBLIOGRAPHY.**—Pender, H. *Electricity and Magnetism for Engineers Part II*, Jackson, D. C., and J. P., *Alternating Currents and Alternating current Machinery*; Steinmetz, C. P., *Theory and Calculation of Alternating current Phenomena*; Franklin and Esty, *Elements of Electrical Engineering* Vol. II; Russell, A. *Alternating Currents*; Timbie and Higbie, *Alternating Current Electricity*; Magnusson, C. E., *Alternating Currents*.

**ALUMINUM.** — (See also *Electrochemical Processes, Industrial; Lightning Protectors; Wires and Cables, Bare.*) The method of manufacturing aluminum wire is similar to that employed in making copper wire (see *Copper*).

**MECHANICAL PROPERTIES.** — The more important mechanical properties of aluminum are discussed below.

**Necessity of Stranding Aluminum Wire.** — Aluminum wire (i.e., solid wire) is little used for aerial spans owing to the danger of failure where accidental abrasions have occurred. Cables not only reduce the above danger, but have greater breaking load, owing to the superior tensile strength of small wires.

**Tensile Strength.** — The tensile strength of aluminum has not been studied so thoroughly as that of copper, but it is well known that like copper, aluminum is much stronger in small, than in large, wires. The following table by H. M. Hobart, which is for solid wires, illustrates this point.

Diameter, inches .....	0.05	0.10	0.15	0.20	0.25	0.30	0.35
Tensile strength, lb. per sq. in. ....	33,300	28,800	26,200	24,800	23,800	23,200	23,000

The Standard Electric Co., of California, uses a solid aluminum wire, 0.294 inch diameter, having a tensile strength of 22,800 pounds per square inch, and a conductivity of 59.9 per cent.

**Elongation.** — The ultimate elongation of hard-drawn aluminum wire varies from 2.0 per cent to 3.7 per cent (in 1 meter length) as the diameter is increased from 1 to 4½ mm. (H. M. Hobart.)

**Modulus of Elasticity.** — Different authorities give values from  $9 \times 10^4$  to  $10 \times 10^4$  in pounds per square inch, the former being given by the Aluminum Company of America.

**Elastic Limit.** — The Aluminum Company of America in their booklet on "Properties of Aluminum," give the following figures for elastic limit in tension, the metal being 99 per cent pure.

	Lb. per sq. in.
Castings .....	8,500
Sheet .....	12,500 to 25,000
Wire .....	16,000 to 33,000
Bars .....	14,000 to 23,000

**Density.** — A density of 2.70 grams per cubic centimeter is given by the U. S. Bureau of Standards (*Circ. No. 31*) as a good average value for commercial hard-drawn aluminum. This is equivalent to 0.0975 pound per cubic inch. Hobart gives 2.71 for the density. F. J. Brislee (*Lond. Elec. Review, Jan. 5, 1912*) gives 2.708 as the density of cast aluminum and 2.705 for hard-drawn rod.

**THERMAL PROPERTIES.** — See article on *Heat and Thermal Properties*.

**CONDUCTIVITY AND RESISTIVITY.** — The Aluminum Company of America give as the average of many thousands of separate determinations, the figure of 2.828 microhms per centimeter cube at 20° C. as the resistivity of commercial aluminum wire. This corresponds to a conductivity of 61 per cent of the annealed copper standard (see *Resistance and Conductance, Electric*).

**Effect of Hardness on Conductivity.** — The resistance of aluminum depends upon its hardness; for example, the resistance of aluminum wire of hard-

ness corresponding to a tensile strength of about 20 kg. per mm. is approximately 2 per cent greater than that of the same wire when thoroughly annealed, and consequently soft. (*E. M. Hobart.*)

**Temperature Coefficient of Resistivity.** — From the data given by G. Grassi (*Elektrotechnica*, 6, p. 10, Jan. 5, 1919); the 20° C. temperature coefficient of 61 per cent conductivity annealed aluminum wire is 0.00408, per degree centigrade, corresponding to a 0° C. coefficient of 0.00444. Grassi also found that the temperature coefficient of aluminum is proportional to its per cent conductivity (as is also the case with copper; see article on *Copper*). American investigators have found a lower coefficient, the figure 0.0039 being most commonly used.

**COMPARISON OF ALUMINUM AND COPPER.** — Aluminum is usually cheaper than copper of the same length and resistance and is said to be cheaper to install (*C. B. Smith, El. W., 1912, Vol. 59, p. 96*). It is, however, subject to the disadvantage of lower tensile strength which often makes it more expensive than copper, except for very high voltages.

The table below compares the various items for wires having the same length and same resistance and is based on the following assumptions:

	Copper	Aluminum
Per cent conductivity.....	98	61
Tensile strength, lb. per sq. in.....	55,000	25,000
Density.....	8.89	2.70
Price per pound.....	<i>P</i>	<i>p</i>

#### COMPARISON OF COPPER AND ALUMINUM WIRES FOR EQUAL RESISTANCES PER UNIT LENGTH

Item	Copper	Aluminum
Cost.....	1	$0.488 \times \frac{p}{P}$
Cross-section.....	1	1.63
Diameter.....	1	1.28
Weight.....	1	0.488
Breaking strength.....	1	0.731
Carrying capacity.....	1	1.13

**Disadvantage of Low Tensile Strength.** — The lower tensile strength of aluminum for equal length and conductance as compared with copper affects the cost of an aerial line in two ways: 1st, by making it necessary to erect the spans with a greater sag or less length in order to reduce the stresses, thereby either increasing the height or the number of poles, and 2nd, by making it necessary to increase the distance between wires on account of the increased sag. The increase in the height of poles for the same spacing amounts to about 10 per cent. (*C. L. Johnson*). Aluminum cables with steel core are now used and overcome these difficulties. See article on *Wires and Cables, Barr.*

**Effect of Large Elongation of Aluminum.** — The extraordinarily great elongation of aluminum enables it to withstand severe mechanical overloads by stretching and thus increasing the sag. However, in dealing with a single

solid wire this cannot be relied on, as a scratch or a single imperfection will often cause the wire to break without any appreciable elongation. This is one reason why cables are to be preferred to single-wire conductors.

**Effect of Low Melting Point of Aluminum.** — The distance between aerial wires is also influenced by the fact that aluminum has a lower melting-point than copper, making it necessary to keep wires at different potentials well separated in order to avoid the danger of short-circuits through foreign bodies. This danger has, perhaps, been exaggerated in the past as the author has the record of a case where a copper wire was thrown across two aluminum cables with 60,000 volts difference of potential between them and an arc was formed between the cables forming an arch 12 to 15 feet high, but with no injury to the cables except the formation of a few minute beads on their surface.

**Formation of Sleet.** — While for equal length and resistance, aluminum wires are larger than copper wires, they do not necessarily collect a proportionally greater load of sleet, as it is found that a film of grease left over from the drawing process often entirely prevents the adhesion of sleet. Conclusive information on this subject is, however, lacking, especially with regard to wire that has been in use for several years.

**Corona Formation.** — At very high potentials, such as 100,000 volts, aluminum conductors possess a marked advantage over copper in the lower corona loss due to their greater diameter for the same conductance.

**Corrosion.** — E. Huber-Stockar gives the results of a number of tests on the corrosion of aluminum in moist air, salt air, salt water, various gases, acids, etc., which indicate that, in respect to its chemical stability, aluminum is in general the equal of copper. There has been much said about the tendency of electrostatic repulsion to reduce impure condensation on aluminum conductors, but this author rejects such statements as unworthy of the slightest credence.

Aluminum wire exposed to the atmosphere increases in resistance. E. Wilson (*Electrician*, 75, p. 886, Sept. 17, 1915), reports a case where commercial aluminum increased in resistance 17.2 per cent in 13 years. Wilson also gives the results of tests on various aluminum alloys.

Bare aluminum conductors laid in the earth have been tried for railway return feeders, with the result that they were rapidly corroded by galvanic action.

Mr. Dusaughey says that aluminum containing over 4 per cent of impurities is very liable to corrode rapidly. This is especially the case if sodium is present.

At ordinary temperatures aluminum is covered with a layer of oxide which protects it against the influence of the weather and of many chemicals.

**Example of Relative Cost.** — According to the official publications of the Ontario Hydro-Electric Commission on a line consisting of two three-phase circuits, each comprising three 0000 A.W.G. cables, the six cables cost \$1450 per mile as compared with \$2050 per mile for copper cables (copper being at 15 cents per pound and aluminum at 23.5 cents per pound), showing a saving of nearly 30 per cent on the cables alone. This saving was reduced to 5.6 per cent only on the total cost of the line, partly because the actual towers weighed 1.72 tons against 1.57 tons for towers for an equivalent copper line, and partly because the cost of cables was only 30 per cent of the total cost of the line, including erection but excluding rights-of-way. (C. L. Johnson.) Owing to a tariff of 3 3/4 cents per pound the price of aluminum is higher in the United States than in Canada and Europe, so that the saving would have been considerably less at United States prices.

**SOLDERS FOR ALUMINUM.** — (*Bureau of Standards, Circ. No. 78, Washington, D. C., 1919*). Aluminum can be welded in a satisfactory manner by the oxyacetylene blowpipe flame, but soldering is often desirable. Alumi-

num solders consist usually of mixtures in varying proportions of Zn and Sn or of Zn, Sn and Al. The surfaces to be soldered are carefully cleaned and "tinned" or coated with a layer of the solder by heating the surface and rubbing the solder into it. The joint between the tinned surfaces may then be made in the usual way with a soldering iron and the solder, no flux being used. A soldered joint is rapidly attacked when exposed to moisture. The joints should never be made by soldering unless they are to be protected against corrosion by a paint or varnish or unless they are heavy, as in the case of repairs in castings.

The composition of the solder may vary within wide limits. For tin-zinc solders, zinc 15 to 50 per cent, the remainder Sn, is recommended. The higher the temperature at which the tinning is done the better is the adhesion of the tinned layer, therefore the solders high in Zn and Al give better results. The joint between previously tinned surfaces may be made by ordinary methods by ordinary soft solders; only the tinning mixture need be special for Al. The tensile strength of a good solder is about 7000 pounds per square inch. The strength of a joint depends on the type and on the workmanship, but much dependence should not be placed upon it.

**SPREE-ALUMINUM.** — E. Huber-Stodkar gives considerable data on an aluminum alloy, known under the name of spree-aluminum. It has nearly double the strength of pure aluminum. Its breaking length is 10.7 kilometers, as compared with 10.3 kilometers for steel, 6.7 kilometers for aluminum and 5.1 kilometers for hard copper. The use of spree-aluminum cable shows a saving in cost of about 7.3 per cent as compared with copper cable of equal conductance.

**AMMETERS.**—(See also *Balances, Currents; Electricity and Magnetism, Principles of; Electrodynamometers; Galvanometers; Voltmeters.*) An ammeter is essentially a galvanometer (q.v.) or electro-dynamometer (q.v.) of rugged construction, provided with a pointer moving over a scale forming an integral part of the instrument and calibrated to read directly in amperes. The moving element is usually supported in jeweled bearings.

**CLASSIFICATION AND USE OF AMMETERS.**—Ammeters which have found general commercial application may be classified as follows:

**Moving-magnet Type**, in which a permanent magnet or polarized vane is caused to move under the influence of a winding which carries the current to be measured. The principle of operation is similar to that of a Thomson galvanometer (see *Galvanometers*). The restoring force is usually a fixed permanent magnet. This type of instrument measures average values and is therefore suitable for direct currents only.

**Moving-iron Type**, in which there is relative motion between a piece of soft iron and a fixed coil carrying the current to be measured. There are a number of subclasses which are distinguished chiefly by differences of mechanical construction. In the plunger type a soft iron core is drawn into the coil. The core is usually in the form of a rod, and the length of the coil is several times its diameter. In the repulsion type, as usually constructed, a piece of iron is repelled by a fixed piece of iron, both being within the coil carrying the current to be measured. The Weston moving-iron ammeter is of this type. In the Thomson inclined-coil ammeter, the coil is fixed at an angle of about  $45^\circ$  with the shaft which carries one or more iron vanes, the latter also making the same angle with the shaft. As the current through the coil increases the vanes turn so as to approach the condition of parallelism with the magnetic field within the coil. The restoring force of all these forms of ammeter is usually that of a spring. This type of ammeter measures effective (r.m.s.) values\* and may be used for either alternating or direct currents, but such ammeters are subject to slight errors in the latter case, due to the tendency of the vane or plunger to hold its magnetism.

**Permanent-Magnet Moving-coil Type**, in which a permanent magnet maintains a strong field in a fixed location, and the current to be measured is sent through a moving coil, entering or leaving by springs that furnish the restoring force or through auxiliary spirals. The principle of operation is the same as that of a d'Arsonval galvanometer (see *Galvanometers*). This type of instrument measures average values and is suitable for direct currents only. Precision d-c. ammeters are usually of this type.

**Electrodynamic Type**, in which the operation depends upon the force exerted by one current-carrying circuit upon another, or by a portion of one circuit upon another portion of the same circuit. (See *Electrodynamometers*.) The usual form of construction includes a pivoted coil which moves in the field of a fixed coil or set of coils. The restoring force is usually due to springs, and the current is led into and out of the moving coil through these springs or through flexible conductors constructed to carry relatively large currents and to have a minimum restoring force. This type of instrument measures effective (r.m.s.)

\* Moving iron instruments do not measure r.m.s. values exactly, on account of the lack of exact proportionality between the instantaneous torque and the square of the instantaneous current, but by careful attention to details in the design such instruments can be made nearly perfect in this respect, so that all things considered, they are sometimes to be preferred to electrodynamic instruments. For precise work, calibration of such instruments made with direct current should not be used on alternating current.

values and may be used to measure either alternating or direct currents. Precision a-c. instruments are usually of the electrodynamic type.

**Hot-wire Type**, in which the expansion of a wire or strip due to the heat developed within it, caused by the current passing through it, is made to move an indicating pointer. The "thermocouple" ammeter, described below, may also be classified as a hot-wire ammeter, although the principle of operation is quite different. Hot-wire ammeters measure effective (r.m.s.) values and are useful for both alternating- and direct-current measurements.

**Induction Type**, in which a metal cylinder or disk with pointer attached is caused to rotate under the action of a rotating magnetic field, usually produced from a single-phase source by means of a phase-splitting device. The principle of operation is similar to that of an induction watt-hour meter (*see Watt-hour Meters*), the motion of the moving element being opposed by a spring. This type of instrument measures effective values of alternating currents only and generally for only a limited range of frequency and wave form.

**Thermocouple Ammeters.** — For measuring small alternating currents, particularly when the frequency is high (500 cycles per second or more), a thermocouple (*see Pyrometers*) may be used; the current to be measured is passed through a wire resistor (*see Wires, Resistor*) to which is soldered one junction of the thermocouple, the free ends of which are connected to an ammeter (or galvanometer) of any of the types noted above. The heating of the resistor wire sets up a direct current in the thermocouple circuit which, in turn, depends upon the effective value of the current through the heater wire. The limitations and errors in the use of such ammeters are discussed at length in a paper on *High Frequency Ammeters* in Scientific Paper No. 206, Bull. Bur. Stds., 1913, Vol. 10. See also article in the Gen. El. Rev. 17, p. 981, Oct., and p. 1210, Dec., 1914.

**Other Types of Ammeters.** — Successful instruments for special needs have been made that would not ordinarily be classed under the above headings, and other instruments might be referred to which combine in a single instrument more than one of the subdivisions.

**Portable and Switchboard Instruments.** — Switchboard instruments are usually of more rugged construction than portable instruments and are somewhat less precise in their indications. Portable instruments are provided with suitable binding posts on their bases and are generally used in a horizontal position. Switchboard instruments are usually provided with back connections and are used in a vertical position. In the so-called "edgewise" instruments the instrument mechanism is horizontal but the pointer is so designed that it indicates on a vertical scale.

**Recording (Graphic) Ammeters.** — A continuous record of current may be obtained by using an ammeter provided with a clock mechanism which slowly rotates a chart (disk-shaped or mounted on a drum) or a continuous paper ribbon under the end of the pointer which carries a pen kept continuously inked. The moving element is comparatively heavy since the deflecting force must be great enough to overcome the friction of the pen and prevent "sticking."

**INSTRUMENT SCALES.** — A uniform scale is usually desirable in any kind of instrument, and with permanent-magnet moving-coil types such a scale is readily obtained, since the deflecting torque is proportional to the current. In moving-iron, electrodynamic and other types in which the deflecting torque depends upon the square of the current, very small deflections are obtained for low values of the current and the scale divisions are crowded for low values.

**DAMPING.** — For ordinary purposes it is essential that the pointer of the instrument come quickly to rest. The moving coil of the permanent-magnet moving-coil instrument is usually wound on a light aluminum frame which is mounted between the poles of the permanent magnet, and a soft-iron core fills the air gap between the poles, other than that necessary to allow free motion of the coil. The metal frame moves through a very strong magnetic field and eddy currents are set up in it which effectually damp its motion. Although it is not difficult to make the instruments perfectly aperiodic, a slight underdamping is often preferred because it gives opportunity to observe at all times that the movement of the instrument is perfectly free.

Magnetic (eddy current) damping or air damping by means of light vanes moving in a more or less perfectly closed air chamber is used with the other types of instruments.

**ELIMINATION OF EFFECT OF STRAY FIELDS.** — Due to the low reluctance of iron compared with air, a soft-iron shield placed around the instrument mechanism will greatly reduce the disturbing effect of an external magnetic field on the readings of the instrument. Many types of switchboard and portable instruments are thus shielded. Permanent-magnet moving-coil instruments are affected by only comparatively strong fields.

**Astatic Instruments.** — Another means of avoiding errors due to stray fields is by making the moving element astatic. The principle of this construction is to divide the moving element into two parts, so arranged that the deflecting torques acting on the two parts due to the field of the instrument are additive, whereas any stray field will produce equal and opposite torques on these two parts.

**Thomson Astatic Instruments.** — The Thomson astatic ammeters and voltmeters are unique in that the deflecting torque and the controlling torque are both caused by the same magnetic field. This field is produced by an electromagnet wound for any specified voltage and provided with binding posts separate from the current posts of the instrument, or by means of a permanent magnet. Two moving coils are mounted diametrically opposite each other upon an aluminum disk. The disk and coils cut across the field which is directed parallel to the shaft carrying the disk. Two small pieces of soft iron are rigidly mounted on the shaft, the magnetic field entering these pieces of iron radially tending to hold the shaft and moving coils in their initial position.

When current passes through the coils of the moving element, the lines of force parallel to the shaft produce a torque which tends to turn the shaft and cause the needle to travel across the scale. This action is opposed by the magnetic field at right angles to the shaft acting on the two pieces of soft iron. The instrument has no controlling springs and since both the deflecting and controlling force are due to the same electromagnet, the accuracy is not affected by changes in magnetic strength. These instruments are particularly suited to service where very strong external fields are present.

**USE OF SHUNTS AND CURRENT TRANSFORMERS.** — *See also articles on Shunts; Transformers, Instruments.* The current which may be led into the moving element of an ammeter (moving-coil or electrodynamic type) is limited by the current-carrying capacity of the springs or special leading-in wires, which must necessarily be light; this current seldom exceeds 5 or 10 amperes. To increase the range of such instruments, and also to avoid the use of heavy conductors in the instruments, shunts or current transformers (the latter for alternating currents only) are used. Ammeters for use with current transformers are usually designed to take a maximum current of 5 amperes, but

their scales are calibrated to read directly the current in the primary of the transformer.

**Millivoltmeter Used as Ammeter.** — Direct-current ammeters designed for use with shunts are usually designed to carry but a very small current (about 0.025 ampere). A wire resistor having practically zero temperature coefficient is permanently connected, within the case of the instrument, in series with the moving coil. The combined resistance of the moving coil and resistor is thus made large compared with the resistance of the shunt, and the error, due to resistance variation, is not large for ordinary changes in temperature. The ammeter proper is then essentially a millivoltmeter (*see Voltmeters*) and measures the drop of potential through the shunt to which it is connected; the scale of the ammeter, however, is often calibrated to read directly in amperes for one or more standard shunts designed for use with it.

**Voltage Drop Across Shunts.** — Shunts for use with switchboard direct-current ammeters of the permanent-magnet moving-coil type are usually designed for a drop of 50 or 60 millivolts at full load, although for some special requirements, where the indicating instrument must be located at a considerable distance from the shunt, double-drop shunts having 120 millivolts are used, and even higher drops are used to meet very special requirements. For precision use with portable instruments the resistance coil is so designed that a drop of 100 or 200 millivolts is required for full-scale reading, the high resistance with zero temperature coefficient practically eliminating temperature errors.

**Use of Portion of Bus Bar as Shunt.** — Sometimes the shunt is dispensed with altogether and the millivoltmeter is connected directly to a portion of the bus bar or main conductor. This arrangement is usually not desirable, because the variation of temperature in the bus bar due to the current flowing through it causes larger errors than the variation due to changes in room temperatures. Some arrangements have been made to compensate for these, but are not very generally used.

**Voltmeter and Shunt for Measuring Alternating Currents.** — An a-c. voltmeter with shunt is not in general suitable for measuring an alternating current, since such instruments are not readily constructed to read low voltages and therefore a relatively large drop in the shunt would be required, also the division of current between the shunt and voltmeter depends (1) upon the inductances of the shunt and instrument, (2) upon the "skin effect" (q. v.) in the shunt. However, hot-wire voltmeters with shunts are sometimes used for alternating-current measurements and are satisfactory at commercial frequencies.

**PRECAUTIONS IN USE OF PORTABLE AMMETERS.** — The following precautions, which in the main also apply to other portable electrical instruments, should be observed:

*An ammeter should always be connected in series with the load. Never connect it across the mains.*

All contact surfaces of nuts, terminals, etc., must be clean.

Transformers and wires carrying heavy currents should be kept at a safe distance from all instruments.

Portable instruments should be always used in a horizontal position, unless specifically designed for use otherwise.

Tapping an instrument while it is being read is usually unnecessary if it is properly constructed and in good order, but when slight friction is present from any cause its effect can be eliminated by gently tapping the instrument. Hard tapping defeats its object.

It is a good plan in testing to place a low-resistance jumper or short-circuit <sup>or</sup> switch around the terminals of the ammeter and to connect a rheostat in series with it and the load. The plug of the short-circuit block should be gradually withdrawn, or the switch gradually opened, and the needle of the meter watched to be sure that the current is in the right direction and does not exceed the rated current of the instrument.

A heavy short-circuit in nearby conductors, even though of extremely short duration, is liable to demagnetize the magnet of a permanent-magnet instrument. After such a short-circuit the instrument should be recalibrated, even though the short-circuit causes no mechanical injury.

When it is desired to measure the average value of a pulsating current (e.g., from a rectifier), permanent-magnet moving-coil instruments should be used. The average value is to be used when the current is used for an electrochemical operation, such as plating, or charging storage batteries. Power measurements in rectified-current circuits should in general be made with an electrodynamic wattmeter.

The power of a rectified current in a noninductive circuit, such as incandescent lamps or electric heating apparatus, may be correctly determined by multiplying the effective current by the effective voltage, both being measured by electrodynamic or hot-wire ammeter and voltmeter. For a discussion of this subject see article by Todd, *Elec. Rev.* (Chicago) Vol. 77, p. 683, 1920.

Instruments containing iron should not be used for a frequency differing largely from that for which they are designed. For high-frequency measurements (above 500 cycles per second), some type of hot-wire or thermocouple instrument should be used. Instruments containing iron are also subject to error due to distorted current waves; for precise work on badly distorted waves they should be compared with an electrodynamic or hot-wire instrument, using the same kind of current in the comparison as that to be measured.

**CHECKING OF AMMETERS.** — The readings of two or more ammeters may be compared by connecting them in series with a rheostat (q.v.) and suitable source of e.m.f. An ammeter may thus be compared with a standard ammeter, and a curve drawn showing the true amperes corresponding to the dial readings. It is usually more convenient to plot the correction to be made to the reading against the actual reading. Corrections to be added to the reading are usually designated as + and corrections to be subtracted from the reading as -.

Instead of using a standard ammeter, a standard millivoltmeter and a standard resistor (see *Resistors, Standard*) may be employed for direct current. The standard resistor is connected in series with the ammeter to be checked and the millivoltmeter is connected across the potential terminals of the resistor. Let  $V$  be the reading of the millivoltmeter in volts,  $R$  the resistance of the resistor and  $r$  the resistance of the millivoltmeter; then the current measured is

$$I = V/R + V/r.$$

The last term  $V/r$  is usually negligible.

An accurate and convenient way of checking an ammeter on direct current is to use a potentiometer (q.v.), when such an instrument is available.

**Checking of A-C. Ammeters.** — Alternating-current indicating instruments, whose deflections are independent of frequency and wave form, when calibrated on direct current indicate correctly effective values when used on

<sup>2</sup> For small currents, two blocks of metal mounted on an insulating base with a tapered slot between the two, into which fits a tapered metal plug, make a convenient short-circuit block; for heavy currents a switch should be used.

alternating current. Electrodynamical instruments usually give readings of equal accuracy on alternating or direct current at commercial frequencies and wave forms. Eddy currents in the metal supports and conductors, however, may cause slight errors in some makes, even at commercial frequencies, and at high frequencies errors are liable to occur in all types unless special precautions are taken to avoid eddy currents. Moving-iron and induction-type ammeters should be compared with an electrodynamic ammeter which has been previously calibrated on direct current.

**ACCURACY OF AMMETERS AND OTHER ELECTRICAL INSTRUMENTS.** — Various methods of expressing the accuracy of electrical instruments have been used. A customary and reasonably satisfactory method is to state that the instrument is correct to within a given percentage of the full scale value. This is understood to apply throughout the scale, and in uniform-scale instruments amounts to saying that no division mark is out of its proper position by more than a certain linear distance.

It is difficult to make general statements of the accuracy of electrical instruments, because this depends on many things, such as operating principle, workmanship, range, and conditions of use. It may be said that 0.1 to 0.2 per cent is about the limit of accuracy attainable in d.-c. instruments, and to get it requires high-grade instruments carefully used in connection with calibration curves obtained by regular and sufficiently frequent comparisons with standards of higher class, such as potentiometers. The accuracy attainable in a.-c. instruments is in general less than in d.-c. instruments.

Portable instruments of high grade are obtainable having a stated accuracy of 0.25 per cent of full scale value; intermediate grade instruments, 0.5 per cent; small portable instruments, 1 per cent. Switchboard instruments of the best grade are usually stated to be accurate to within 1 per cent of full scale value.

The accuracy obtainable in service depends not only on the inherent accuracy of the instrument, but also to a very great extent on the conditions of use. This subject is discussed in detail in a paper on "The Accuracy of Commercial Electrical Measurements" by H. B. Brooks, *Trans. A.I.E.E.*, Vol. 39, 1920.

**INSTALLATION OF SWITCHBOARD INSTRUMENTS.** — The same general considerations apply to all switchboard instruments, i.e., ammeters, voltmeters, wattmeters, etc. Instruments previous to installation should be kept in a dry, cool place. Switchboard instruments should not be put in place until all the work on the boards or in the vicinity of their location has been done so that they may not be damaged by violent shocks.

During shipment moving parts, etc., are sometimes blocked and instructions furnished with instruments by makers should be carefully followed in unpacking and assembling.

It is not customary to ground the cases of d.-c. instruments or of a.-c. instruments above 650 volts; these latter are usually protected by insulated covers. The cases of instruments on secondary circuits below 650 volts are usually grounded.

**Determination of Capacity of Instruments.** — In providing instrument equipment for switchboard service the relation between ammeters, voltmeters, wattmeters and the circuit conditions should be carefully considered so the proper sizes may be provided. The size should be so chosen that a good indication can be obtained under all ordinary load conditions, and at the same time the highest loads can be accurately indicated.

**REPAIRS OF INSTRUMENTS.** — Most portable and switchboard instruments in use at the present time are constructed with the idea of having

their parts readily accessible for repair. Instruments, however, are usually very delicate in comparison with other apparatus, particularly with reference to the pivots and jewel bearings. Any extended repairs should, therefore, not be attempted unless equipment and experience suitable for the work in hand are available.

**COST OF AMMETERS AND VOLTMETERS.** — The following figures are approximate only, and should be used only as a rough guide. Shunts and instrument transformers are not included; see articles on *Shunts* and *Transformers, Instrument*.

COST OF AMMETERS AND VOLTMETERS (1920-21)

Type of instrument	Switchboard instruments	Portable instruments
Permanent-magnet moving-coil type:		
Small instruments .....	\$6-\$10	\$12-\$17
Medium-size instruments .....	\$13-\$24	.....
Regular-size instruments, high-grade .....	\$23-\$34	\$43-\$100
Polarized-vane type .....	\$2-\$4	.....
Moving-iron type:		
Unshielded, portable, single-range .....	.....	\$25-\$48
Shielded, portable, two-range .....	.....	\$54-\$100
Round pattern .....	\$20-\$29	.....
Horizontal edgewise pattern .....	\$36-\$51	.....
Electrodynamic type:		
Medium-size instruments .....	.....	\$33-\$42
Regular-size instruments, high-grade .....	.....	\$60-\$104
Induction type:		
High-grade .....	\$24-\$40	\$54-\$65
Low-grade .....	.....	\$32
Thermocouple type:		
Small instruments .....	\$16-\$19	.....
Regular size instruments .....	\$53-\$76	.....

See also an extensive bibliography on electrical instruments and meters in the 1914 report of Meter Committee of the National Electric Light Association.

**AMPERE-HOUR METERS.**—(See also *Ammeters; Wattmeters.*) Ampere-hour or quantity (coulomb) meters may be divided into practically two classes, i.e., electrolytic meters and electromagnetic or motor meters. They are used in this country chiefly for storage-battery work; small capacity ampere-hour meters are also used, particularly abroad, as watt-hour meters, being calibrated in this case to read directly in kilowatt-hours at some definite voltage.

**ELECTROLYTIC METERS.**—This type of meter is used extensively in Europe, but is rarely used in this country. The meter generally consists of some form of glass container or "U" tube containing an electrolyte, such as water, or an aqueous solution of a salt of mercury, or of caustic soda. The action of the current passing through the solution decomposes it and since the rate of decomposition is proportional to the strength of the current, the deposit of metal or the number of cubic centimeters of gas evolved can be calibrated to measure the quantity of current. (See *Electrochemistry, Principles of.*) Such meters can also be used as watt-hour meters (q.v.) in which case they are usually calibrated to read directly in kilowatt-hours at some assumed voltage. In some types the entire current to be measured is passed through the electrolyte and in others the main current passes through a shunt and only a very small part of the current passes through the electrolyte. In a satisfactory design of electrolytic meter the drop at full load does not exceed  $1\frac{1}{2}$  to 2 per cent on a 200-volt circuit, and the meter is accurate to within 2 per cent or better (depending on the design) at all loads between 10 per cent and 150 per cent load.

**MOTOR METERS.**—The essential parts of the motor ampere-hour meter are the motor element, the brake or speed-regulating device and the register or gear train which records the integrated current passed through the meter. The motor consists of an armature rotating in a magnetic field produced either by a permanent magnet or by an electromagnet. The meters are generally arranged so that only a shunted portion of the current flows through the armature and when electromagnet fields are used they are connected in series with the armature. The construction of these motors is otherwise similar to that of a watt-hour meter (q.v.). The commutator and other electromagnetic types of motor meters are all designed with the idea of producing a device which will be cheaper and if possible more rugged than the ordinary watt-hour meter. The absence of a constantly excited potential circuit in the meter also avoids the constant loss of energy which takes place in such a circuit irrespective of the load. In the motor meter the drop across the shunt varies in meters of different manufacture from about 50 to 100 millivolts in the mercury meter, and from 0.8 to 1.5 volts in the commutator meter.

**Commutator Ampere-hour Meter.**—The commutator type of meter in its simplest form usually consists of one or two permanent magnets which provide a driving field within which rotates an armature with three coils and a three-part commutator. In some designs the armature coils are mounted flat on an aluminum disk which in addition to supporting the armature coils produces the retarding or braking action in connection with the field magnet. In another design there is a stationary iron core between the poles of the field magnet and a drum armature rotating in the gap between the stationary iron core and the pole faces of the field magnet. No braking device is used in this latter type, and the motor runs at a speed proportional to the impressed e.m.f., taking only sufficient power to overcome the friction in the bearings and in the gear train.

To compensate for friction at light loads a slight auxiliary potential difference is sometimes maintained across the brushes by placing the armature in series with a high resistance across the line. This arrangement is adjusted so that the meter will not run with no current through the main shunt, but at light load the

extra potential difference at the brushes will be sufficient to provide a torque which will compensate for the frictional torque of the moving parts. In a recent type of A.E.G. ampere-hour meter the light-load compensation is effected by movable brushes automatically controlled (*Elekt. Zeits.* 40 p. 213, May 8, 1919).

**Oscillating Motor Ampere-hour Meter.** — A special form of the electromagnetic motor meter differing from all other designs is the oscillating meter. In principle, this meter is a clock which is controlled by the current. The hair spring of the clock is replaced by a disk carrying a few small iron wires. This special balance wheel is supported between two coils which carry the current to be measured or a shunted portion of it. The magnetic field from the coils magnetizes the iron wires and in conjunction with the main spring of the clock causes the special balance wheel to oscillate at a rate proportional to the strength of the magnetic field and therefore proportional to the current passing through the meter. The movement of the clock is transferred to a registering mechanism geared to register ampere-hours, or kilowatt-hours at a constant voltage.

**Mercury Ampere-hour Meter.** — The motor meter of the mercury type utilizes mercury to carry current to the armature, the mercury really taking the place of the brushes and commutator of the ordinary direct-current motor. One form of the meter consists in principle of a copper disk or copper thimble armature mounted in jeweled bearings and immersed in the mercury. The current is led into the mercury chamber through suitable terminals and since mercury has about fifty-five times the resistance of copper, the greater part of this current goes through the copper (approximately diametrically across the disk) and out the other terminal by way of the mercury. This arrangement applies to meters with permanent-magnet fields. In case electromagnet fields are used, the driving torque is approximately proportional to the square of the current, hence a braking system must be used to produce a retarding force varying with the square of the speed, such as air or fluid friction. When this is done the rate of revolution of the armature when running at a constant speed is proportional to the current passed through the meter. When permanent-magnet fields are used, a device is sometimes used to compensate for the increase of fluid friction with increase of speed; this device takes some such form as an auxiliary coil, in series with the motor element, which produces a flux which augments the flux cutting the driving disk.

The mercury motor meters utilize iron or in some cases moulded compound for the mercury well, and in the design care must be taken to provide non-spillable joints at the point where the spindle of the armature enters the mercury chamber. All metal in the meters should be of such composition as not to be readily affected by mercury even though not in direct contact with it.

**SPECIAL FEATURES.** — Ampere-hour meters used for showing the state of charge of storage batteries are sometimes provided with special features. For example, a "compensation for overcharge" causes the meter to run more slowly on a given value of charging current than on the same value of current during discharge. The percentage difference in the two cases is chosen to provide for the excess that must be put into the battery because it is not 100 per cent efficient. This is accomplished by a "variable resistor element" in parallel with the main mercury chamber. A pivoted copper bar in this element is immersed in mercury, and is cut by some of the flux from the driving magnets. It will thus change its position with the reversal of current direction, and will vary the resistance of the element. The "compensation for light-load accuracy and internal battery losses" consists of a thermocouple heated by a potential winding and delivering a small current continually to the motor element in the direction corresponding to battery discharge. This action may be adjusted to cause the meter to record the loss of charge when the battery is not in use. The "thermal

shunt method" of compensation for high discharge rates consists in making the shunt to the motor element of iron or other material of high temperature coefficient, and so designing it that it will heat up at the heavier loads. This causes the ampere-hour meter to have a higher percentage registration as the load increases.

Ampere-hour meters are sometimes provided with contacts which actuate auxiliary devices, such as circuit breakers, bells, or other signaling devices. This feature is used in connection with battery charging and electro-plating.

**CALIBRATION OF AMPERE-HOUR METERS.**— Ampere-hour meters are adjusted and calibrated as follows:

**Electrolytic Meters.**— As noted above, in the modern types of electrolytic meters mercury is deposited in a glass tube or water is decomposed, the gases passing off into the atmosphere. In the first type a marked scale is placed beside the registering tube into which the electrolyzed mercury falls. This mercury is run back into the mercury reservoir after the reading is taken, by tipping up the cell which is hinged at the top and held vertical by a removable clip at the bottom. To calibrate the instrument an ordinary ammeter may be placed in series with it and the time that the current passes noted on a watch. In testing the types in which gases are evolved and pass off into the atmosphere, it is only necessary to obtain the number of cubic centimeters of liquid per division of the scale, which can be done with a graduated burette. Only the water is decomposed by the passage of the current. To renew the electrolyte after the reading is taken at the end of a period, it is only necessary to add water.

**Motor Meters.**— In testing ampere-hour meters several adjustments are necessary, since a shunt, a series adjusting resistance and the gear train are involved. In addition, care must be taken to see that there is no excessive friction in any of the moving parts. The general method is to pass a measured constant current through the meter and to determine the time with a stop watch for a certain number of revolutions. Knowing the shunt constant (ratio of total to shunt current) and the register or gear-train ratio the correct speed at a certain current can be calculated and the shunt or adjusting resistance in series with the motor element adjusted to give the correct speed. To determine the accuracy for any set of readings the following formula can be used.

$$\frac{(\text{No. of rev.}) \times (\text{meter constant})}{\text{No. of seconds}} = \text{current.}$$

The "meter constant" is marked on each meter; it is the number of ampere-seconds per revolution of the disk.

**WEIGHTS AND COSTS.**— Mercury ampere-hour meters of American manufacture are made in different sizes for different types of services. Exclusive of shunts, the larger meter weighs about 16 lb. and the smaller meter 8 to 10 lb. In small capacities with self-contained shunt, the larger meter sells for \$30 to \$40, and the smaller meter for \$12 to \$20. External shunts are furnished with the larger meter above 100 amperes, and above 40 amperes with the smaller meter. These shunts range in price from \$25 to \$30 for 300 amperes and from \$65 to \$75 for 3000 or 4000 amperes. These prices are only approximate, and should be used only as a rough guide.

**BIBLIOGRAPHY.**— See the Bibliographies in the articles on *Ammeters* and *Watt-hour Meters*.

**ANGLES.** — (See also *Trigonometric Functions; Trigonometry.*) Plane angles may be expressed in degrees or in radians. The degree is arbitrarily taken as  $\frac{1}{360}$ th of the plane angle about a point; the radian is defined as the angle subtended by an arc of unit length in the circumference of a circle having unit radius. The angle in radians subtended by any arc of any circle is

$$\text{Angle in radians} = \frac{\text{arc}}{\text{radius}}$$

The relation between radians and degrees is

$$\begin{aligned} 1 \text{ radian} &= 57.30 \text{ degrees.} \\ 1 \text{ degree} &= 0.01745 \text{ radians.} \end{aligned}$$

**Angle of Curvature.** — In railroad practice the angle of curvature is the angle subtended by a chord 100 feet in length, the curve being the arc of a true circle. The relation between degree of curvature  $D$  and radius of curvature  $R$  is

$$R = \frac{50}{\sin \frac{D}{2}} \text{ feet.}$$

For  $D$  small, the chord is very approximately equal to the arc, consequently under these conditions

$$R = \frac{5730}{D} \text{ feet,}$$

where  $D$  is in degrees. The error involved in this approximate formula is less than 2 parts in 1000 for  $D$  less than  $10^\circ$ , and to less than 1 per cent for  $D$  less than  $30^\circ$ . (See also *Railways, Location and Permanent Way for.*)

**Solid Angles.** — The solid angle at any point  $P$  subtended by any surface  $S$  is equal to the portion of the surface of a sphere of unit radius which is cut out by a cone having its apex at the point  $P$  and its base coinciding with the perimeter of  $S$ . The total solid angle about a point is then equal to  $4\pi$ . The unit of solid angle as thus defined is called a steradian. A solid angle of  $2\pi$  steradians is called a hemisphere and a solid angle of  $\frac{\pi}{2}$  steradians is called a spherical right angle. See table in *Units and Conversion Factors.*

**ARC, ELECTRIC.** — (See also *Distribution Systems; Furnaces, Electric; Illumination, Interior and Street; Lamps, Arc; Rectifiers.*) An electric arc is an incandescent vapor bridge consisting of material electrically impelled from a negative to a positive electrode. A spark is also an incandescent vapor bridge, but it differs from an arc, in not depending upon the electrodes for its material medium. The establishment of an arc requires the expenditure of energy for the latent heat of evaporation of the electrode and for the motion of the vapor stream. As no energy can be expended for these purposes until the current flows, an arc cannot start spontaneously. The following expedients are, therefore, adopted to start arcs.

(1) Bringing the conductors into contact with each other and separating them after the current has commenced to flow.

(2) Stressing the dielectric between the conductors until it breaks down electrically and becomes conducting.

(3) Using a subsidiary arc to furnish the initial vapor bridge. The first of these methods is used in carbon-arc lamps and the last in the mercury-arc rectifier.

**CARBON ARC.** — Until recently the only arc used for illumination was the arc between carbon electrodes, though at the present time there are several materials used, such as magnetite, mercury and the mixtures of various substances with carbon.

**Crater.** — The vapor column of the carbon arc, impinging on the positive electrode, raises the end of the latter to a very high temperature and volatilizes the carbon. The effect of this is to cause a hollow to be burned in the tip of the positive electrode. This hollow is called the crater.

**Temperature.** — The maximum temperature of the arc cannot be measured by direct means and the various estimates, which have been made, range from  $3500^{\circ}\text{C.}$  to  $6000^{\circ}\text{C.}$ , abs. Using Wien's law connecting temperature and wave length corresponding to maximum radiated energy, Lummer and Pringsheim found that this wave length was  $0.7\ \mu$  and the corresponding temperature somewhere between  $3750^{\circ}\text{C.}$  and  $4200^{\circ}\text{C.}$ , abs., the latter figure being the crater temperature at atmospheric pressure. By raising the pressure to 22 atmospheres, a temperature of  $6000^{\circ}\text{C.}$ , abs. may be attained. (*W. Mathiesen, Arcs under Pressure, Elekt. Zeits. 37, pp. 549 and 567, Oct., 1916; 38, p. 573, Dec., 1917.*)

**Source of Luminosity.** — The light of the arc is derived either from the vapor column or from a body heated to incandescence by the vapor column.

In the old carbon electrode arc no special effort was made to utilize the luminosity of the vapor column, the incandescent spot or crater on the positive carbon being relied upon for practically the entire light. For this reason the positive carbon was always placed above the negative in order that the crater might better shed its light downward.

The flame arc, on the other hand, owes the greater part of its luminosity to the vapor column and very little or none to the heat of the positive electrode.

**Hissing.** — When the crater is surrounded by the hot gases constituting the arc, the arc is silent, but if the crater extends over the tip of the carbon and comes into contact with cool air, a peculiar hissing sound is evolved.

**Characteristic of Arcs between Carbon Electrodes.** — A peculiarity of the solid carbon arc is that, with any particular length of arc, if the current be increased, the difference of potential across the carbons will decrease. This occurs continuously until a certain point, when in the open arc the voltage

drops quite suddenly. If the current is still increased the voltage will again become steady at a much lower value. Between the values before and after the drop, the arc is unstable and hisses. The beginning of the hissing period is indicated by the dotted line in Fig. 1, and the hissing continues throughout the lower part of the curve.

The hissing point being absent in inclosed arcs, the curve for such arcs is quite continuous.

Fig. 1

**Steadying Resistance.** — In order to maintain a steady current in an electric circuit it is necessary that any decrease in the voltage across the terminals of the circuit shall produce a decrease in the current. Hence, as the arc characteristic shows an increase of current with decreasing voltage there must be placed in circuit with the arc a resistance great enough to compensate for this tendency, if the arc is to be kept in a stable condition. The method of calculating the resistance required to maintain a stable arc for a given current is as follows:

- Let  $e$  = generator terminal volts =  $OE$ ,  
 $v$  = arc terminal volts,  
 $x$  = resistance in circuit, exclusive of arc and generator resistance,  
 $i$  = current in amperes,

then, since  $e = v + ix$ ,

the resistance  $x$  must be such that

$$x = \frac{e - v}{i}.$$

On the arc characteristic (Fig. 2) find the point  $P$  corresponding to the current  $i$  and set off  $OE = e$  along the vertical axis. Then join  $EP$  and continue  $EP$  until it cuts the horizontal axis at  $X$ . The resistance  $x$  is then equal to  $\tan \angle EXO$ . If  $EX$  cuts the curve not only at  $P$ , but at  $S$  above  $P$ , it would appear that the e.m.f.  $e$  could support either of two arcs. The point  $S$ , although affording a mathematical solution, is not physically possible, as it would involve an increase of voltage, producing a decrease of current, as may be seen by moving  $EX$  upward, parallel to its original position. Hence the arc corresponding to  $P$  is the only one possible. If  $EX$  cuts the curve not only at  $P$ , but at some point below  $P$ , say  $T$ , the same reasoning shows the arc at  $P$  to be unstable, while that at  $T$  is stable.

Fig. 2

For any point  $P$ , therefore, the arc is stable only if the line  $EX$  does not cut the curve below  $P$ . Hence, to find the proper value of the resistance  $x$ , for a given current  $i$ , draw a line tangent to the arc characteristic curve at the point having the abscissa  $i$ , then  $x$  must be equal to or greater than the tangent of the angle made by this line with the axis of abscissas.

**Generator Voltage and Hissing Current.** —

- Let  $E$  = generator voltage,  
 $V$  = potential difference between carbons just before current is increased to hissing point,  
 $I$  = maximum amperes which will not produce hissing,  
 $D$  = drop in volts from silent to hissing,  
 $i$  = rise of current from silent to hissing,

then  $E = V + \frac{I}{i} D$  or  $i = \frac{D}{E - V} I$ .

Thus, if the generator voltage is great compared to the arc voltage, and therefore the steady resistance great, the rise of current at hissing will be less than when the voltage is small.

**Resistance of the Arc.**—The relation between the drop of potential across the arc and the current flowing through it depends upon whether the arc is in the steady state corresponding to the current flowing or whether the current has been changed without giving time to the vapor column and electrodes to accommodate themselves to the new strength of current. Let  $V$  be the drop of potential across a direct-current arc and  $A$  the current flowing. If the current be increased by a small amount  $dA$  for so short a time that it produces no effect upon the arc itself, it will be accompanied by a rise in potential difference  $dV$ , and the ratio  $\frac{dV}{dA}$  will be the resistance of the arc. This may be accomplished experimentally by superimposing upon the direct-current arc a small rapidly-alternating current and measuring the value of the alternating p.d. and current. Unless a very high frequency (about 100,000 cycles) is used, the ratio  $\frac{dV}{dA}$  will be negative, due to the fact that the power factor of the arc is not unity for low frequencies and this ratio, therefore, does not represent the resistance (see *Duddell's papers in Bibliography*).

**Back Electromotive Force of the Arc.**—The product of the direct current of an arc and its resistance, measured as described above, is the ohmic drop in the arc. This is usually less than the actual p.d. by 7 to 15 volts, which represent a back electromotive force. This back electromotive force really consists of two, the larger near the positive electrode, opposing the flow of current, and the smaller near the negative, helping the flow. By varying the direct current carried by the arc, the back e.m.f. is not noticeably affected, but the resistance tends to become infinite for very small currents, and small for large currents. A variation in the length of the arc between solid carbons produces no effect upon the back e.m.f., whereas with cored carbons the back e.m.f. decreases with increase of length. The value of the back e.m.f. depends upon the make of carbons employed. In his experiments which established the existence of a true back e.m.f. in the arc, Duddell used an alternating current of about 1 per cent of the strength of the direct current and having a frequency of 100,000 ~ per second.

**ARC AS TELEPHONE RECEIVER.**—A direct-current arc may be used as a telephone receiver which can be clearly heard in a quiet room at a distance of 10 or 12 feet. The arrangement of apparatus, which gives the best results, is shown in Fig. 3, which is Duddell's improvement of the H. Simon circuit. In Duddell's experiments  $AB$  was a solenoid about 30 cm. long, wound with about 1000 turns of No. 18 D.S.C. wire and having an iron core of about 15 mm. diameter. Six hundred turns of the solenoid were connected to the microphone  $M$  and battery  $B$  and four hundred to the arc and condenser  $C$ .

Fig. 3

The arc was between cored carbons of 11 to 13 mm. diameter separated 20 to 30 mm. and took 10 to 12 amperes. The condenser capacity was 2 or 3 microfarads. The resistance  $R$  was the usual ballast resistance and the choke coil  $L$  served the purpose of confining the telephonic currents to the arc circuit.

**ARC AS A TELEPHONE TRANSMITTER.**—The arc may be used as a telephone transmitter, but it is unsatisfactory on account of hisses and spits

due to the irregularities of the carbons and to the access of air to the crater. The arrangement of circuits is shown in Fig. 4, the apparatus  $R$ ,  $L$  and  $C$  being the same as in the receiver circuit.

**MUSICAL ARC.**—A direct-current arc of suitable length and current between solid carbons will give a musical note, if it be shunted with a con-

Fig. 4

Fig. 5

denser in series with a choke coil, as shown in Fig. 5. The pitch corresponds to the periodic time

$$T = 2\pi\sqrt{LC},$$

where

$C$  = capacity of condenser, farads,

$L$  = inductance of choke coil, henrys.

The choke coil must not have an iron core, or the hysteresis and eddy currents will destroy the effect. A closed circuit, such as a ring of wire placed near the inductance coil, has the same effect. Further details of the musical arc are given below.

#### THE ARC AS A SOURCE OF HIGH-FREQUENCY CURRENT.—

The musical arc owes its pitch to the action of the arc in transforming a part of the direct current into alternating current, the frequency of which can be varied between very wide limits by altering the self-inductance and capacity with which it is shunted. The inclosed arc works just as the open arc. In some of Duddell's experiments, the alternating current through the condenser circuit was as large as 3 amperes. Only condensers suitable for high voltages should be used, as, although the arc p.d. may be quite low, the condenser p.d. rises to several hundred volts. Alternating currents of frequencies of from 500 cycles to 500,000 cycles per second are easily obtainable.

Arcs between solid carbons always work well as converters, while those between cored carbons will not work under any conditions. In fact the general conditions under which the arc works as a converter are that  $\frac{dV}{dI}$  must be negative and numerically greater than the resistance of the condenser circuit, exclusive of the condenser itself. The expression  $\frac{dV}{dI}$  should be taken as referring to small instantaneous changes of the arc voltage and current.

Fig. 6 shows a means of operating several arcs together so as to obtain a greater output than would be possible with a single arc. Direct current is supplied to the arcs from the mains, through the choking coils  $L_1$  and  $L_2$ , the ballast resistance  $R_1$  and  $R_2$  and ammeters  $A_1$  and  $A_2$ . Alternating current is delivered by the arcs to the circuit containing the capacity  $C$  and inductance  $L$ . A form of arc used for generating high-frequency currents for use in radiotelephony is the Poulson arc, which is described in the article on *Telephony*, *W. & C.*

Fig. 6

**OTHER APPLICATIONS OF THE ELECTRIC ARC.**—In addition to its application for welding and electrochemical manufactures (q.v.), the thermal effect of the arc is utilized for burning steel. An application of this was made by the contractors of the Pennsylvania Railroad (East River tunnel), who used a carbon rod one foot long and one inch diameter, bolted to a copper rod, provided with an asbestos shield, one foot in diameter. The operators worked with asbestos masks and aprons and dark-colored eye glasses.

Direct-current was used, the carbon electrode being connected to the positive and the steel to be cut to the negative feeders. The current was varied by means of water rheostats, the voltage at the tool varying between 45 and 60 volts. The current varied from 250 to 400 amperes per tool for burning off rivet heads and light section plates and from 600 to 800 amperes for burning plates  $\frac{1}{2}$  inches thick. The best results were obtained with 40 volts, 600 amperes and a  $\frac{1}{4}$ -inch to  $\frac{3}{4}$ -inch arc. A fair day's work (8 hours) removed 300 rivet heads, although a record of 350 was reached. In the same time 4 feet 6 inches of  $\frac{1}{2}$ -inch plate could be burned off. (*H. Japp, Proc. A.S.C.E. 1909, Vol. 35, No. 9, p. 1230.*)

Portable plants, consisting of a gasoline engine-driven generator of about 25 kw. capacity, mounted on a truck, are now in use for wrecking buildings. Such an outfit is capable of burning off a 15-inch I-beam in 30 minutes, using the full-rated output of the generator. The arc has also been used for cutting scrap iron and steel in rolling mills (*G. Kearney, Gen. El. Rev., 20, p. 876, Nov. 1917*).

Experiments on rock removal for tunnel projects have been carried out by the Southern California Edison Co. of Los Angeles. Both direct-current and alternating-current (three-phase) arcs were tried. With direct-current, 500 amperes at 30 volts, 1 pound of rock per minute was removed at a cost of  $\frac{1}{4}$  cent per pound, and with a three-phase arc, 450 amperes per phase with 40 volts between terminals 1 pound of rock per minute was removed at a cost of  $\frac{1}{4}$  cent per pound (*Engineer, 128, p. 57, July 18, 1919*).

Eng.*, 1901, Vol. 30, p. 232, *Trans. of Roy. Soc. Series A*, 1904, Vol. 203, pp. 305-342; Rasch, E., *Electric Arc Phenomena*, New York, 1917; Simon H., *The Arc as a Telephone*, *Ann. Physik u. Chemie*, 1898, Vol. 54, p. 233; Solomon, M., *Electric Lamps*, N. Y., 1908; Van Zandt, J. P., *Electric Oscillatory Phenomena of Speaking Arc*, *Elec. World*, 1916, Vol. 67, p. 1415.

**AUTOMOBILES, ELECTRIC.**—(See also *Batteries, Storage, Alkaline Type and Lead Type; Batteries, Storage, Applications of; Trucks, Industrial Electric*). There are two types of electric automobiles, namely the battery car and the "gasoline-electric" car. The former type carries a storage battery from which energy is delivered to the driving motor; the latter type, in most instances, carries no battery but electric energy is supplied to the motor by a small generator which is itself driven by a gasoline engine. In other cases storage batteries are used in combination with a motor generator connected to the engine. Thus the machine may be driven by energy from either battery or engine. The battery car only is discussed in this article. A battery car is commonly referred to as "an electric," regardless of whether it belongs to the passenger or the commercial class.

**HISTORICAL DEVELOPMENT.**—The first battery-driven automobile in this country was built by Fred M. Kimball in Boston in 1888. This machine had 6 cells of lead storage battery and could travel 10 miles on good roads at an average speed of 5 m.p.h. In 1891 there was exhibited at the Mechanics' Fair in Boston an electric surrey built by the Holzer-Cabot Electric Co. Little more was done in the development of electric automobiles until about 1897 when the passenger vehicle was developed in two directions: one for pleasure took the forms of Victoria runabouts, dos-a-dos and surreys, and the other for business purposes in the form of public taxicabs or vehicles for hire. The latter development expanded during the following four years to the use of fleets of 100 to 400 cabs and broughams in New York, Boston, Philadelphia, Washington, Buffalo and Chicago for public service on a hired basis; these disappeared from use about 1902 or shortly afterwards, largely for financial reasons, but also on account of the fact that large solid or pneumatic tires were not well developed at that date and storage batteries had not progressed beyond the heavy types used for stationary equipment in power stations.

From 1900 to 1903 the commercial type of electric truck began to be employed for merchandise delivery and progressed gradually but steadily until 1910, when the electric light companies recognized in it a desirable "off-peak" power consumer. The Electric Vehicle Association of America with considerable activity materially furthered the use of electric vehicles, both passenger and commercial, until 1914, when there were 37,000 in use; 25,000 passenger cars and 12,000 trucks (*El. World, Jan. 3, 1914*). The average price of the former at that date was \$2200 and the latter \$2800; this represented \$88,000,000 invested by the public in this type of automobile. Following 1914 there was a rapid decline in the rate of production of electric vehicles due largely to general business conditions, but principally to the competitive influence of mass production in the gasoline vehicle industry; although the electric still maintains its superiority in economic operation. In 1920 there were but three manufacturers of each type aggressively conducting production in their respective fields with encouraging reaction, principally in a renewed demand for the commercial type. Another class of the electric vehicle, in the form of indoor industrial material and freight handling trucks, has been in progressive development since 1904; see *Trucks, Industrial Electric*.

**APPLICATIONS OF ELECTRIC TRUCKS.**—The three types of vehicles which are at present available for urban street haulage are the horse-drawn wagon, the gasoline motor car and the electric battery car. In comparing these three types for use in any given service, the chief factors to be considered are relative speed, distance between stops, length of stops required by the service, expense per vehicle and reliability (i.e., number of days per year upon which

the wagon can be depended for operation). The first three of these factors may be determined by trial or by observation.

In considering the matter of speed it should be remembered that with motor cars the wear and tear on the machine increases approximately as the square of the speed, so that the speed should be such as to give minimum cost of service. The last two of the above factors, namely expense and reliability, can be absolutely determined for any set of operating conditions only by several years of use of each type of vehicle. It is possible, however, to closely estimate the "expected" values of expense from the experience of others in similar kinds of work. See section below on *Costs*.

The electric truck has found its widest commercial application in city services where the hauls are of moderate length, say from two to ten miles, and where the daily service does not exceed 30 miles on the average, with occasional daily mileages of 40 to 50. For very short hauls where the standing time of the wagon is a large proportion of the working time, so that the work per day of each delivery unit is not largely influenced by the speed of the unit, the horse-drawn wagon can perform the work cheaper than any motor vehicle. For the so-called "long hauls" the gasoline truck would be expected to work to better advantage than an electric truck because of higher running speed or greater distance capacity in a day, or both. The rated values of speed and distance on a single battery charge of electric trucks are given in Table V below. The effect of hills or poor pavements would be equivalent to a decrease in the rated values of both speed and mileage. Systems of operating in which discharged batteries are exchanged for charged batteries during the day in order to increase the mileage capacity beyond the rated value have been used with signal success in a few instances, but in general the battery equipment is usually of sufficient capacity to perform the daily service required, or is in some cases supplemented by high-rate boosting charge during the noon hour or other convenient period.

**DESIGN.** — The necessity of producing cars which would travel at moderate speeds with a low rate of energy consumption has forced the designers of electric automobiles to use equipment which would meet this requirement, even though in some instances less efficient equipment would cost less or might wear longer than that used. Thus tires of low-energy consumption, batteries with large capacity per unit of weight and "anti-friction" bearings in transmission and axles are used almost universally. Consequently an electric automobile is essentially a high-grade machine, for any inefficient equipment directly influences the operating qualities.

**Weight and Speed.** — In the design of an electric battery car the two primary features are the total weight and the speed under normal conditions. In special cases a car may be built to meet unusual requirements of distance traveled per charge, in which case either the speed or weight must depart from the limitations of common practice. Any decrease in the total weight of the car will result in an increase in either speed or distance capacity or both; or if the weight is brought back to the original value by the use of additional battery capacity, the speed or distance may be still further increased. This has been one of the chief considerations leading to the adoption of lighter batteries, such as the Edison and "thin" paster lead plate, in place of the heavier type lead plate batteries commonly used where their additional weight is not a critical factor. General practice as regards weight and speed for various types of electric automobiles is indicated in Table I.

TABLE I.—SPEEDS AND WEIGHTS OF ELECTRIC AUTOMOBILES

Class of car or rated capacity of truck	Approximate weight in lb., including empty body	Approximate speed in miles per hour	Weight allowance for body, lb.
2-passenger runabout *	2,200	15 to 25	....
2-passenger Victoria *	2,400	15 to 21	....
2-passenger coupe *	2,600	15 to 20	....
4-passenger brougham	3,980	23 to 25	1010
5-passenger coach	3,860	22 to 24	1060
1,000-lb. truck	3,500	12 to 14	500
2,000-lb. truck	4,500	10 to 12	600
4,000-lb. truck	6,000	8 to 10	800
7,000-lb. truck	8,500	6.5 to 8	1100
10,000-lb. truck	9,500	6 to 7	1400
12,000-lb. truck	11,500	6 to 6.5	1600

\* These vehicles are not now (1920) manufactured, but many of them are in use.

Similar data for a representative line of electric trucks are given in Table V below.

**Load Efficiency.**—By load efficiency of a motor truck is meant the ratio of the load on the machine to the gross weight of the machine, including chassis, body and load. Thus, from the above table, a representative value for the rated load efficiency of a 5-ton capacity electric truck is

$$= \frac{10,000}{10,000 + 9,500} = 0.51.$$

The rated load efficiencies for gasoline trucks of large capacity, 2 tons or more, are practically the same as the values for electric trucks, but small capacity gasoline cars of good design may have a rated load efficiency as high as 30 per cent as compared to about 24 per cent for electric cars with the customary lead battery equipments.

**Motors.**—Four-pole series motors are now used almost exclusively for electric automobiles. In the majority of cases but a single motor is used on each vehicle. The field coils are usually arranged in two groups which may be connected first in series and then in parallel. All manufacturers do not rate their motors on the same basis, but good practice is indicated by that of the General Electric Co., whose motors will carry their normal rated load continuously with a maximum temperature rise of 63° C. above the surrounding air at 25° C. or will carry 2½ times their rated load for 1 hour with a maximum temperature rise of 75° C. Ratings are based on bench tests, so that when the motor is installed in a car the overload capacity is usually increased due to the improved ventilation. Large overload capacity is necessary to meet severe street and grade conditions, and unusually good commutating characteristics are required.

An automobile motor must also operate satisfactorily over the varying range in the voltage furnished by the battery in the charged and discharged conditions. The motor speeds which are used with single reduction drives range from 750 to 1000 r.p.m.; the speeds which are used with double reduction drives range from 1000 to 2000 r.p.m.

**Number of Motors.**—All electric passenger cars and most electric trucks are now being equipped with a single motor. It was formerly common

practice to use two motors on the larger trucks on account of flexibility in control, but a single motor is now being used on account of space limitations, saving in weight and better electrical efficiency. The peculiar construction of the Couple-gear (see below) equipment requires a departure from this practice. Otherwise, either two or four motor equipment is used now only when unusually high tractive effort is required.

**Motor Characteristics.**— Along with the tendency during recent years to standardize battery equipments at 42 to 44 lead cells and 60 Edison cells, the tendency among motor manufacturers has been to develop a line of motor frames, for each of which two windings could be provided. Thus an 80- or 85-volt motor is usually installed with a 42- to 44-cell lead battery and a 60-volt motor with a 60-cell Edison battery. The windings are so proportioned that a motor has approximately the same speed and torque at both voltage ratings. This development has made it unnecessary to alter either the motor suspension or the mechanical transmission system in changing a car's battery equipment from lead to Edison or vice versa. 24-, 36- and 48-volt motors can also be obtained.

TABLE II.—G. E. STANDARD AUTOMOTIVE MOTOR RATINGS  
FOR ROAD VEHICLES

G.E. 1091	48	45	1750	200

The characteristic curves for a typical Westinghouse motor with the 60-volt and 80-volt windings are given in Figs. 1A and 1B. The relatively small change in efficiency for overload with the field coils in parallel is noteworthy. The "torque ratio" of this motor, i.e., the ratio of torque at  $2\frac{1}{2}$  times rated current to torque at rated current, is approximately 5 with both windings.

Table XI on page 57 gives a partial list of General Electric automobile motors with their normal ratings.

A. — 60 volts, 33 amperes

B. — 80 volts, 25 amperes

Fig. 1. Characteristic Curves of Typical Automobile Motors

Before recommending motor equipment for automobile service the motor manufacturers usually require that the purchaser submit data upon the weight, speed, battery, wheel dimension, etc., for the car on which the motor is to be used.

**Size of Motor Required.** — In selecting the size of motor the voltage should be chosen on the basis of 1.9 volts per cell for lead batteries and 1.5 volt per cell for Edison batteries. The average discharge voltages of both types of batteries at their normal rates are higher than these values, but it has been found desirable to install motors on the basis of these values so that at high rates of discharge the terminal voltage may not fall too far below the rated motor voltage.

The current rating of the motor (and also of the battery) should be approximately the value of the current required to drive the car at the rated speed on hard level asphalt. The current input into a vehicle motor when driving a car at constant speed is given by the expression

$$I = \frac{2vWr}{E\epsilon}$$

where  $v$  = speed of car in miles per hour,

$W$  = total weight of car and load in tons,

$r$  = car resistance in pounds per ton of total car weight,

$E$  = motor terminal voltage,

$\epsilon$  = over-all efficiency of motor, controller and transmission.

The value of  $\epsilon$  at the rated speed is the product of the efficiencies of motor and transmission, usual values falling between 60 and 75 per cent. For value of  $r$  see next paragraph.

**Car Resistance.** — The car resistance depends upon the following conditions: speed, grade, diameter of wheels, load per square inch of tire contact

or per inch of tire width, construction and composition of tire, method of attaching tire to wheel rim, and road surface. The effect of speed is to change  $r$  in a manner dependent upon the type of tire, the value of  $r$  having a minimum usually at a speed between 6 and 10 m.p.h.; air resistance varies approximately as the square of the speed and need not be considered for speeds of less than 20 m.p.h. The effect of up-grades is to increase  $r$  by 20 lb. per ton for each per cent grade. The car resistance with pneumatic tires on hard, level asphalt is given by Churchward (*Soc. of Auto. Eng. Handbook, 1913*) as ranging from 15 lb. per ton for special tires designed for electric runabouts up to 35 lb. per ton for the standard type of tire used on gasoline touring cars; the resistance is greatly affected by the air pressure, increasing rapidly as the air pressure is reduced. Churchward also gives the car resistance with solid tires on hard level asphalt as ranging from 18 to 26 lb. per ton. Other tests have shown a car resistance of 30 lb. per ton for a small capacity electric truck equipped with solid tires (*El. W., May 17, 1913, Vol. 61, p. 1040*).

**Effect of Road Surface.**—Three sets of values of relative car resistance on various level road surfaces as compared to the value on hard, level asphalt are given in the following table. One set of values is given by Churchward in the *Soc. of Auto. Eng. Handbook (1913)* the set is based on tests conducted at the Massachusetts Institute of Technology in 1913 (*El. W., May 17, 1913, Vol. 61, p. 1040*), and the third set is the result of tests by Kennelly and Schurig, *Proc. A.I.E.E., Vol. 35, 1916*.

TABLE III—RELATIVE VALUES OF CAR RESISTANCE

Road surface	Churchward	M.I.T.	Kennelly and Schurig
Asphalt, hard	1.0	1.0	1.0
Wood block	1.15	1.1	1.18
Macadam	1.15 to 3	1.15	1.2
Granite block	1.75	2.0	1.47
Dirt road	1.1 to 2.0	...	1.31
Brick	.....	1.4	1.25
Snow, packed	.....	1.3	....
Snow, fairly hard, without chains	.....	1.7	....
Snow, fairly hard, with chains	.....	1.9	....
Snow, soft, about 3 in. deep	.....	2.1	....
Sand	20	...	....

**Transmission Systems.**—The transmission systems between motor and wheel which are in common use may be grouped in two classes, known as the "chain" and the "shaft" or gear drives. A single-speed reduction is used in a few makes of cars, but a double reduction is used on a majority of machines. If the first reduction is made by chain and the second by gear, or vice versa, the transmission system is usually designated according to the means employed for the final reduction; e.g., if the final reduction is accomplished by a chain, the system is referred to as a chain drive although the first reduction may be by gears.

**Chain Drive.**—With chain drive the motor is mounted transversely and a double-speed reduction is used almost without exception. The connection between motor and countershaft is usually by silent chain (Morse or Rey-

noid type, see article on *Chains and Chain Drive*), although spur and herringbone gears are also used; see article on *Gears and Gearing*. The final drive is usually by roller chain, either (a) between countershaft and differential in the rear axle or (b) between countershaft and a sprocket on each of the rear wheels. Chain-driven passenger cars are usually equipped with (a) and chain-driven commercial cars with (b). The chain method of drive possesses the advantages of low cost and ease of adjustment; its disadvantages are noise, rapid wear due to collection of dirt unless properly housed, poor efficiency when not properly adjusted, and unequal wear on the two sides of the car. The chain drive has been losing favor during recent years among both designers and operators and is now (1921) practically abandoned.

**Shaft or Gear Drive.** — With shaft drive the motor is usually mounted lengthwise of the car, and either a single- or double-speed reduction is used. For single reduction both bevel and worm gears are used as the connection between propeller shaft and differential in the rear axle. For double reduction the motor is usually connected to the propeller shaft by spur gear, herringbone gear or silent chain, and the propeller shaft is connected to the differential by a bevel gear. The propeller shaft is usually fitted with universal joints. The shaft drive has become standard in passenger cars because it runs quieter than chain drive, and because it can be easily protected from dirt by housing. The shaft drive has the disadvantage of greater weight below the springs than in the case of the chain drive, which tends to increase the wear on tires.

**Worm Drive.** — There has recently been a decided tendency among designers of passenger cars and light trucks to use the single-reduction worm gear instead of the double-reduction bevel or chain arrangements, the advantages claimed for the worm being better transmission efficiency and less trouble from adjustment.

**Walker Balanced Gear.** — In the trucks built by the Walker Vehicle Co. the motor is built into the rear axle, which is made hollow and of a sufficient diameter to contain the motor. The armature shaft is also hollow, so that the drive shafts may extend through from the sockets of the differential to the center of each rear wheel. The wheels are driven by a spur-gear reduction mounted inside the wheels. The wheels have steel-plate sides instead of spokes, so that the gears may run in oil and are thoroughly protected from dirt.

**Couple-Gear Wheel.** — A device built by the Couple-Gear Freight Wheel Co. has the electric motor mounted inside the wheel. The motor armature carries a pinion on either end which engages with a gear ring on either side of the wheel. The sides of the wheels are dished steel plates. These wheels are being used on both front-wheel-drive and four-wheel drive machines. Being located in the wheels, they do not interfere with the use of the ordinary steering knuckle arrangement.

**Steinmetz System.** — A new method of motor excitation consists of connecting a storage battery cell across the field terminals of a series motor employed in vehicle operation. At normal load the drop in voltage between field terminals counterbalances the voltage of battery cell. On starting and heavy grades the current required causes a greater drop in voltage between the field terminals, thus diverting a charging current through

Fig. 2. Diagram of Steinmetz Motor System

cell. Similarly if the motor current required in service decreases, the field will discharge through the field winding. Thus, the field strength varies within narrow limits and in such a system the coasting of the vehicle down hills and the braking or stopping of the vehicle may be employed to recharge a vehicle storage battery. With this system a motor is used in which both field and armature rotate; each being connected separately to the two driving wheels, no differential being required, and on account of the increased relative speed between field and armature a much lighter motor than the normal type, with stationary field and rotating armature, is required for any given service.

**Efficiency of Transmission.** — (See also article on *Gears and Gearing*.) The following figures on the transmission efficiency of different types of automobile mechanisms.

Source of loss of power	Efficiency, per cent
One chain, and one and one-half pairs of bearings.....	89.5
One set of gears, two pairs of bearings.....	82.0
One set of gears, equivalent of two chains, three pairs of bearings.....	74.0
Two sets of gears, four pairs of bearings.....	70.0

The following figures, given by F. Burgess (*Trans. Soc. Auto. Eng., 1912, Vol. 7, Part 2, p. 190*), are the results of an efficiency test of a straight type worm and worm gear for rear-axle drive of electric automobiles. The worm gear was made of phosphor bronze and had 39 teeth; the worm was made of case-hardened steel and had 4 threads.

R.p.m. of worm	Temperature of worm gear, °F.	Input, trans. dyn. h.p.	Output, brake h.p.	Efficiency, per cent
1203	74	1.64	1.03	61.2
1216	86	3.41	3.17	93.2
1370	90	5.48	5.13	93.7
1389	94	6.78	6.34	93.0
1400	108	9.43	8.5	90.2

**Batteries.** — There are three types of batteries in general use in electric vehicles, namely, the pasted lead, the "Iron-clad" lead, and the Edison. The performance characteristic (except life) of the first two are identical and are described in the article on *Batteries, Storage, Lead Type*; the characteristics of the Edison battery are described in the article on *Batteries, Storage, Alkaline Type*. The desirable characteristics of a battery for vehicle service are given in the article on *Batteries, Storage, Applications of*.

**Number of Cells; Number of Plates.** — Practice among electric automobile manufacturers is now practically standardized upon the installation of 42 or 44 cells of lead battery and 60 cells of Edison battery in both passenger and commercial classes of cars, as these numbers permit of charging from a 115-volt circuit with minimum loss in the rheostat. There are, however, in use many old designs of pleasure cars in which from 24 to 38 lead cells are used, and the small capacity delivery wagons in which 48 Edison cells are also employed. A 24-volt to 48-volt battery is used on industrial trucks. For a given watt-hour capacity a battery of a small number of cells is cheaper to buy and

maintain than one of a large number of cells, but is more expensive to draw from constant-potential d-c. mains on account of rheostat losses.

As pointed out above the rated current output of a vehicle battery in hours should not be exceeded by the current required to drive the car at rated speed on hard, level asphalt (see section above on Size of Motor). Thus when the current under these normal conditions is known, the number of plates per cell can be determined from a knowledge of the discharge rates of the various types of plates which are under consideration. For A-type Edison batteries the normal (5-hr. rate) is 7.5 amp. per positive plate; conservative designers use this rate in applying batteries rather than the value of 9.5 amp. which can be obtained for 4 hours. The discharge rates per positive plate of 5% by 8% for 4 hours and for the so-called "normal" times of discharge for the types of vehicle batteries made by the Electric Storage Battery Co. are given in the accompanying table.

Type of plate	"Normal" discharge		Amperes per positive plate discharged during 6 hr.
	Time, hours	Amperes per positive plate	
Exide	4	7	5.13
Hycap	5	5.5	4.8
Thin	6	4.25	4.13
Iron-clad	4.5	7	5.6

It will be noted that the above rule of installing a battery whose 4-hour discharge rate is approximately equal to the current required for running at rated speed under good street conditions will furnish a minimum practicable battery capacity, and that this capacity may have to be increased materially in order that the car may meet the necessary mileage requirements when operating on grades or poor roads. There is a tendency among electric car manufacturers to recommend battery equipment for given conditions which is much more liberal than they recommended a few years ago.

**Construction of Battery Box.**—In passenger cars a tight wood-lined compartment is usually supplied for carrying the battery. In commercial cars the battery compartment is also wood lined, and provision is commonly made for ventilation to facilitate charging in warm weather. The details of a typical underslung battery box are shown in Fig. 3. With this construction strips may be laid in the spaces between the floor boards in order to make the compartment entirely inclosed, as is frequently desirable in cold weather. A tight covering should be provided with an underslung battery box to prevent dirt and water falling upon the battery from the floor of the car.

**Controllers.**—Controllers are usually of the drum type with two running positions, known as the "field-series" and the "field-parallel" positions. The motor field coils are arranged in two groups for connection either in series or in parallel.

Fig. 3. Typical Underslung Battery Box

cells of the battery are connected permanently in series. In starting, or 2 or 3 resistance notches are used before the "field-series" notch is reached. A shunt on the fields is frequently used between the "field-series" and the "field-parallel" notches. For normal full-speed running the two sets of field coils are in parallel. An emergency speed is obtained by putting a resistance around the fields when connected in parallel. It was formerly customary to split the battery into two groups which could be connected in series-parallel in order to obtain 4 economical running speeds, but this was experienced from the unequal discharge of the two halves of the battery. In the magnetic type of control which is used to some extent in passenger cars the changes in connection are affected by relays operated by an auxiliary electric circuit. Some forms of regenerative control have been tried with only moderate success, although in hilly localities regenerative control may be desirable on account of protecting the mechanical brakes.

**Tires.** — Tires for use on electric automobiles are generally more resilient than the standard types of tires commonly used on gasoline automobiles. "High efficiency" or special electric tires, both solid and pneumatic, have been developed by most of the tire manufacturers in response to a demand by the operators of electric cars for tires with low consumption of energy. Standard types of tires may consume as much as 100 per cent more energy than the special electric tires. Experience has shown that the smooth starting characteristic of an electric motor produces much less abrasion than the uneven acceleration with a gasoline motor, so that the rubber compounds in tires for electric cars are usually softer than the compounds in tires for gasoline cars and yet the lives of both types in point of distances traveled are approximately the same. Electric pneumatic tires are usually of the cord type; i.e., the "fabric" consists of parallel strands of cotton impregnated with rubber gum. Some types of solid electric tires, such as the Mott, have the sides undercut at intervals to allow for the "flow" of the rubber when under compression.

**Carrying Capacity of Tires.** — In general a tire of small transverse load will consume less energy than a tire of the same compound with large load when operating on a smooth, hard surface; also, a large wheel diameter gives less energy consumption than a small one as well as improving the riding qualities on uneven surfaces. The Society of Automobile Engineers have recommended the use of 32-, 36- and 40-in. tires as standard practice. (See *Trans. Soc. Auto. Eng., 1914.*) But in selecting tire equipment it should be remembered that there is a limit to the load which any size of tire will stand without permanent injury by disintegration. The maximum carrying capacities per wheel at present (1920) recommended by the B. F. Goodrich Co., are given in Table IV, as are also the recommended inflation pressures for pneumatic tires of the fabric type; the recommended inflation pressures for cord tires are approximately 80 per cent of the values in the table.

**Examples of Commercial Car Design.** — Table V gives data from the standard specifications of a number of the electric trucks.

**PERFORMANCE; ENERGY CONSUMPTION.** — The energy consumed by an electric automobile will depend very largely upon the care of the driver in coasting up to stops instead of braking directly from full speed; other important factors in determining the energy consumption are efficiencies of battery and driving mechanism, tire equipment, nature of roads and grades, number of stops and miles per day, etc. However, for a car which is operated under similar conditions day after day, the energy consumption per mile should be reasonably uniform, so that any considerable increase in energy consumption may indicate either careless driving or poorly adjusted mechanism, as for instance a dragging brake. Table VI gives a series of approximate values for

TABLE IV.—MAXIMUM CARRYING CAPACITY OF TIRES

Size of tire, inches	Maximum load, pounds per wheel				Recom- mend inflat pressur lb. per sq. in.
	Solid		Pneumatic *		
	Single	Dual	Rear wheel	Front wheel	
2 1/2	700	1400	....	....	..
3	1000	2000	375	450	45
3 1/2	1300	2600	570	600	55
4	1700	3400	815	1200	65

energy consumption per mile which are based upon a large number of reports upon the operation of electric cars in large cities; these reports were collected in connection with the Vehicle Research study conducted during 1912 to 1914 by the Electric Research Laboratory of the Massachusetts Institute of Technology. These figures are representative of experience with modern types of cars under average city conditions; the consumption for a given set of conditions may vary from the figures by as much as 20 per cent, either above or below.

#### Garage Load Curves.—

Fig. 4 shows a typical daily load curve for a public garage handling 75 electric passenger cars; Fig. 5 shows a similar typical daily curve for the private garage of a large department store (see paper by E. E. Witherby, *Proc. N. E. L. A.*, 1913). The "off-peak" character of the electric vehicle load is indicated by these curves. In order to attract such off-peak load most light and power companies are now offering special rates for vehicle charging, frequently with the provision that no charging shall be done during the time of the power company's daily peak load.

**OPERATION.**—In the operation of electric automobiles particular attention should be paid to the proper care of the storage batteries. The battery manufacturing companies issue complete instructions for the proper handling of their cells. The

manufacturers of the battery, as well as the manufacturers of the car, are usually ready to confer with the operator of a car to the end that he may obtain satisfactory service from his machine. They should be consulted on the first indication of trouble in their respective portions of the equipment, should the cause of the trouble not be understood.

Fig. 4. Daily Load Curves of a Public Garage Handling Passenger Cars

Fig. 5. Daily Load Curves of a Private Garage Handling Trucks

The following points upon the care and operation of electric cars should be observed:

1. A battery must always be charged with direct current and in the right direction.
2. Never bring an exposed flame near a battery while charging or immediately afterwards.
3. Do not allow the battery temperature to exceed 110° F.
4. Keep the cells filled to the proper level by adding distilled water only. Never put acid in an Edison battery under any circumstances.
5. Keep the outside of the cells free from foreign substances, both solid and liquid.
6. For boosting a lead battery during a specified short period, the maximum current rate  $I$  which may be used without reaching the gassing point is the quotient of the ampere-hours  $Q$  previously discharged (read from ampere-hour meter), divided by 1 plus the hours  $H$  available for boosting, viz.,  $I = \frac{Q}{1 + H}$ .
7. The mechanism of a car should be inspected carefully at least once in two weeks.
8. A car should be entirely overhauled at least once each year, in order that worn parts may be located and replaced.

**COSTS.** — The initial cost of passenger electrics depends so largely upon the character of body and fittings that it is impossible to quote any but the most general figures; prices range from \$2800 to \$5000, the most popular cars selling at from \$4000 to \$5000. It is likewise impossible to quote definite figures on the cost of operating pleasure cars; prices for electricity for private charging vary from about 3 cents per kw-hr. upward; the cost of storage in public garages ranges from \$15 to \$40 per month, plus a charge for electricity at from 4 cents per kw-hr. upward.

The initial cost of commercial electrics ranges from about 60 cents per pound for large trucks to 75 cents per pound for light cars, based upon usual equipment of solid tires, lead batteries and express or stake bodies. (*For typical weights see Tables I and V.*) Special equipment such as winches or dumping bodies is additional. The operating expense will vary widely for different conditions, so that it is impossible to predetermine the total cost of operating a truck of a given rating without knowing the requirements of the service, the nature of the roads, and the general method of handling and caring for the car. The data in the following table are deduced from estimates by Pender and Thomson given in *Vehicle Research Bulletin No. 3*, issued in 1913 by the Massachusetts Institute of Technology. The figures are based upon reports of the operation of a large number of cars during from 1 to 4 years in city trucking and delivery services.

TABLE VII.—COST OF OPERATING ELECTRIC TRUCKS

**AUTO-TRANSFORMERS AND COMPENSATORS.** — (See also *Starters, Motor; Transformers.*) An auto-transformer or single-circuit transformer, also called a "compensator," consists of a transformer having the usual iron core but only one electrical circuit instead of two. This circuit is tapped at various points as shown in Fig. 1, and the primary and secondary circuits, while independent outside the transformer, unite in the same winding in the transformer. If an alternating voltage is impressed across the points *ab*, a magnetizing current will flow in the winding setting up an alternating flux which will link every turn and induce therein an alternating voltage. The voltage between any two taps, as *ac*, is proportional to the number of turns between the taps; thus any ratio of voltages may be obtained. If the secondary *ac* is loaded a current will flow in the primary and the primary and secondary currents will flow in the two parts of the winding as indicated in the figure.

Fig. 1. Auto-transformer

**VOLTAGE AND CURRENT RELATIONS.** — Let  $N_1$  be the total number of turns between *a* and *b*,  $N_2$  the turns between *a* and *c*,  $E_1$  the voltage across the terminals *a* and *b* and  $E_2$  the voltage across the terminals *a* and *c*. Then, neglecting the resistance and reactance of the winding,

$$E_2 = \frac{N_2}{N_1} E_1.$$

Let  $I_1$  be the current entering the terminal *b*,  $I_2$  the current in the external circuit connecting *a* and *c*, and  $I_{ac}$  the current in the transformer winding between *a* and *c*. Then, neglecting the resistance and reactance of the winding and the magnetizing current,

$$I_2 = \frac{N_1}{N_2} I_1,$$

$$I_{ac} = I_2 - I_1 = \frac{N_1 - N_2}{N_2} I_1.$$

The current in the turns between *b* and *c* is

$$I_{bc} = I_1.$$

**Auto-transformer Versus the Two-circuit Transformer.** — For  $N_2 = \frac{1}{2} N_1$  the current in the turns between *a* and *c* would be just equal, neglecting the exciting current, to the current in the turns from *b* to *c* (but opposite in direction). Consequently for a 2 to 1 transformation but one winding of an ordinary two-circuit transformer could be used, provided a tap was available at the middle point of this winding, and the rated output of the transformer could be obtained without the current in this winding exceeding its rated value. Since under these conditions there would be no current in the second winding, the heating of the transformer would be less than it would be were the transformer used as an ordinary two-circuit transformer, and therefore a greater output could be obtained without exceeding the nominal temperature rise.

In general, for the same power input into the connected load an auto-transformer requires but  $\frac{E_1 - E_2}{E_1}$  of the copper required for a two-circuit transformer.

here  $E_1$  is the high-tension and  $E_2$  the low-tension voltage. The higher the ratio of transformation the less the saving in copper. There is also a serious objection to an auto-transformer of high ratio of transformation, in that an accidental ground on the high-tension lead,  $b$  in Fig. 1, would establish a high voltage between the low-tension leads and the ground, which may cause a dangerous shock to a person touching either low-tension lead or may cause their damage. This may be partially prevented by grounding the common point of the high- and low-tension circuits, the point  $a$  in Fig. 1, in which case an accidental ground on the high-tension side would produce a short-circuit, which would open the circuit breaker in the primary circuit, provided the resistance between the two grounds is low and the circuit breaker operates properly. These two provisions, however, may not always be realized even though reasonable care is taken, and it is therefore not considered good practice to use an auto-transformer of high ratio of transformation, except in special cases where economy of space is an important factor and danger from shock can be guarded against, e.g., on a-c. locomotives.

**RATING OF AN AUTO-TRANSFORMER.**— In commercial practice the rating of an auto-transformer in volt-amperes is taken equal to the difference between the high- and low-tension voltages multiplied by the rated current in that part of the winding,  $bc$  in Fig. 1, across which this voltage exists. The capacity of an auto-transformer for a given work bears to the capacity of a two-circuit transformer for the same purpose the ratio  $\frac{E_1 - E_2}{E_1}$ .

For example, to step down the voltage of the supply mains from 500 to 400 volts and supply a load of 100 kv-a. would require an auto-transformer having a rating of  $\frac{500 - 400}{500} \times 100 = 20$  kv-a. as against a two-circuit transformer having a rating of 100 kv-a. The weight, dimensions and cost of an auto-transformer are very nearly the same as for an ordinary two-circuit transformer having the same voltage and kv-a. rating.

**APPLICATIONS.**— Auto-transformers are used chiefly where the required change in voltage is small, e.g., for motor starters (see *Starters, Motor*), and for balancing the voltage between two or more circuits. The smaller the ratio of transformation the greater is the gain in cost and efficiency resulting from the use of an auto-transformer instead of a two-circuit transformer. Auto-transformers are also used to provide a neutral for the Edison three-wire system; see *Distribution Circuits*. In single-phase railway work single-phase auto-transformers are used on the locomotives for transforming the trolley voltage (from 600 to 6000 volts) to the motor voltage (about 500). This is a rather high ratio of transformation for an auto-transformer, but as the saving in weight is very important and as one terminal is grounded, it has proven satisfactory for this service; see *Locomotives, Electric*.

Auto-transformers are frequently constructed three-phase (and occasionally two-phase). These are generally used for starting polyphase motors by providing a lower voltage for the starting period. They are also occasionally used in high-tension distribution. If the voltage applied to an a-c. motor is reduced to one-half, the motor starting current will be one-half and the volt-amperes one-quarter. Thus the starting current in the line will be one-quarter. A three-phase auto-transformer may be either Y or delta-connected. The Y connection is shown under *Motors, Polyphase Induction, Methods of Starting*. The delta connection cannot be made to give a balanced voltage less than half that of the higher voltage, as may be readily seen from an inspection of Fig. 2.

**DESIGN.**— The design of an auto-transformer is quite similar to that of a two-circuit transformer (q.v.) and the leakage reactance is calculated in the same way. For low-leakage reactance the primary and secondary coils must not be entirely separated, but each must be divided into sections and inter-

Fig. 2

mixed to as great an extent as possible. Having found the magnetizing current, core-loss, resistance and reactance in the usual manner, the calculations follow the same methods as for power transformers. In general, the efficiency at unity power factor is given by the equation

$$\text{Efficiency} = \frac{E_2 I_2}{E_2 I_2 + (r_1 - r_2) I_1^2 + r_2 (I_2 - I_1)^2 + \text{core-loss}}$$

where  $r_1$  is the total resistance of the winding measured between the high-tension terminals and  $r_2$  the resistance measured between the low-tension terminals. The efficiency is better than that of a two-circuit transformer of the same kv-a. rating.

**TESTS, SPECIFICATIONS, ETC.**— See *Transformers*.

**DIMENSIONS, WEIGHT AND COSTS.**— For the same kv-a. rating the dimensions, weight and cost are very nearly the same for auto-transformers as for ordinary two-circuit transformers; see *Transformers*.

A.I.E.E.*, 1915; Sorenson and Newton, Blume, Montsinger, *Trans. A.I.E.E.* 1914; *G. E. Review*, Nov., 1916, May, 1914, *Electric Journal*, Nov., 1916, March, 1916, Feb., 1919, April, 1919.

**BALANCES, CURRENT.** — (See also *Ammeters; Electro-dynamometers.*) The Kelvin balance consists of a system of two coils mounted one at each end of a rigid beam and free to move between two pairs of field coils. The balance may be used as an ammeter, voltmeter or wattmeter. It may be used for either c. or d.-c. measurements, but for d.-c. work it has been practically superseded by laboratory standard voltmeters. For a-c. work it is used only as a laboratory standard for calibrating other instruments.

A current balance when carefully constructed may be used for the absolute measurement of electric current, since the force of attraction between the coils can be calculated in terms of their dimensions and the current flowing. It has been successfully used to determine in absolute measure the electrochemical constant of Faraday (see *Electrochemistry, Principles of*).

**Principle of Operation.** — The principle of the current balance is similar to that of the electro-dynamometer. The connections for current measurements are shown in Fig. 1. The current passes through all the coils in series and as a result of the action of the magnetic fields, the left-hand end of the beam is depressed and the right-hand end is elevated. The beam on which the middle coils are mounted has an index pointer and carries a weight that may be slid along a scale on the beam. With no current on and the sliding weight at zero on the scale, a counter weight on the swinging system is so adjusted that the index pointer on the system is opposite a fixed mark and the system is balanced.

Fig. 1. Connections for Current Balances

Passing current through this system destroys the balance which is restored by sliding the weight along the beam. Since the torque exerted on the moving system is proportional to the square of the current, the current flowing will be proportional to the square root of the distance through which the weight has to be moved to balance the beam.

In the case of the wattmeter the current passes through the fixed coils, while the coils on the moving system serve as the potential coils. In this case the power is directly proportional to the distance through which the weight has to be moved to balance the system.

**Range and Cost.** — Kelvin balances are built in 5 standard sizes. The useful range and approximate cost of each instrument is given below (pre-war prices).

Type	Range, amperes	Approx. cost
Centi-ampere .....	0.025-1	\$150
Deci-ampere .....	0.25-10	150
Deca-ampere .....	5-100	150
Hekto-ampere .....	30-600	150
Kilo-ampere .....	100-2500	250

**BIBLIOGRAPHY.** — Laws, F. A., *Electrical Measurements*; Kempe, *Handbook of Electrical Testing*.

**BATTERIES, PRIMARY.** — (See also *Cells, Standard; Electrochemistry Principles of.*) A primary battery or cell is a device for the *direct* transformation of chemical energy into electrical energy. It is becoming common practice though not yet universal, to use the term "cell" for a single unit, and the term "battery" for a group of two or more units or cells.

For convenience of treatment primary batteries may be classified as wet batteries, dry batteries and standard cells. The latter are treated in the article on *Cells, Standard*. The wet battery at one time was largely used in laboratory testing, for telephones, bells and other devices requiring small amounts of energy. In recent years it has been largely supplanted by the dry battery and small storage battery cells (see *Batteries, Storage*). Dry cells, exclusive of the small flash light cells, are now (1921) used, in this country alone, to the extent of some hundred million a year, chiefly for gas-engine ignition and telephone work (see *Gas Engines and Telephone Instruments*).

**Poles and Electrodes.** — The pole or terminal of a battery which is at the higher potential is called the *positive* pole or terminal, the other pole being called the negative pole or terminal. The negative pole is the anode or *positive electrode* or plate and the positive pole is the cathode or *negative electrode* or plate. For example, in a copper-acid-zinc battery the copper is the positive pole and the negative electrode or plate.

**THEORY OF PRIMARY CELLS.** — The modern theory of primary cells is fully discussed in the article on *Electrochemistry, Principles of*. Only one or two points of practical moment will be mentioned here.

**Electromotive Force.** — A cell consists essentially of two metallic conductors or poles dipping into an electrolyte. Copper or carbon is commonly employed for the positive pole and zinc for the negative pole. The electrolyte may be sulphuric or nitric acid or sal-ammoniac, caustic soda or other salt. For a cell made of given materials the open-circuit e.m.f. is always the same provided the temperature, degree of concentration of the electrolyte and the purity of the materials are the same. The terminal e.m.f. or potential difference (p.d.) on closed circuit is always less than the open-circuit e.m.f. due (1) to the internal resistance of the battery, (2) to the polarization of the battery and (3) to the exhaustion of the battery.

**Internal Resistance.** — Let  $E$  be the initial open-circuit e.m.f. of the cell and  $V$  be the p.d. across its terminals, when it is supplying a given current  $I$ ; then the "apparent" internal resistance of the cell is

$$r = \frac{E - V}{I}$$

This is not the true resistance of the cell, for its net e.m.f. when a current  $I$  is being drawn from it is less than the initial open-circuit e.m.f. due to polarization (see below) and partial exhaustion. If, however, after measuring the p.d. in a closed circuit the current is interrupted and the open-circuit e.m.f., say  $E'$ , is measured *immediately* (i.e., before the polarized condition of the cell has had time to change) then the true internal resistance of the cell is

$$r = \frac{E' - V}{I}$$

**Polarization. Depolarizers.** — Polarization is the name applied to the changes produced in the relative concentrations of the electrolyte at the two poles of a cell or to the production at the poles of new chemical substances (such as hydrogen) as a result of the flow of current through it. A depolarizer is any substance which when placed in the electrolyte or on the poles of the cell will partially or wholly prevent these changes. Polarization always tends to reduce the effective e.m.f. of the cell. When a cell which has been polarized

open-circuited, the relative changes in concentration gradually disappear, due to diffusion, and any new substances formed also tend to diffuse uniformly through the electrolyte, with the result that the open-circuit e.m.f. returns in time to nearly its original value, provided the active materials are not exhausted.

The chief cause of polarization in a cell is the formation of hydrogen gas at the positive pole or to the transfer of the metal from the negative pole to the positive pole. The depolarizer is usually an oxidizing agent which reduces the hydrogen or metal liberated at the positive pole to a form readily soluble in the electrolyte and thereby prevents its accumulation at the positive plate. This is the principle on which depends the depolarizing action of the various metallic oxides, such as manganese peroxide or cupric oxide. The same result may be obtained by surrounding the positive pole by a solution of a salt of itself which has the same acid radical as the electrolyte surrounding the negative pole, but which is less soluble, the two solutions being kept practically separated by a porous cup which renders the diffusion of one into the other very slow.

**TYPICAL WET BATTERIES.** — Numerous forms of wet batteries have been used; only some of the more common forms can be described here. The materials used and the e.m.f. developed and approximate range of internal resistance are listed in the following table.

TYPICAL WET BATTERIES

	Daniell	Gravity	Bunsen	Chromic acid	Edison-Lalande	Leclanché type
Positive pole.....	Cu	Cu (b)	C	C	C	C
Negative pole.....	Zn (a)	Zn (a)	Zn (a)	Zn (a)	Zn (a)	Zn
Electrolyte.....	H <sub>2</sub> SO <sub>4</sub>	ZnSO <sub>4</sub>	H <sub>2</sub> SO <sub>4</sub>	H <sub>2</sub> SO <sub>4</sub>	KOH	MnO <sub>2</sub>
	or ZnSO <sub>4</sub>	or MgSO <sub>4</sub>				
Depolarizer.....	CuSO <sub>4</sub>	CuSO <sub>4</sub>	HNO <sub>3</sub>	CrO <sub>3</sub>	NaOH	CuO
Separator.....	Porous pot	None	Porous pot	With or without pot	None	NH <sub>4</sub> Cl With or without pot
E.m.f., volts.....	1.07 to 1.14	1	1.9-1.95	2	0.75	1.5
Resistance, ohms.....	0.3 to 30	0.1 to 6	Low	0.5 to 4	0.02 to 0.1	1 to 5

a. Amalgamated. b. In the Krüger cell copper-plated lead is used.

**Daniell Cell (Fig. 1).** — A typical form of this cell is shown in Fig. 1. Other forms, differing in certain details, are Muirhead's cell, the Siemens & Halske Daniell cell, Minotto's cell (which may also be classed as a gravity cell, *see below*), etc. *J* is a glass or glazed earthenware jar containing a concentrated solution of copper sulphate, *P* is a porous pot containing dilute sulphuric acid (about 10 per cent by volume) or zinc sulphate solution or both, *C* is the positive copper pole and *Z* the negative zinc pole which is usually amalgamated. The chemical reaction which takes place may be represented by the formula

Fig. 1. Porous Pot Daniell Cell

A current of 1 ampere for 1 hour deposits 1.186 grams of copper and liberates 1.119 grams of zinc. Hence

0.042 oz. copper is deposited per ampere-hour,

0.043 oz. zinc is used up per ampere-hour,

0.164 oz. copper sulphate crystals are used up per ampere-hour,

0.106 oz. zinc sulphate is formed per ampere-hour.

The latter when crystallized out will form 0.189 oz. zinc sulphate crystals. These figures do not include any loss of zinc due to local action, which may amount to 10 per cent or more.

**E.M.F. of Daniell Cell.** — The e.m.f. of a Daniell cell varies from about 1.07 volts to 1.14 volts, depending on the density of the copper sulphate solution and on the amount of zinc sulphate present in the dilute sulphuric acid. The cell has its highest e.m.f. at the start when the sulphate of copper solution is saturated and no sulphate of zinc has formed. Hence, in order that the e.m.f. shall remain more nearly constant, it is better to start with *both solutions saturated*. The resistance of the cell will be higher and its e.m.f. lower than when dilute sulphuric acid is used, but this lower value of about 1.10 volts will be maintained nearly constant while the cell is sending a current.

**Internal Resistance of Daniell Cell.** — This depends not only upon the dimensions of the cell but also upon the porosity of the pot or other separating medium. The type of cell shown in Fig. 1, having a pot 7 inches high which is quite porous, has an internal resistance of about 0.3 ohm. The resistance of the Siemens type of Daniell cell is from 10 to 15 ohms, and the resistance of Minotto's modification of the Daniell cell, in which a layer of sawdust or sand is used in place of the porous cup, may be as high as 30 ohms.

The resistance of a Daniell cell, like that of liquids generally, *diminishes* with *increase* of temperature.

**Local Action.** — Impurities in the zinc form with the zinc small short-circuited voltaic cells, resulting in a wasting away of the zinc without producing a current in the external circuit. This can be largely prevented by amalgamating the zinc, i.e., coating it with mercury, which is readily done by thoroughly cleaning the zinc by dipping it into dilute sulphuric acid and then rubbing mercury over its surface. In the Daniell cell metallic copper also forms in the pores of the porous cup where the zinc touches it; this can be prevented by covering with paraffin those portions of the cup which may come into contact with the zinc.

**Care of Daniell Cells.** — The type of cell shown in Fig. 1 must be taken to pieces when not in use. If it has to be put to one side for only an hour or two, it will be sufficient to lift the porous pot with the contained zinc rod bodily out of the cell, and to place it in another empty jar, or stand it in a dish while out of use.

**Gravity Battery (Fig. 2).** — The principle of this cell is the same as that of the Daniell cell, except that no porous pot is used, the copper sulphate and zinc sulphate being maintained separate by gravity. There are various modifications in the form of construction, known as the Meidinger cell, Calland cell, Kelvin tray battery, Krüger cell, etc. The gravity cell is still used in telegraph and telephone work.

The copper electrode is placed at the bottom of the cell, and is then covered with copper sulphate crystals. The zinc electrode is then put in place and the jar either filled with dilute zinc sulphate or with dilute sulphuric acid.

**Care of Gravity Battery.**—The resistance of the cell increases rapidly with decrease of temperature; it should therefore be kept at a reasonably high temperature, say 70° F. A gravity cell must, of course, not be moved about, or if moved great care must be taken to avoid the two liquids being mixed together. To prevent the copper sulphate wandering to the zinc plate, it is well to allow the cell to send a weak current through an external circuit of considerable resistance even when the cell is not in ordinary use. The electrolyte should be renewed when the blue sulphate solution turns brown. The line of separation between the copper and zinc sulphates, or the "blue line," should be about halfway between the two electrodes.

**Bunsen Cell.**—In the Bunsen cell a zinc plate is placed in dilute sulphuric acid, as in the Daniell, but the copper plate is replaced by one of carbon and the copper sulphate solution by strong nitric acid, which is generally said to act as the depolarizer. The Grove cell differs from the Bunsen only in the use of platinum in place of carbon. Both cells give a high e.m.f., from 1.9 to 2.95 volts, and have low internal resistances, so they may be used for producing fairly large currents. When working the cells give off dark brown fumes of nitric peroxide,  $\text{NO}_2$ , and should be placed in the open air or under a chimney.

The chemical reaction which takes place may be represented by the formula  $\text{Zn} + \text{H}_2\text{SO}_4 + 2 \text{HNO}_3 = \text{ZnSO}_4 + 2 \text{H}_2\text{O} + 2 \text{NO}_2$ .

**Care of Bunsen Battery.**—A Bunsen or Grove battery must be taken to pieces at the end of each day's use, since the mixing of the liquids through the walls of the very porous cup used to separate them would render the battery practically useless the next day. The porous pots should be placed in water after use, so that all the zinc sulphate solution may be dissolved out of the pores of the earthenware, for, otherwise, when the pots are dried the zinc sulphate solution will crystallize in the pores and cause the pots to fall to pieces.

**Chromic Acid Cell (Fig. 3).**—The chromic acid or potassium bichromate cell was devised by Poggendorff. In the original type of cell no porous pot was employed. In the Fuller cell, shown in Fig. 3, a porous pot is used. The depolarizer used is chromium peroxide, popularly called chromic acid, which may be purchased ready prepared, or may be formed by heating potassium or sodium bichromate with sulphuric acid (1 part by weight of the bichromate, 3 parts of acid and 9 parts of water). In the type of cell shown in the figure the wire connected to the zinc rod is well amalgamated or coated with gutta-percha to insulate it. In the porous pot containing the zinc, there is put a quantity of mercury to maintain the amalgamation, and either dilute sulphuric acid or a solution of common salt  $\text{NaCl}$ . The chromic acid solution is placed in the jar containing the carbon plate.

The chemical reaction which takes place may be represented by the formula  $3 \text{Zn} + 2 \text{CrO}_3 + 6 \text{H}_2\text{SO}_4 = \text{Cr}_2(\text{SO}_4)_3 + 3 \text{ZnSO}_4 + 6 \text{H}_2\text{O}$ .

This cell has an e.m.f. of about 2 volts, and is suitable for producing a fairly strong current for a short time. When much used the cell becomes saturated with the potassium and chromium sulphates, and a double salt, chrome alum,  $\text{K}_2\text{Cr}_2(\text{SO}_4)_6$ , crystallizes out and sticks so firmly to the bottom of the cell that it is somewhat difficult to remove.

Fig. 2. Gravity Daniell Cell

Fig. 3. Fuller's Mercury Bichromate Cell

**Edison-Lalande Cell.** — In this type of cell the positive pole is a plate of compressed cupric oxide (CuO), the surface of which is reduced to metallic copper. The cupric oxide acts as the depolarizer. The negative pole is amalgamated zinc and the electrolyte a strong solution (1 to 3 by weight) of caustic potash or of caustic soda.

A layer of heavy oil is poured over the solution to prevent evaporation and "creeping." No local action or polarization takes place in this cell; under normal conditions it is an easy matter to set it up to give any required number of ampere-hours, and to so proportion the constituents that they are all exhausted at the same time. This is a matter of considerable importance where closed-circuit working is employed, as in some systems of telegraphy and in alarm circuits. Although the e.m.f. of the Edison-Lalande cell is low, its resistance is also low, and the cell is capable of producing large currents. The cell may be left set up for months without deterioration.

The chemical reaction which takes place may be represented by the following formula

**Leclanché Cells.** — In the original form of this type of cell the positive pole was a plate of carbon embedded in a mixture of solid manganese peroxide and broken carbon contained in a porous pot. The electrolyte is sal ammoniac,  $\text{NH}_4\text{Cl}$ , and the negative pole zinc. The manganese peroxide acts as the depolarizer. The only object of the porous pot was to hold the carbon and manganese peroxide. In the later forms of this cell, such as the "agglomerate," Corsak, etc., the porous pot is dispensed with and a mixture of carbon and manganese peroxide are moulded together with a suitable binder, or the mixture of carbon and manganese peroxide is held together by a wrapping of canvas or sacking.

The chemical reaction which takes place may be represented by the formula

If, however, too little sal ammoniac be present, zinc oxide or zinc oxychloride is formed instead of zinc chloride, and the solution becomes milky; hence when this happens, more sal ammoniac should be added.

The e.m.f. of a Leclanché cell is about 1.5 volts, but falls rapidly when the cell is used to send a strong current. It will, however, regain its value if the cell be left for some time unused, and it does not sensibly diminish when the cell is put to one side, even for some months. Hence, while the Leclanché cell is much inferior to the Daniell cell for the purpose of sending a steady current for an hour or two, it is much superior to the Daniell cell for producing intermittent currents at any time during the course of a year or more — for example, such currents as are employed for the ringing of electric bells, for house telephones, and for railway signaling.

**Care of Leclanché Cells.** — When the sal ammoniac becomes exhausted it should be thrown out and a new solution made. Three or 4 ounces of sal ammoniac for a jar of ordinary size is required, the jar to be filled about one-third with water before putting in the electrodes.

**DRY CELLS.** — The modern dry cell may be looked upon as a modification of the Leclanché cell, the chief difference being that only enough water is added to the electrolyte to moisten an absorbent layer of pulp-board, blotting paper, cheese cloth or starch paste, this lining separating the positive and negative poles. The negative pole, which also serves as a container, is a hollow zinc cylinder; the bottom of this cylinder is also usually made of zinc. About 2

per cent of the dry cells made in this country have these dimensions. The positive pole is a carbon rod, which may be either cylindrical or fluted. The absorbent layer above mentioned is placed next the zinc and is saturated with a solution of sal ammoniac and zinc chloride. The zinc chloride is necessary to reduce the rapid deterioration which would otherwise take place on open circuit. The space between this lining and the carbon electrode is filled with a mixture of granulated carbon and manganese peroxide, the latter being the depolarizer. The top of the cell is usually sealed with a pitch composition.

**Desiccated Cells**, sometimes called reserve cells, are usually constructed the same as the ordinary dry cell. The chief difference is that the cell is assembled without water, provision being made for filling the cells with water before they may be required for use. Desiccated cells will not deteriorate so long as they remain dry. It is necessary to fill them with water several hours before use, and 24 hours may be necessary before the cell will give its maximum current on short circuit.

**E.M.F. of Dry Cells.**—In new cells of practically all types the open-circuit e.m.f. is between 1.5 and 1.6 volts. The decrease in e.m.f. when the cell stands on open circuit is very slight, being only about 0.1 after the cell has stood many months. An open-circuit e.m.f. materially less than 1.5 volts is generally an indication of serious deterioration or of some other defect. The effect of temperature on the open-circuit e.m.f. is slight, amounting to only a few hundredths of a volt for all ordinary temperature ranges. Due to the relatively rapid polarization and increase of internal resistance with use, the average terminal voltage during the useful life of the cell is only about 1 volt.

**Internal Resistance.**—The internal resistance of a high-grade dry cell when new is usually less than 0.1 ohm, which may increase to 0.5 ohm within 9 or 12 months, even though the cell is not used during this time. The polarization of the cell in actual service causes a much greater decrease in the terminal e.m.f. than does the internal resistance drop, and therefore the internal resistance test is of little practical value.

**Short-circuit Current.**—Nine out of every ten users of dry cells consider the short-circuit current, i.e., the current produced through an ammeter having a relatively small resistance connected directly between the poles of the battery, as a direct measure of the value of the cell. There are other factors, however, which must be considered, such as the temperature of the cell, the service for which it is to be used, etc. According to D. L. Ordway (*Trans. Am. Electroch. Soc.*, 1910, Vol. 17, p. 326) a standard 2.5 by 6-inch dry cell should give when new a short-circuit current (external resistance not over 0.01 ohm) of from 18 to 25 amperes; a cell giving a short-circuit current much above 25 or below 16 amperes should be looked upon with suspicion. A cell giving a short-circuit current much in excess of 25 amperes is liable to polarize rapidly, whereas if the short-circuit current is much under 16 amperes, it is probable that the cell has been made a long time or that cheap materials have been used.

The effect of temperature on the short-circuit current is pronounced. Between 10 and 80° C. the current increases about 1 ampere for each 10° increase in temperature. This effect is even more pronounced at very low temperatures. The short-circuit current returns to its normal value when the cell is restored to normal temperature.

**Shelf-life.**—The shelf-life of a dry-cell of the ordinary sizes is usually considered as the time in months that the cell may stand on open circuit without its short-circuit current falling below 10 amperes. This current is about half the short-circuit current when the cell is new, and represents a value which is probably lower than the minimum point at which a dealer could dispose of a

cell to the average consumer. The average shelf-life of high-grade cells is from 10 to 12 months, though the very best cells have a shelf-life of from 12 to 15 months. Many makes of cells have a shelf-life of only 8 to 10 months; and cells are on the market having a shelf-life of only 1 or 2 months.

The shelf-life is increased by storing the cells at a low temperature. Ordway gives the following results on standard dry cells kept in storage at the stated temperatures. These cells give initially a short-circuit current of about 20 amperes.

Temperature at which cells were stored, ° C.....	0	25	50	75
Short-circuit current at 25° C. after 5 months....	18.1	17.4	0.5	0.4

**Ampere-hour and Watt-hour Capacity.** — The short-circuit current, however, is not a measure of the ampere-hours obtainable from the cell, as is indicated in the following table, taken from Ordway's paper. The ampere-hours given are those obtained from the various cells when discharged continuously through a resistance of 16 ohms until the closed-circuit voltage fell to 0.5 volt.

Brand of cell.....	A	D	G	J	M	P	V	X
Short-circuit current.....	33.0	24.5	22.5	20.9	20.1	19.2	11.6	6.6
Ampere-hours.....	24.0	33.5	40.0	18.2	11.7	30.3	13.6	4.5

The letters are arbitrary designations.

Although the short-circuit current falls off with the age of a cell, even though the cell is not used, the ampere-hour capacity does not decrease in the same ratio. Ordway gives the following tests on samples from the same lot.

	Freshly made	9 months after manufacture
Short-circuit current.....	22.4	3.6
Ampere-hour capacity (through 2 ohms to 0.25 volt).....	24.9	20.2

**Effect of Rate of Discharge on Capacity.** — Ordway gives the following results of tests on standard 2.5 by 6-inch cells, when the cells are discharged continuously through 2, 4, 8, 16, 24, 32 and 40 ohms respectively. By "end point in volts" is meant the terminal voltage per cell at the end of the stated number of hours.

#### HOURS OF CONTINUOUS SERVICE OF 2.5 BY 6-INCH DRY CELLS

End point in volts	Resistances used in ohms						
	2	4	8	16	24	32	40
1.2	4.3	10	39	142	260	414	549
1.0	9.3	35	94	296	548	889	1148
0.8	16.5	51	143	414	751	1078	1550
0.6	28.2	76	225	954	1240	1600	1763
0.4	55	207	648	1197	1711	2280	3040
0.2	160	450	882	1318	1914	2626	3140

## WATT-HOURS FROM 2.5 BY 6-INCH DRY CELLS DISCHARGED CONTINUOUSLY

End point in volts	Resistances used in ohms						
	2	4	8	16	24	32	40
1.2	3.7	4.3	8.1	15.2	18.8	21.7	23.8
1.0	6.7	13.0	16.5	26.9	33.4	39.8	42.0
0.8	9.7	16.3	21.5	32.8	40.3	44.6	50.6
0.6	12.5	19.4	26.6	46.9	49.5	52.7	53.2
0.4	15.4	27.3	39.1	52.6	54.3	58.2	54.8
0.2	19.8	31.6	41.5	53.3	55.2	59.3	57.1

Capacity on Intermittent Service. — Neither the ampere-hour nor watt-hour capacity of a cell on *continuous* service is a measure of its capacity on *intermittent* service. What the user wishes to know is the actual number of hours of service that he can obtain from a cell when used to operate a definite piece of apparatus, which as a rule takes current only intermittently, e.g., for telephone or ignition service. From curves given in Ordway's paper for 3 cells connected in series and discharged through the stated resistances the following table has been made up.

## HOURS OF INTERMITTENT SERVICE OF 2.5 BY 6-INCH DRY CELLS

(The hours given are the hours the cell is actually supplying current)

End point in volts, 3 cells	Continuous discharge			5 minutes each hour night and day			5 minutes each hour, 8 hours per day, 6 days per week		
	5 ohms	10 ohms	20 ohms	5 ohms	10 ohms	20 ohms	5 ohms	10 ohms	20 ohms
	3.6	4	12	30	4	45	80	3	15
3.0	9	25	65	29	65	145	12	30	60
2.4	15	40	100	48	90	190	23	45	75
1.8	25	60	150	65	130	225	35	70	100
1.2	42	140	475	80	160	250	52	100	150
0.6	95	...	...	93	200	290	70	115	165

From the above table it is apparent (1) that the terminal voltage falls off more rapidly on continuous discharge than on intermittent discharge, counting hours of *actual discharge* only, but (2) that during the latter stages the terminal voltage falls off more rapidly for the intermittent discharge, this latter effect occurring earlier as the external resistance is increased. The second effect is probably due to the deterioration of the battery while standing on open circuit. It should be kept in mind that the length of time the cells were in service during the intermittent tests were respectively 12 and 40 times the period of actual discharge.

**Proper Arrangement of Cells for Best Results.** — The data given in the above tables may be used as a basis for the determination of the number and proper arrangement of cells for a given service. For example, if a certain piece of apparatus has a resistance of 8 ohms and cannot be operated at a voltage under 0.8, then 143 hours of service can be obtained from a single battery. If however 4 cells in parallel are used, the drain on each cell will be one-fourth as great as before, which is equivalent to discharging each cell through 32 ohms. Therefore the 4 cells will give 1078 hours of service, or 270 hours per cell. If the 4 cells were connected in series, then drain on each would be 4 times as great as for a single cell, which is equivalent to discharging each cell through 2 ohms, but each cell could discharge to 0.2 volt instead of 0.8. The 4 cells in series would then give 160 hours, or only 40 hours per cell. The parallel arrangement is therefore the best in this case.

For ignition service 6 cells in series are usually required in order to obtain a sufficiently high voltage. On heavy service of this kind two or more such series groups connected in parallel are usually more economical than a single group. For telephone service 3 cells in series are usually required in order to obtain a sufficiently high voltage. For such light service a single group of cells is more advantageous than two or more groups in parallel; any gain which might at first sight be effected is more than offset by the deterioration caused by local action on standing. This may be seen by a consideration of the data on intermittent service given above.

**Tests of Dry Batteries.** — The proper testing of dry batteries has been the subject of considerable discussion during the last few years. See *Trans. Am. Electrochem. Soc.*, 1909 to date. A preliminary report was submitted by a committee of this society in April, 1912. The following is a brief summary.

In measuring the terminal voltage of a dry battery a voltmeter having a fairly high resistance, 300 ohms or more, should be used. The ammeter and leads for measuring the short-circuit current should have a combined resistance of 0.01 ohm. The internal resistance test is not recommended.

**Service Tests.** — Dry batteries to be used in telephone work should be tested by discharging 3 cells, connected in series, through 20 ohms resistance for a period of 2 minutes, each hour, during 24 hours per day and 7 days per week, until the closed-circuit voltage of the battery at the end of a period of contact falls to 2.8 volts (0.93 volt per cell). Report the results as the number of days during which the closed-circuit voltage remains above the limiting value of 2.8 volts. This test has been modified and supplanted by the so-called A.T. and T. test, which is as follows: three cells connected in series are discharged through 20 ohms for 10 periods of 4 minutes each in 10 consecutive hours of 6 days per week. On the seventh day every other period is omitted. The end of the test is taken at 2.8 volts for the battery on closed circuit. The results are expressed as the number of days the test lasted.

For ignition service discharge 6 cells connected in series through 16 ohms resistance for 2 periods of 1 hour each per day, seven days per week, the periods being 11 hours apart. Determine at the end of every 12th period of closure the current which the 6 cells are capable of sending through a 0.5 ohm coil in series with an ammeter, the two being in parallel with the 16-ohm coil. The test is considered completed when the current through the 0.5 ohm coil at the end of a period of closure falls below 4 amperes. Report the results as the number of hours of actual discharge to this limiting value of the current.

For flash-light service discharge the battery through a resistance of 4 ohms for every cell in series, for a period of 5 minutes, once each day, until the closed circuit voltage at the end of a discharge period falls to 0.75 volt per cell in series. Report the result as the number of minutes of actual discharge until the voltage reaches this limiting value. At the present time (1921) the end point is geo-

ally taken as 0.50 volt per cell instead of 0.75 volt, because the modern lamps are usable to a lower voltage.

Full details for making these tests, together with a description of proper automatic arrangements for opening and closing the circuit at the designated times, will be found in the *Trans. Am. Electrochem. Soc.*, 1912, Vol. 21, p. 282. The timing device is an ordinary cheap clock provided with suitable contacts by means of which the hand closes the circuit.

**Shelf-life Test.** — Keep the cells open-circuited in a dry room at normal temperature. Determine the short-circuit current at the end of every 8 weeks. Report results as the number of months before the short-circuit current falls below 10 amperes.

**SPECIFICATIONS FOR DRY BATTERIES.** — See *Circular No. 79, Bureau of Standards*, April 25, 1919.

**COST OF DRY BATTERIES (Pre-war prices).** — Dry batteries of standard size (2.5 by 6 inches) cost at retail from 10 to 25 cents, depending upon the quality of the battery. When bought by the barrel, good dry batteries may be had for 10 cents apiece.

**BATTERIES, STORAGE, ALKALINE TYPE.** — (See also *Automobiles, Electric; Batteries, Storage, Applications of; Batteries, Storage, Lead Type*) The alkaline type of storage battery consists in its best-known form, i.e., the Edison battery, of an iron-nickel element immersed in dilute caustic-potash solution. The alkaline type of storage battery was first exploited commercially by Edison in 1904. At the present time (1921) it is being used extensively for the propulsion of electric vehicles, the operation of railroad block signals, the electric lighting of trains and in radio work.

**THEORY OF ALKALINE STORAGE BATTERY.** — Numerous active elements have been used in the alkaline type of storage battery. The elements in the Edison type of alkaline battery consist of nickel hydroxide for the active material of the positive plate, iron for the active material of the negative plate and a solution of potassium hydrate and lithium hydrate for the electrolyte.

The fundamental principle of the Edison storage battery is the oxidation and reduction of metals in an electrolyte which neither combines with nor dissolves either the metals or their oxides. Also, an electrolyte which, notwithstanding its decomposition by the action of the battery, is immediately re-formed in equal quantity, and is, therefore, a practically constant element without change of density or conductivity over long periods of time. Therefore, only a small quantity of such electrolyte is necessary, permitting a very close proximity of the plates. Furthermore, it is unnecessary to take hydrometer readings until about three hundred cycles of charge and discharge have been made; this is simply to determine when it is necessary to empty out the old solution and put in new. The active materials of the electrodes being insoluble in the electrolyte, no chemical deterioration takes place therefrom.

The chemical reactions in charging the Edison storage battery are: (1) the oxidation from a lower to a higher oxide of nickel in the positive plate, and (2) the reduction from ferrous oxide to metallic iron in the negative plate. The oxidation and reduction are performed by the oxygen and hydrogen set free at the respective poles by the electrolytic decomposition of water during the charge. The charging of the positive plate is, therefore, simply a process of increasing the proportion of oxygen to nickel. The proportions of nickel to oxygen in definite oxides of nickel are as follows:

Atomic Proportions by Weight				
	Ni	O	Ni	O
NiO	1	1	1	.373
Ni <sub>2</sub> O <sub>3</sub>	1	1.33	1	.364
Ni <sub>3</sub> O <sub>4</sub>	1	1.5	1	.409
NiO <sub>2</sub>	1	2	1	.545

The relative amounts of oxygen necessary to oxidize nickelous oxide, or NiO, which is the oxide corresponding to the green nickel hydrate used in making the battery, to the various oxides are given in the three reactions:

The NiO<sub>2</sub> is capable of reacting with NiO according to the reaction

would be represented by a ratio of 1 : 1.33 ( $\text{Ni}_2\text{O}_3$ ) or lower, depending on the discharge.

The discharge of the cell is simply the reversal of the above reactions, the hydrogen reducing the higher oxides of nickel to lower oxides and the oxygen oxidizing the iron to ferrous oxide.

**"Gassing."** — In the alkaline type of cell, as in the lead type of cell, a certain amount of the water ( $\text{H}_2\text{O}$ ) is broken up on charge by the electrolytic action of the charging current. The rate at which gas is evolved during a charge at the normal rate of current remains approximately constant during the first half of the charge, and increases rapidly during the latter portion of the charge. Of the total amount of gas evolved during a 7-hr. charge, about one-half is evolved during the first 3 hr. of the charge. As the oxygen and hydrogen thus liberated form an explosive mixture, provision should be made with a battery of any considerable size to carry the gases away to prevent their becoming a source of danger.

**DESIGN.** — The only alkaline type of battery in use at present (1921) in the United States is that made by the Edison Storage Battery Co. This battery is made up of a positive plate having as the active material a high nickel oxide, a negative plate having as the active material powdered iron, and an electrolyte consisting of dilute potassium hydrate solution.

**Positive Plate.** — The positive or nickel plate consists of perforated steel sheet, nickel plated, filled with alternate layers of nickel hydroxide and pure metallic nickel in thin flakes. The nickel is added to give the necessary conductivity to the active material.

The tube is formed from a perforated ribbon of steel, nickel plated, and has a spiral lapped seam. This tube, after being filled with active material, is reinforced with steel bands, which prevent the tube expanding away from and breaking contact with its contents. The tubes are flanged at both ends and held in contact with a steel supporting frame or grid made of cold-rolled steel, nickel plated.

**Negative Plate.** — The negative or iron plate consists of a grid of cold-rolled steel, nickel plated, holding a number of rectangular pockets filled with powdered iron oxide. These pockets are made up of very finely perforated steel, nickel plated. After the pockets are filled they are inserted in the grid and subjected to pressure between dies which corrugate the surface of the pockets and force them into contact with the grid.

After the plates have been prepared, as outlined above, the positive or nickel plate is further oxidized electrolytically and the nickel hydroxide converted to a high oxide of nickel, probably  $\text{Ni}_2\text{O}_3$ . The negative or iron plate is reduced electrolytically, the powdered iron oxide being converted into metallic iron. See section above on *Theory* for an explanation of the chemical action.

**Separation and Insulation.** — After the plates are assembled into a complete element, narrow strips of hard rubber are inserted between the plates to insulate them from each other. The side insulator is provided with grooves and a step or projection at the bottom to insulate the complete element from the steel container. The step acts as a support to the element as well as insulating the plates from the bottom of the container. At the ends of the element, that is, between the outside negative plates and the container, are inserted smooth sheets of hard rubber.

**Assembly.** — The jar is made from cold-rolled sheet steel, nickel plated. The walls of the jar are corrugated to give the greatest amount of strength with minimum weight.

The cover is of sheet steel, nickel plated, provided with three mountings, two

being pockets for containing stuffing boxes about the terminal posts. The top mounting is an opening for filling the cell with electrolyte, and for the occasional (every four or five discharges) addition of distilled water to take the place of that which is lost during charge. This opening is provided with a hinged cap, on the under side of which is loosely hung a spherical segment of hard rubber. The latter, when the cap is closed, seats upon the circular opening beneath and is lifted by escaping gas, permitting its free egress. It closes the cell however to the admission of foreign gases or other matter from without. The cap is opened only for filling and is held open or closed by a flat steel spring.

The plates are grouped on steel connector rods with steel spacing washers, all being attached to a steel terminal post. The terminal posts are insulated from the cover by means of hard and soft rubber washers and bushings.

The cells are assembled in wood trays, the positive and negative terminals of adjacent cells being connected together by copper connecting links. Each individual cell is insulated from the adjacent cell and from the containing tray.

**RATING AND PERFORMANCE.** — It is standard practice to rate an Edison battery in terms of the amperes it will give continuously for 5 hours. The rated capacity in ampere-hours is then 5 times this current rate. The normal rate of charge is the same as the normal rate of discharge and the time of normal charge is given as 7 hours. In the trade designations employed, e.g. A-6, the letter designates the size of the plate and the numeral the number of positive plates per cell, i.e., in the A-6 cell there are 6 positives; see below under *Dimensions, Weight and Cost*. The values of the rated current and output for each size of cell are given in the following table; the average voltage per cell during discharge is 1.2 volts. The G type is rated on a 3¼ hour basis with a normal charging time of 4¼ hours. The normal current rate is 50 per cent higher than the A type of equivalent ampere-hour capacity.

RATED PERFORMANCE OF EDISON CELLS

Size of cell	Normal rate of charge and discharge, amperes	Rated capacity		Watt-hours per pound of cell for rated capacity	Average watts during discharge at normal rate
		Ampere-hours	Watt-hours		
B-2	7.5	37.5	48	12.2	9
B-4	15	75	90	13.0	18
B-6	22.5	112.5	135	13.7	27
A-4	30	150	180	13.3	36
A-5	37.5	187.5	225	13.4	45
A-6	45	225	270	14.1	54
A-8	60	300	360	13.1	72
A-10	75	375	450	13.2	90
A-12	90	450	540	13.2	108

The capacity of new cells increases for at least twenty cycles of charge and discharge. This betterment may be as much as 30 per cent above rating and comes from an improvement of conditions in the nickel electrode which is brought about by regular charging and discharging. It is expedited by overcharging. The capacity then decreases slowly with use until the electrolyte is renewed, which should be done before the capacity has fallen to the rated

value. The capacity again increases for a few charges and subsequently falls.

**Voltage Characteristics.** — The charge and discharge voltage characteristics of an Edison battery vary with the conditions, among which are temperature, condition of electrolyte, time since last discharge or charge, etc. Typical charge and discharge voltage curves at the normal rate are given in Fig. 1. It will be noted that the voltage rises rapidly at the beginning of charge, decreases somewhat during the second hour, and then rises gradually during the remainder of the charge.

This hump in the voltage curve is characteristic of the Edison battery, and may lead to confusion as to battery's condition of charge. The value and duration of this hump may vary considerably even on successive charges of the same battery. The final charging voltage, with current on, is approximately 1.8 volts per cell, but ranges from 1.7 to 1.95 volts per cell. The rise in voltage near the end of charge is not sufficient to serve as a very satisfactory criterion of complete charge, but the Edison Storage Battery Co. recommends that if the extent of the previous discharge is unknown, the charge at the normal rate should be continued until the voltmeter reading has remained constant for 30 minutes at about 1.8 volts per cell.

Fig. 1. Voltage Curves at Normal Rate

Effect of Temperature on Charging Voltage. — The normal average temperature of a battery on charge is between 90 and 100° F. The values of average and maximum charging voltage are higher for low temperatures of the electrolyte than for high temperatures. The range is indicated by the results of a series of tests given in the accompanying table.

Temperature, deg. Fahr.	Average voltage	Maximum voltage
35	1.88	1.94
55	1.81	1.93
75	1.76	1.88
95	1.70	1.84
115	1.67	1.77

**Discharge Voltage.** — On discharge the voltage performance of an Edison battery is more uniform than on charge, although during the early portion of the discharge the voltage is liable to vary considerably from the values indicated in Fig. 1. This depends chiefly on the length of time the cell has stood on open-circuit since the completion of the charge. The average discharge voltage is 1.2 volts per cell when discharged to 1.0 volt per cell (with current on) at the normal (5-hour) rate.

As with lead cells the open-circuit voltage is valueless as an indication of the state of charge. The open-circuit voltage in general will be about 20 per cent higher than the corresponding terminal voltage at normal rate of discharge.

**Specific-gravity Characteristics.**—The normal specific gravity of the electrolyte is about 1.200, and decreases slowly as the cell is used. (See section below on Tests of Electrolyte.) The specific gravity does not change materially on charge or discharge. A slight concentration has been noted on discharge, but the variation is too small to have commercial significance. The specific gravity decreases 0.002 with each 10° F. increase in temperature.

**Variation of Capacity with Rate of Discharge.**—The ampere-hour capacity of an Edison

battery is practically independent of the rate of discharge, provided the discharge is carried to a sufficiently low voltage. In this connection it may be pointed out that no harm is done an Edison battery by discharging it to zero voltage. The total ampere-hour outputs of a battery,

when discharged to zero voltage at various current rates from one-third normal to four times normal, after a normal charge in each case, vary by only 2 per cent.

As the low voltage part of a discharge cannot be considered useful, it is customary to consider the discharge completed for any rate of discharge when the voltage has reached a value differing from 0.9 volt per cell by an amount equal to the difference between the resistance drop in the cell corresponding to this rate and that corresponding to the resistance drop at the normal rate. Thus

for a cell with an internal resistance (for values see paragraph below on Internal Resistance) of 0.003 ohm and a normal rate of 30 amperes, the terminating voltage for a discharge at 60 amperes would be  $0.9 - 0.003(60 - 30) = 0.81$  volt.

Fig. 2 shows a series of voltage curves for discharges at various rates following normal charges. The discharge has been discontinued in each case in accordance with the above rule. The variations of average voltage, ampere-hour output and time of discharge, with discharge rate are shown in Fig. 3, where values of these factors for the normal (5-hour) rate are each taken as 100 per cent.

**Variation of Capacity with Rate of Charge.**—The energy contained in a newly charged Edison cell depends upon both the rate and length of charge. Fig. 4 gives the variation in the time of discharge at normal rate for various charge rates and periods for a particular battery. In this particular test when the cell was discharged at the normal 5-hour rate to 0.9 volt, after a 7-hour

Fig. 2. Discharge at Various Rates

Fig. 3. Relation of Output Characteristics to Rate of Discharge

charge at this same rate it gave this current for 5.9 instead of 5 hours. The curve for the normal rate of charge shows that the capacity for a 10-hour charge is 13.5 per cent and for a 14-hour charge 27.0 per cent greater than for a normal (7-hour) charge. The results of a series of charges of various lengths and subsequent discharges, both at the normal rate, are given in the accompanying table.

Fig. 4. Capacity at Normal Rate Discharge after Charging at Various Rates and Periods

Length of charge, hours	5.5	7.0	10.0
Length of discharge, hours	5.0	5.8	6.4
Average discharge voltage	1.10	1.203	1.203
Ampere-hour efficiency, per cent	91	83	64
Watt-hour efficiency, per cent	66	59	45

**Variation of Efficiency with Length of Charge.**—As shown by Fig. 4 the capacity of a cell depends upon the rate as well as upon the length of charge. For charge and discharge at the normal rate, the watt hour efficiency is approximately 72 per cent for a short charge (i.e., one hour or less), it drops to about 58 per cent for a normal or 7-hour charge, and has smaller values for larger charges, being approximately 30 per cent for a 15-hour charge. The normal rate of charge has been chosen by the manufacturers such that for an output of approximately the rated number of ampere-hours at the normal rate the efficiency is higher for the normal rate of charge than for a rate which is considerably higher or lower than the normal.

**Variation of Capacity with Temperature.**—With the Edison battery, as with all alkaline batteries, there is a critical electrolyte temperature for each rate of discharge below which the capacity falls to a low value. The higher the rate of discharge the higher is this critical temperature. If the electrolyte throughout the cell has been chilled below the critical point for a given rate of discharge, the full capacity can be obtained as soon as the cell is warmed above the critical range. A series of tests, reported by W. E. Holland (*Central Station, N.Y., 1911*), showed that the temperature should be kept above 55° F. if a large current is to be required. In the operation of Edison batteries in electric automobiles in cold weather it is recommended that the batteries be given a warming charge shortly before the car is taken from the garage. See also next paragraph.

**Rate of Cooling of Electrolyte.**—The rate of cooling of the electrolyte depends upon the initial temperature of the battery, the circulation of air in

contact with the battery, the temperature of this air, and the rate at which current flows from the battery. Another series of tests reported by Holland (*Central Station, Nov., 1911*) showed that in an open box a battery which had been charged in a room temperature of approximately 65° F. could stand idle in still air at 8° F. for a period of about 4 hours before the electrolyte dropped to 55° F. When placed in a closed box it took about 13 hours for the battery to cool from an initial temperature of 90° F. (which a battery would have at the end of a normal charge) to the critical temperature for high discharge rates. These tests pointed out the efficacy of a closed battery box for keeping cells warm. (*See also Automobiles, Electric.*)

**Internal Resistance.**—The effective internal resistance of a cell determines the immediate change in voltage at the cell terminals with a sudden change in the discharge rate. For method of measuring see section on *Testing*, below. The value in ohms of the mean effective internal resistance for an A-type cell discharging at normal rate is approximately equal to 0.012 ohm divided by the number of positive plates as given by the designation of the cell size, and for a B-type cell is approximately equal to 0.014 ohm divided by the number of positive plates. For two or more cells in series the total effective internal resistance is the product of this value by the number of cells in series. The internal resistance of Edison cells is such as to cause an immediate drop in terminal voltage of between 7 and 8 per cent with a sudden increase in current equal to the normal rate. The virtual internal resistance increases slightly during the progress of a discharge.

**Retention of Charge.**—The rate of loss of charge of a battery during idleness varies with the temperature at which it stands. The loss is slight in the cold and becomes greater as the temperature increases. The variation for cells charged under normal conditions and discharged after resting for various periods in one case at normal temperature of 75° F., and in another case at 35° F. is shown in Fig. 5. Accordingly a cell which has not been used for 10 days following a normal charge may be expected to retain at least 85 per cent of its initial capacity. It will be noted that the rate of loss of capacity after the second day is practically the same at both temperatures.

Fig. 5. Retention of Charge when Standing Idle

**TESTING.**—There are described below only those tests which are of interest in the commercial operation of the batteries. The methods of conducting several of the tests are the same as for the lead type of battery and are described more fully in the article on *Batteries, Storage, Lead Type*.

**Tests of Electrolyte.**—The normal specific gravity of the electrolyte at 80° F. is 1.200 as measured by hydrometer but may range from 1.160 to 1.230. Specific gravity is not necessarily a true indication of the suitability of the electrolyte, since harmful impurities may get into the electrolyte when watering or in other ways. The manufacturers recommend that the electrolyte be removed when the specific gravity has fallen to 1.160; this will usually be required after from 8 to 10 months of daily service. It is advisable to discharge the battery before renewing the electrolyte, and to give it a 12-hour charge, at the normal rate after renewing.

**Test for Internal Resistance.** — The internal resistance of a battery may be determined by momentarily opening the switch during discharge and noting rise in voltage. This rise represents the  $IR$  drop in the battery due to its internal resistance and cell connections. Hence the value of the internal resistance at the given point of discharge will be the quotient of the volts rise divided by the current rate. This value divided by the number of cells in series give the internal resistance per cell. Since on interrupting the current the voltage may rise for some time, due to change in the e.m.f., a better voltage reading may be obtained by momentarily reducing the current flow instead of opening the circuit. In this case the resistance is found by dividing the difference in voltage at the two rates by the change in current.

**Capacity; Efficiency.** — In testing for the capacity of an Edison battery at a given rate, the discharged battery should first be charged for 7 hours at a normal (5-hour) discharge rate. The battery is then discharged at the desired constant-current rate until the terminal voltage has reached the value determined by the rule given in the paragraph above on *Variation of Capacity with Rate of Discharge*. The capacity in ampere-hours is the product of time of discharge in hours by the rate of discharge in amperes. The watt-hour efficiency of the battery is the ratio of the energy given out on the discharge to the energy put in on the charge. The term "volt efficiency" is used to express the relation of the average voltage of discharge to the average voltage of charge. For charge and discharge at the normal rate the value of the volt efficiency will be close to 72 per cent for any length of charge not extremely short or long. Thus 72 per cent is the limit of possible efficiency at the normal rate. The watt-hour efficiency on any normal rate test may be calculated accurately enough for all practical purposes by taking 72 per cent of the ampere-hour efficiency, i.e., by taking 72 per cent of the ratio of ampere-hours output to ampere-hours input.

**Test Electrodes.** — The best substance for a third electrode in analyzing voltage curves of alkaline batteries is a partially reduced oxide which will undergo reduction in the electrolyte without polarization, and which is insoluble in the electrolyte. Either cupric oxide or the high nickel oxide of a charged Edison positive fills these conditions for alkaline cells. For a discharge at normal rate the readings of the cell electrodes to a test electrode of cupric oxide are: iron, approximately 0.44 volt, nickel, 0.9 to 0.5 volt; for a test electrode of nickel oxide the readings are: iron, approximately 1.28 volts, nickel — 0.1 to - 0.4 volt.

**INSTALLATION.** — The A- and B-types of cells are usually assembled by the manufacturer in wooden trays holding from 2 to 12 cells each, according to requirements. There is an air space between cells for ventilation and insulation. The standard form of tray is made "bottomless" in order to prevent short-circuits between cells from the collection of dirt and moisture. If A-type cells are to be used where they will be pulled horizontally for filling, etc., trays with bottoms are used on account of the greater strength. Data on typical assemblies in bottomless trays are given in the following table:

Size of cell	B-2	A-4	A-6	A-12
Width of standard tray, in.	6 $\frac{1}{2}$	6 $\frac{1}{2}$	6 $\frac{1}{2}$	9
Over-all height (filler cap closed), in.	9 $\frac{3}{4}$	14 $\frac{3}{16}$	14 $\frac{3}{8}$	15 $\frac{1}{2}$
Length of trays, in.:				
2-cell tray	5	7 $\frac{3}{4}$	10	13 $\frac{1}{2}$
5-cell tray	10 $\frac{3}{4}$	17 $\frac{1}{2}$	22 $\frac{3}{4}$	32 $\frac{1}{2}$
8-cell tray	16 $\frac{3}{8}$	27 $\frac{1}{4}$	36 $\frac{1}{8}$	....
12-cell tray	24 $\frac{3}{8}$	40 $\frac{3}{8}$	....	....

For the extra high container which is sometimes furnished (designated by B) the over-all height for B-type is 2 in. greater and for A-type 3 in. greater than the figures given in the above table.

The over-all height with filler cap open is about 1½ in. greater than the height with filler cap closed.

If a battery is to be used for stationary service a clearance of 6 in. above cells should be allowed so as to permit the proper filling of the cells in place. In vehicles from which the battery is removed for filling the clearance need be only ¼ in.

**OPERATION.**—An Edison battery should never be operated in any manner except in accordance with the instructions received from the Edison Storage Battery Co. Disobeying these instructions may result in forfeiture of the guarantee with regard to the life of the cell. As the detailed instructions differ somewhat for various services, only general directions which apply to all services are noted below.

**Charging.**—The batteries are now usually shipped in a charged condition. The initial charge should continue for 12 hours at the normal rate. A similar overcharge should be given after 30 days of service, one after 60 days of service, and another after each renewal of electrolyte. The normal charging rates are given above in the section on *Raising and Performance*; the time of a normal charge is 7 hours. The boosting rate may be as high as desired provided the temperature does not exceed 115° F. in any of the cells. The best results are obtained when the temperature is kept between 75 and 95° F. Under average operating conditions the charge in ampere-hours necessary to replace a discharge is from 15 to 25 per cent greater than the discharge. The Edison Storage Battery Co. recommends that if an ampere-hour meter is used, it should be set to operate 20 per cent slow on charge.

**Precautions as to Gases.**—The battery should be well ventilated while charging, and no open flame or arcing contact should be allowed near the cells while charging or immediately afterward, as the evolved gases may be exploded.

**Standing Idle.**—An Edison battery may be allowed to stand idle in any state of discharge provided the level of the electrolyte is kept above the plates. After long idleness an overcharge may be required to bring the battery up to rated capacity.

**Watering Cells.**—The level of the electrolyte must be kept above the plates by adding distilled water from time to time. The frequency of adding water will depend upon the amount and rate of charging. The manufacturers of the battery supply an indicating filler which is of assistance in preventing slopping and over-filling.

**Cleaning.**—The trays and containers must be kept dry, and dirt or other foreign material must not be allowed to collect between or under cells. Dirt and dampness may cause leakage which may result in corrosion of the containers. The outside of the cans may be cleaned with a steam or air blast. If a container becomes leaky it should be returned to the manufacturer for repair.

**DIMENSIONS, WEIGHT AND COST.**—The Edison battery is made in two standard types, the plates of the A-type being approximately 4¾ by 9¾ in. and those of the B-type 4¾ by 4¾ in. Plates of other dimensions can be obtained for special purposes. The sizes of cells are commonly designated by the type letter and a number which indicates the number of positive plates, as for instance, an A-6 cell has 6 positive and 7 negative plates. The several sizes of cells together with data on the dimensions and weight of each are given in the following table:

DIMENSIONS AND WEIGHTS OF EDISON CELLS

Size of cell	Over-all dimensions of cell, in inches			Weight in pounds	
	Length	Width	Height	Complete cell	Average per cell with trays and connectors
B-3	1.5	5.1	8.8	4.6	5.5
B-4	2.6	5.1	8.8	7.4	8.7
B-6	3.8	5.1	8.8	11.0	12.0
A-4	2.7	5.1	13.4	13.3	14.5
A-5	3.2	5.1	13.4	16.8	18.5
A-6	3.8	5.1	13.4	19.0	21.0
A-8	5.0	5.3	14.0	27.0	30.0
A-10	6.2	5.5	14.0	34.0	37.5
A-12	7.4	5.5	14.6	41.0	45.0

For services, such as the lighting of railroad cars, which require that the plates work for long periods without the addition of water, the A-type plates are assembled in containers (designated by H) about 3 in. higher in each case than those indicated in the table, in order to obtain additional space above the plates for the electrolyte. The weight per cell is then about 15 per cent heavier than the above.

Before the war the cost of Edison cells assembled in trays was approximately 29¢ per pound, including weight of trays and connectors. This is equivalent to a cost of approximately \$410 per kilowatt at the normal (5-hour) rate of discharge or \$105 per kilowatt at the one-hour rate of discharge. The manufacturers guarantee that these cells will show at least their rated capacity after being used a specified time, the usual guarantee period for A-type cells being at least 4 years and for B-type cells, at least 5 years.

**BATTERIES, STORAGE, APPLICATIONS OF.** — (See also *Batteries, Storage, Alkaline Type; Batteries, Storage, Lead Type.*) The following list shows some of the more important applications of storage batteries; they are briefly treated in the following pages.

Central Stations	}	Emergency reserve — "Stand-by service." Load or voltage regulation. Taking peaks. Day load on small systems. Exciter reserve. Remote-control switch operation.
Isolated Plants	}	Mine hoists, steel mills and other heavy motor regulation; see Index. Carrying entire load during certain hours of light load. Load and voltage regulation in office buildings or hotels where electric elevators are in service. Giving 24-hour service in residences. Operation of drawbridges.

Other uses are:

Regulation of long feeders; see *Trolley Systems, in head.*

Propulsion of pleasure cars, trucks, street cars, and marine boats, launches, industrial trucks and tractors, mine, and industrial locomotives, etc.

Gas-engine ignition.

Railway passenger-car lighting; see *Lighting of trains Electricity.*

Railway signaling, see *Signaling, Railway.*

Telephone and telegraph (q.v.).

Portable and small stationary lamps.

Fire and burglar alarm (q.v.).

Electroplating.

Dental and other surgical work.

Automobile starting, lighting and ignition; see *Ignition Electric; Starting and Lighting Systems for Automobiles.*

**Extent of Application in the United States.** — The first application in America of storage batteries to central-station service was in 1886. In 1919 there were in service in the United States, for central-station "stand-by" work 193 storage batteries of the lead-lead acid type, having a combined capacity approximately 177,000 kw-hr. at the one-hour rate of discharge. Most of these are of the Faure or Pasted type, some are of the Planté type, or a combination of Planté and Faure types.

There were in service in the United States in 1920 approximately 7000 cells of the lead-lead acid type, operating telephones, lighting railway cars and operating signals.

At the end of 1920 there were in operation lead batteries for other uses approximately as follows:

For automobile, starting lighting and ignition 15,000,000 cells aggregating approximately 3,000,000 kw-hr.

For farm lighting plants 3,000,000 cells aggregating 1,000,000 kw-hr.

For electric passenger cars, street trucks, mine and industrial locomotives, industrial trucks and tractors, 1,166,000 cells aggregating 444,000 kw-hr.

**TAND-BY BATTERIES IN CENTRAL LIGHTING STATIONS.** — Merely the storage battery in a central lighting station served a dual purpose: as a source of current in an emergency, and second, to take short peaks and thus cutting down the generating capacity in service and increasing economy of plant operation. In certain cases the batteries are used in this manner to-day, but owing to the desire always to have the full battery reserve in case of emergency, the peak battery feature is being abandoned and the stand-by feature only is being retained.

This method is considered by some authorities to be even more conducive to economy of station operation than that in which the battery was also used on peak, inasmuch as the presence of a fully charged battery behind the generating apparatus permits station operation at a much higher load factor than were the battery fully or partly discharged. Furthermore, as one of the important factors in the life of the battery is the amount of work it does, this life is greatly increased if the battery be used only for emergency service.

**Connections for Battery and Its Auxiliaries, Stand-by Service.** —

Fig. 1 shows a general standard scheme for the operation of a battery on a three-wire lighting system, either for peak work or stand-by emergency work. As will be noted in this scheme, the neutral of the battery is connected to the neutral of the system.

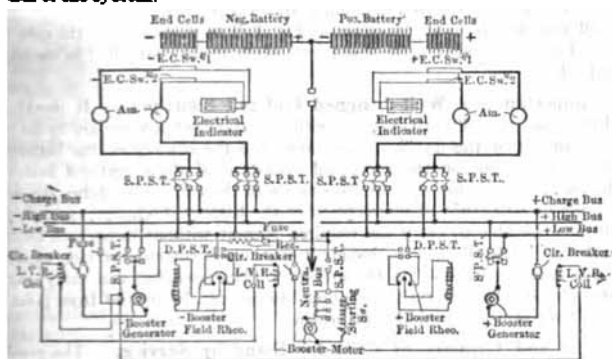

Fig. 1. Connections for Stand-by Service.

**Charging.** — For stand-by emergency work it is standard practice to take the battery off the bus for charge and in most cases the battery is floated on one bus. In this service the battery is kept fully charged and floating on the bus-bars continuously, except during charge. Except in case of an emergency discharge having been required from the battery, it will only be necessary to give the battery an occasional overcharge about once a week or once in two weeks in order to keep the active material in proper condition. Since this overcharge is given at the normal rate for only a few hours, once every week or every two weeks, a time for this overcharge can be selected when it will be safe to take the battery off the bus. It will also be noted that on charge, sufficient voltage is obtained for charging the complete battery by adding to the bus voltage the voltage of a simple shunt motor driving two booster generators. It is necessary with the 3-wire system to use two generators, one on each side of the system, in order to be able to charge the two halves of the battery at different rates in case the battery has become unbalanced on discharge. The diagram shows a simple shunt motor driving two booster generators.

**End-Cells and Switches for Stand-by Service.** — The connections between the two sides of the battery and the outside bus-bars of the system are made through "end-cell switches," by means of which the number of cells on the system can be varied at will within certain limits. This scheme shows two end-cell switches in parallel on each side of the system, this number of switches being installed in this case in order to provide sufficient capacity for the discharge.

The number of end-cell switches necessary on each side of the system depends upon the current to be carried, upon the number of bus-bar voltages to be maintained from the battery simultaneously, and upon whether or not it is desired to keep the battery on the bus during charge. It is frequently required to connect the battery on more than one bus. In such cases there must be one end-cell switch on each side of the system for each bus. If it is not desired to keep the battery on the bus during charge, and if the battery is to float on only one bus, one end-cell switch on each side of the system will be sufficient, provided one end-cell switch has sufficient current-carrying capacity.

If, however, it is deemed advisable to keep the battery on the bus at all times, it will usually be necessary to have at least two end-cell switches on each side of the system and the number of end cells required will be greater than the number of end cells required where the battery can be taken off the bus during charge. This point is referred to again in the next section.

It will be noted from the diagram in Fig. 1 that on discharge the cells are connected in series and that the voltage on discharge is controlled by means of the end cells.

**Importance of Well-designed End-cell Switches.** — It should be noted that the end-cell switches used with this standard scheme are by far the most important of the auxiliary apparatus and the efficacy of the battery is absolutely dependent on the successful operation of these end-cell switches. The factors necessary for successful operation of the end-cell switches are, first, there must be no chance of interruption of the battery discharge; second, the switch must be able to carry the required current without dangerous heating or sparking. End-cell switches having a continuous current-carrying capacity of 10,000 amperes are now on the market. These switches can carry 40,000 amperes for six minutes and the contact brushes can be moved from position to position without injurious sparking or heating.

**Number and Capacity of Cells for Stand-by Service.** — The number of cells and the capacity of the cells depends upon the lowest bus voltage maintained under normal operating conditions, the minimum allowable voltage at the end of discharge in case of emergency, and the load required to be carried during emergency.

If the battery can be taken off the bus for charge, the number of cells in the main battery will be equal to the lowest bus voltage (between outside bus-bars) divided by 2.1. The number of cells in the entire battery will be equal to the lowest allowable voltage in emergency divided by the final voltage of a cell at the rate of discharge required by the emergency. The difference between the number of cells in the main battery and the total number of cells will, of course, be the number of end cells. When the total number of cells in the battery is determined it will become necessary to put half the number of end cells, including half the end cells, on each side of the system.

If it is deemed necessary to keep the battery on the bus at all times during charge and discharge, the total number of cells will be determined as indicated above, but the number of cells in the main battery will be equal to the lowest bus voltage divided by 2.7, since this is the average cell voltage at the end of charge. In this case, at least two end-cell switches on each side of the system will

ired. On charge one end-cell switch on each side of the system is connected to the main bus and is set at such a position that the total voltage of the cells in circuit during charge equals the bus voltage. The other end-cell switch is so set as to include the cells being charged. That is, at the start of charge, the circuit from the charging booster to one end-cell switch will include all of the cells, and the circuit from the lighting bus to the other end-cell switch will only include sufficient cells to give the lighting-bus voltage. As the charge proceeds, the end-cell switch in the charging circuit will be shifted to cut out end cells as the charge is completed, and the end-cell switch connecting the battery with the lighting bus will be shifted to cut out cells as the voltage of the battery comes up so that the voltage of the cells in circuit on the lighting bus can be held at the lighting-bus voltage.

It is seen that with this operation the end-cells included between the two end-cell switches will have to carry the charging current plus or minus any current transferred between the battery and the lighting bus. It is thus apparent that with this method of operation, unless especial care is taken to float the battery at the true lighting-bus voltage, the end cells will be worked unequally. It is seen that, if it is desired to keep the battery on the bus at all times, the amount of end-cell copper is considerably increased and the cost of the battery installation is proportionately increased, for the number of end-cells required is greater than the number of end cells required when the battery can be taken off the bus for charge. On account of this increase in cost and the possibilities of unequal work on the end cells, it is desirable to install the simpler scheme shown in Fig. 1.

**Determination of Size of Stand-by Battery.**—As an example of the method used in determining the number and capacity of cells required for this class of work, suppose it were desired to install a battery to take care of an emergency of 20,000 amperes for 20 minutes at a normal bus voltage of 230 volts with a minimum allowable voltage during emergency of 225 volts. The normal rate of discharge is 8 times the normal rate, as shown in Figs. 3 and 6 in the article on *Batteries, Storage, Lead Type, and it will be noted from Fig. 6 that the final voltage per cell at the end of this rate is 1.5 volts. The number of cells will be 225 divided by 1.5, or 150 cells. If it is desired to follow standard practice, taking the battery off the bus for charge, the number of cells in the main battery will be equal to the normal bus voltage, 230, divided by 2.1, or 110 cells.*

It will, therefore, be necessary, in this case, to install a battery having 150 cells, including 40 end cells, each cell having a capacity of 20,000 amperes for 20 minutes. This battery will be installed with 75 cells, including 20 end cells, on each side of the neutral. In standard stand-by practice the 20 end cells on each side of the neutral will be connected to the end-cell switches, with two cells per switchpoint for a few of the cells and with 3 or 4 cells per switchpoint for the remainder of the end cells. A certain number of two-cell connections will be required in order to take care of the variation in the bus voltage, and it may be necessary to cut in and out cells while the battery is floating. The rest of the equipment necessary should be in accordance with the diagram shown in Fig. 1.

**LARGE REGULATING BATTERIES FOR RAILWAY WORK, C.**—Often the load (particularly a railway load) on the power house is subject to frequent and violent fluctuations, causing severe strains on the generating apparatus in service and in many cases requiring the operation of a larger number of units than would be necessary to furnish a steady average load. This not only results in a lower load factor and consequent loss of economy, but it reduces the surplus capacity of the generating station by the extra

amount of apparatus required in operation. Another loss in economy is to the rapid changes in the cut-off point of reciprocating engines, due to violent fluctuations of load. Fig. 2 shows a simplified wiring diagram of a scheme generally used.

**Carbon Regulator.**—The carbon regulator shown in Fig. 2 consists of piles of carbon disks arranged in two groups on opposite sides of the tip of a lever, the lever being subjected at one end to the tension of a spring and at the other end to the pull of a coil connected in series with the main bus-bar. Variations in the force applied to opposite ends of this lever will increase the pressure on one group of carbon disks and decrease the pressure on the other, thus varying their relative resistances. These piles are connected in series across the battery terminals, and the field winding of the booster exciter is connected between the middle point of the battery and a point in the circuit between the two groups of carbon disks. Variation in the resistances of these two piles, produced by variation of the pressure of the lever, will cause current to flow in one direction or the other through the field of the exciter, thus controlling the operation of the booster and compelling the battery to charge and discharge with small variations of current in the series coil.

Fig. 2. Connections for Regulating Service.

In this manner the load on the generator can be maintained constant within a few per cent on either side of the average value for which the apparatus has been adjusted. The load on the generator is determined by the tension of the spring, which may be adjusted to balance any average current in the series coil. If the average load on the line should exceed for a considerable period of time the generator load for which the spring is adjusted, the battery will be subjected to a sustained discharge which may in time exhaust its available capacity. On the other hand, the average load on the line falls off for a considerable period of time, the battery will be subjected to a sustained charge which may produce excessive and unnecessary overcharge. To follow these variations in average load, it is necessary to adjust the spring from time to time.

**Automatic "Average" Adjustor.**—In order to eliminate the need for such frequent adjustment by hand in cases where the average load is continually changing and where the generator is capable of handling these comparatively slow changes, the automatic average adjustor has been designed. This piece of apparatus consists of a small motor connected by a reducing gear to a drum which controls the tension of the carbon regulator spring. The armature of this motor is connected across the main bus-bars through a fixed resistor which maintains a practically constant current through the armature. The field of the motor is connected across the terminals of the booster.

Whenever the booster voltage is in the direction to discharge the battery, the motor field is energized and the motor revolves in the direction to increase the tension of the spring, thus gradually increasing the load on the generator and relieving the battery of its discharge until the booster voltage comes back to zero. If, on the other hand, the booster voltage is in the direction to charge the battery, the motor of the average adjustor will operate in the opposite direction, gradually relieving the tension on the spring and reducing the average load on the generator until the booster voltage is again brought back to zero.

Whenever the booster voltage is in the direction to discharge the battery, the motor field is energized and the motor revolves in the direction to increase the tension of the spring, thus gradually increasing the load on the generator and relieving the battery of its discharge until the booster voltage comes back to zero. If, on the other hand, the booster voltage is in the direction to charge the battery, the motor of the average adjustor will operate in the opposite direction, gradually relieving the tension on the spring and reducing the average load on the generator until the booster voltage is again brought back to zero.

the battery is again restored to its floating condition. This transfer of load between the battery and generator is brought about slowly so that the battery is free to relieve the generator of all quick fluctuations of load. The battery, however, is relieved from a considerable amount of sustained peak charge and discharge.

**Load-limiting Device.** — To prevent the average adjuster from throwing the generator beyond its capacity, a load-limiting device has been used. This consists of an electrolytic valve in series with the field of the motor. Ordinarily this valve is short circuited by a switch. When the adjuster which regulates the tension of the spring has traveled to a certain point corresponding to the maximum permissible load on the generator, a projection on the shaft of this drum engages with the switch and opens it, whereupon the valve prevents current from passing through the motor field in a direction to cause a further increase in the spring tension. The valve will, however, permit the current to flow in the opposite direction so that as soon as the load has decreased sufficiently to cause the battery to charge, the motor will rotate so as to relieve the tension on the spring and at the same time permit the valve to close, thus restoring the original adjustment.

**Automatic Current Stop.** — While the capacity of a storage battery to withstand an excessive momentary overload without injury is practically unlimited, the booster must be protected by an automatic circuit breaker. When the rating of this circuit breaker is exceeded on heavy overload and the breaker opens, the entire maximum load is thrown on the generator. This usually results in opening the generator circuit breaker also and interrupting the supply of current to the line. To avoid this and permit the battery to furnish the maximum current which the booster can handle without danger of overloading the latter or opening the circuit, there has been designed an automatic current stop. This stop is arranged to automatically prevent the battery from discharging above a certain predetermined value, for which this stop has been adjusted. All load demand above this predetermined value is thrown upon the generator. The generator is thus subjected only to the excess of load above the maximum capacity of the battery booster, instead of having the entire load be suddenly thrown on it when the battery circuit breaker opens. The setting of this automatic current stop can be changed within certain limits to meet the requirements.

**Batteries for Controlling Alternating-current Loads.** — For controlling fluctuations of an alternating-current load a solenoid which is responsive to the average component of the alternating current is substituted for the series coil shown in Fig. 2. The general operation of this scheme is the same as described above, except that it is, of course, necessary to discharge the battery on to the alternating-current bus through suitable alternating-current-direct-current transforming apparatus. There are in service at present several battery installations which regulate fluctuating alternating-current loads. Most of these installations are based on the carbon regulator principle, as outlined above.

**Number of Cells and Capacity of Cells and Booster.** — The number and capacity of cells required for regulating work depends upon the bus voltage and the nature of the fluctuating load. It is also frequently desirable to have a regulating battery for emergency and peak work, and the extent of the emergency and peak requirements will also be a factor in fixing the capacity of the battery. The number of cells installed will be equal to the bus voltage divided by 2.1, since this is the floating voltage per cell. A reference to Fig. 2 shows that during the regulation of load fluctuations all of the battery discharge current flows through the armature of the booster generator. It is thus seen that it is necessary for the booster to generate sufficient voltage to make up for the drop

in battery voltage on discharge. This drop in battery voltage depends upon capacity of the battery, and the amount and duration of the discharge. Before the booster can be properly designed it will be necessary to have complete data on these points.

**Emergency Work.**— For emergency work, where the battery is carrying the entire load without the assistance of any generating apparatus, it may not be necessary to keep the booster in circuit, depending upon whether or not it is desired to maintain a constant bus voltage. If it is not desired to maintain a constant bus voltage, a saving can be effected by cutting the booster out of circuit and allowing the battery to discharge directly on to the system.

**Peak Work.**— For peak work, where the battery must work in parallel with the generators, it will either be necessary to keep the booster in circuit in order to maintain the same voltage as the generator or else to give the generators a drooping characteristic so that the battery can discharge in parallel with the generators without the aid of the booster.

**Current Capacity.**— If it is desired to float the battery on the system at all times in order to regulate load fluctuations, it will be possible to float the battery about 75 per cent fully charged. If this battery must have a definite capacity always available for peak or emergency work, it is seen that the battery must be of sufficient capacity, when 75 per cent fully charged, to deliver the current called for by the emergency or peak conditions.

**Determination of Size of Regulating Battery.**— In all cases where a battery is to be considered for any one of the above conditions or any combination of them, it is recommended that the complete data summarized below be sent to the battery manufacturer with a request for a complete report covering the battery and accessories recommended to suit the conditions. The data necessary are as follows:

- Number, type and capacity of boilers, if the plant is a steam plant.
- Schedule of boiler operation, if the plant is a steam plant.
- Number, type and rating of generators.
- Schedule of generator operation.
- Bus voltage maintained.
- If the generators are of the alternating-current type, give frequency, number of phases, and the number and rating of any static transformers used.
- If the station in question is a substation, describe the complete substation equipment along these same lines.
- Give complete 24-hour load curve showing half-hour readings of the load on the station bus bars. A graphic recording meter chart will be sufficient, if such an instrument is available.
- If possible, obtain five-second readings on the total indicating ammeter and wattmeter, over a period of one-half hour during the time of maximum fluctuations.
- If the battery is required to assist the generators on the peak, give the amount of load in kilowatts required from the battery and the length of time the load is required. It would be well to have an exact load curve showing the shape of this peak, if it is possible to obtain such a record.
- If the battery is to be used for emergency, give the amount of the load to be carried, the time over which this emergency extends. In all cases state the nature of the load required, that is, whether it is a motor load, a light load, etc.

#### BATTERIES FOR REMOTE-CONTROL SWITCH OPERATION

It is standard practice in central stations of any magnitude to install a station battery of sufficient capacity to give ample insurance against interruption

switch-control circuit. It is the usual practice to utilize this battery, not for the operation of the remote-control switches, but for the operation of signal lamps and a sufficient number of emergency lamps throughout the on. In some stations the remote-control switches are operated from the exciter bus bars, but it is better practice to operate these switches together with signal lamps and the emergency lamps from a separate source of power.

**Control Battery Connections.**— Fig. 3 shows a scheme which is more or less standard with the larger central-station companies. This figure shows a motor-generator set consisting of an induction motor driving a direct-current generator whose voltage can be varied from 110 volts up to 168 volts, the generator voltage being required to completely charge the 62 cells in series. Under normal operation the battery is connected on the 130-volt bus with the motor-generator set, the battery switches being thrown into positions 1 and 2. It should be noted that with this arrangement all 62 of the cells are floating on the bus.

Fig. 3. Connections for Control Battery

When it becomes necessary to charge the battery, the battery switches are thrown into positions 1 and 4, and the generator voltage is raised slightly to start the charge of the entire 62 cells. With this arrangement the voltage at the load bus bars will be the voltage of 55 cells. At the finish of charge the battery switches are thrown into positions 3 and 4. It will be noted that in these positions the group of 7 end cells is out of circuit, as they have received their complete charge, and the motor-generator set will be furnishing power to charge the 55 cells and to carry the load.

**Size of Battery.**— With this arrangement the voltage at the bus bars may vary from 145 volts to the minimum voltage of the battery on discharge. The number of cells for this scheme can be varied to suit the voltage conditions. The capacity of the battery is fixed by the maximum current demand, the total per-hour current demand over the period of estimated possible shutdown, and the minimum allowable voltage on the load bus bars. With these conditions known, it will be possible with the aid of trade catalogues showing the charge and discharge curves of the battery and the battery capacity at various rates to select a battery to suit the conditions.

**Control Battery on Exciter Bus.**— If the oil-switch load is furnished from the exciter bus it will be necessary to float the emergency battery on the exciter bus or to supply automatic means for throwing the battery on the exciter bus when the voltage of the exciter bus drops below a certain predetermined value. This method is used, unless the battery is of sufficient capacity to carry the entire exciter load, it will be necessary to place a reverse-current circuit breaker between the battery and the exciter load, so that when the exciter bus "goes out" the battery will be automatically cut off from the exciter bus and left on the remote-control switch bus.

**EXCITER BATTERIES.**— It is standard practice with the larger central-station companies to install a battery of sufficient capacity to carry the total minimum exciter load for from one hour to two hours continuously. The number of cells will depend upon the voltage of the exciter bus, which is usually 250 but is sometimes as high as 250 volts.

If it is desired to maintain constant the voltage on discharge, it will be necessary to utilize end cells by means of an end-cell switch. In this case the number of cells in the main battery will be equal to the bus voltage divided by 2.1, and

the total number of cells in the battery will be equal to the bus voltage divided by the voltage per cell at the end of discharge for the discharge rate used. The difference between the number of cells in the main battery and the number of end cells in the whole battery will be the number of end cells. These end cells can be connected to the points on the end-cell switch singly or in pairs depending upon the voltage regulation desired. If it is not desired to maintain a constant voltage on an exciter bus, the end cells will not be required. The total number of cells will be kept on the bus bars and as the voltage of the battery falls the field excitation of the generators can be maintained constant by changing the generator field rheostats.

The ampere capacity of the cells will be determined by the amount and duration of the load to be carried. Knowing the ampere capacity, the length of time and the minimum allowable voltage during the period, the number of cells and the type of battery can be determined by the use of the charge and discharge curve and battery rating given in trade catalogues.

**LINE BATTERIES FOR RAILWAY WORK.** — (See also *Trolley Systems*.) The functions of a storage battery floating on an electric railway at a distance from the power house are as follows:

1. To improve the line voltage and displace a certain amount of feed wire.
2. To relieve the power house of fluctuations of load.
3. To keep the cars moving when the power supply is temporarily interrupted.
4. To supply power for the operation of a few cars or lights at night when the power house is shut down.

**Location.** — Before any calculations can be made, the location of the battery must be decided. Where there are no other determining factors, the battery would ordinarily be located about three-quarters of the distance from the power house to the end of the line, or, if the line is fed from both ends, midway between the feeding points. In some cases the location of the maximum momentary load, due, for example, to a severe grade or to the passing of two cars at a side will influence the location of the battery. In other cases the location of a suitable piece of property owned by the company, or the location of a car barn where attendance would be available, may be the determining factor.

**Line Battery without Boosted Feeder.** — In this class of line-battery installation the number of cells is determined by the average line voltage at the proposed battery site on the basis of approximately 2.1 volts per cell. The average voltage at the battery site, as determined by voltage readings taken at frequent intervals, such as five or ten seconds, over a considerable length of time, should be found to be 500 volts, the number of cells suitable for this average voltage would be 238. If it is found that, owing to changes in load conditions at different hours of the day or on different days of the week, the average voltage varies considerably for prolonged periods of time, it may be necessary to provide means for changing the number of cells connected to the line. This may be accomplished by separating a group of cells at one end of the battery, and arranging suitable switches so that these cells may be connected either in series with the main battery when the average voltage is high or in parallel with an equal number of cells of the main battery when the average voltage is low. It is found preferable to connect these end cells in parallel with a portion of the main battery, and thus keep them active rather than disconnect them from the system entirely.

**Calculation of Size of Battery Required.** — See article on *Trolley System Overhead*, and *Bulletin No. 134* of The Electric Storage Battery Co.; also Ch. 44 of Lyndon's *Storage Battery Engineering*.

**BATTERIES FOR SMALL CENTRAL STATIONS AND ISOLATED PLANTS.** — The objects of a battery installation in small electric lighting and power plants may be any one or all of the following:

1. Twenty-four-hour service with but a few hours daily operation of engine.
2. Reduction in size of engine and dynamo otherwise required.
3. Improved voltage regulation.
4. A source of current during breakdown of machinery, or while repairs are being made.

**Twenty-four-hour Service.** — In this service the battery supplies the current during the hours when the engine is not running. As the capacity of a battery of normal size in many instances in this class of work, especially in residential service, is not generally exhausted in daily operation, it may usually be charged by running the engine and dynamo only two or three hours each day at the most convenient time. In summer, when the lighting hours are shorter, it may be sufficient to charge only once in two or three days.

**Reduction in Size of Generator.** — If the plant is so designed that the combined capacities of the dynamo and the battery are equal to the maximum load requirements, a smaller engine and dynamo may be installed than would be required if the dynamo alone had to carry the total maximum load. The battery will then be discharged in parallel with the dynamo, to assist it by taking a part of the total load on special occasions, as when the maximum number of lights is in use.

**Improved Regulation.** — Objectionable fluctuations of voltage and consequent flickering of lights, due, for example, to the operation of an electric elevator or other motor work, may be eliminated by floating the battery across the lighting bus.

**Emergency.** — In case of temporary derangement of the engine or dynamo, which may occur when the lighting service is most important, or in case repairs to the machinery are required, a battery will serve to tide over the break and avoid any interruption in the current supply.

**Small Regulating Battery with Counter Cells.** — Fig. 4 shows an ideal arrangement for small battery lighting plants where the capacity of the battery does not greatly exceed 300 ampere-hours at the normal rate. This figure shows 62 cells in the main battery with 8 counter cells, the whole being designed to operate on a 110-volt bus-bar. It will be noted that the battery is charged with two halves in parallel. During charge each half is placed across the bus-bars in series with a fixed resistance. At the beginning of charge the counter cells are all in circuit and assist the fixed resistances in reducing the bus voltage to the proper charging voltage. The counter cells are cut out of circuit as the battery voltage rises. On discharge, all of the cells in the main battery and the full number of counter cells are connected in series. As the voltage falls on discharge the counter cells are cut out of circuit, thus maintaining a steady voltage at the bus-bars. The number of cells and counter

Fig. 4. Connections of Small Regulating Battery

cells and counter cells are cut out of circuit as the battery voltage rises. On discharge, all of the cells in the main battery and the full number of counter cells are connected in series. As the voltage falls on discharge the counter cells are cut out of circuit, thus maintaining a steady voltage at the bus-bars. The number of cells and counter

cells shown in the figure are selected to maintain a steady voltage of 110 volts at the normal rate of discharge. The counter cells are composed of unformed battery plates or grids, and since they have very little active material they have practically no capacity. Each counter cell will, however, furnish an opposing voltage of approximately 2.3 volts; this counter voltage is practically constant over the range in current demand for an ordinary small station.

**Small Regulating Battery with Charging Booster.** — For larger-sized plants this method of operation is not economical owing to the loss in the charging rheostats and the loss in the counter cells. For a straight lighting plant where a battery of more than 400 ampere-hours capacity is required, it is usual to use the scheme shown in Fig. 5. It will be noted in this scheme that the cells in series are connected to the bus for discharge, the voltage being controlled by cutting in and out the end cells at one end of the series. On charge the required voltage to complete the charge is obtained by adding to the bus-bar voltage the voltage of a small booster generator.

**Size of Battery.** — For ordinary small plants which operate at a bus voltage of 110 the standard equipment consists of 64 cells, including 12 end cells. The capacity and type of the cells are fixed by the ampere-hour requirements and the minimum-voltage requirements on discharge. For any bus voltage other than 110 volts the complete number of cells, including the end cells, can be determined by dividing the minimum allowable bus voltage by the minimum voltage per cell at the end of discharge at the rate which will be used.

The number of cells in the main battery will be equal to the bus voltage divided by 2.1. The difference between the number of cells in the main battery and the total number of cells will give the number of end cells. An end-cell switch having one point more than the number of end-cells required will be necessary.

**Small Battery without Voltage Regulation.** — If voltage regulation on discharge is not required, the scheme shown in Fig. 6 can be used. It will be noted that this scheme is practically the same as shown in Fig. 4 except that the counter cells have been omitted and only 56 cells are used.

**Small Battery on 3-Wire System.** — In small central stations or isolated plants which utilize the 3-wire 110 to 220-volt system, the battery is arranged in two halves, one on each side of the neutral. A group of end cells on each side of the system and two booster generators direct con-

Fig. 5. Connections of Small Battery with Booster

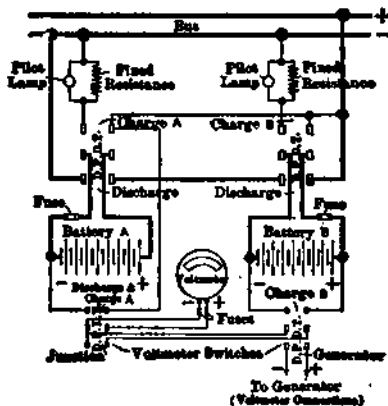

Fig. 6. Connections of Small Battery without Booster Cells

ected to one motor are used. This scheme of operation is shown in general in Fig. 1 which is described in detail above in the section on *Stand-by Batteries*.

**Small Battery for Low-voltage Lighting—So-called Farm Lighting Plants.**— Since the advent of the tungsten lamp 32-volt plants are growing very popular.

Numerous manufacturing concerns have gone extensively into this business and there are several concerns to-day marketing these plants by the thousands. One concern in America during 1920 marketed considerably more than 50,000 complete farm lighting plants.

All of these plants consist of a gas engine driving a 32-42-volt generator, a switchboard and a storage battery. The capacity of the low-voltage farm lighting plant varies from  $\frac{1}{2}$  kw. to 5 kw. Usually where the capacity required exceeds 5 kw., especially when the distance of transmission exceeds a few hundred feet, it is better to go to 110 volts, as the low-voltage plant is designed primarily for small loads and short distances of transmission.

There are various schemes of operation which are now successfully used, but they all include a storage battery. These schemes vary all the way from the one extreme, where only sufficient storage battery is installed to automatically start up the engine-generator unit when the load is switched on, to the other extreme where a storage battery of quite large capacity is used and all the load is usually taken from the storage battery, the engine generator set being run only at intervals (about once a week) to charge the battery.

Because of the multiplicity of schemes it will not be attempted here to describe any of them in detail and it is suggested that those interested obtain literature from numerous manufacturing concerns putting out these plants.

As an evidence of the growth in the use of storage batteries for this application there were in service at the end of 1920 in low-voltage farm lighting plants approximately three million storage battery cells aggregating a capacity of one million kilowatt-hours.

#### SMALL REGULATING BATTERIES FOR ELEVATORS, ETC. —

Fig. 7 shows a scheme of load regulation which has been adopted as standard for situations where it is desirable to operate a lighting load and a fluctuating motor load from the same generator. This scheme is known as the "constant-current" scheme.

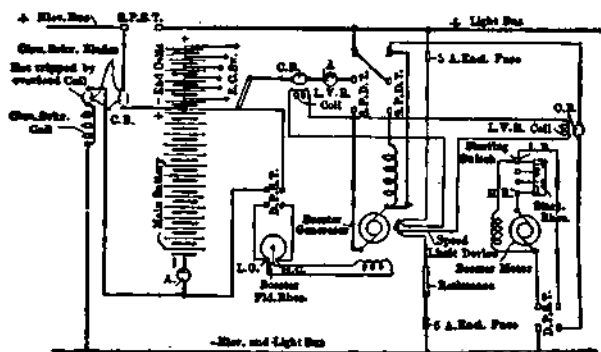

Fig. 7. Connections for "Constant-current" Regulation

**Elevator Load Regulation.** — This scheme finds its greatest use in office buildings, hotels, etc., where electric elevators are in service. The load on such a plant is a very fluctuating one on account of the heavy current required for starting the elevators. This starting current is generally about twice the elevator running current. Moreover, as the elevators are not in service continuously, the average current per elevator is usually much less than the running current per elevator. There is generally, therefore, a considerable difference between the average load on the station and the maximum momentary load. This difference varies with the number and type of elevators, the character of elevator service and the magnitude of the lighting load. If the fluctuations above and below the true average are a comparatively large percentage of the true average load, they are liable to cause fluctuations in the generator voltage with consequent flickering of lights. In addition to this objection, the generating capacity necessary without a battery must be increased and it is necessary to operate the whole plant at a poor load factor.

**Constant-current Scheme.** — Reference to Fig. 7 shows that the battery and the elevator circuit are in multiple, and that the booster is in series between the lighting bus and the elevator bus. The booster in the constant-current scheme, as the name would imply, is wound in such a manner that the current going through it is rendered constant. Therefore, the parallel system of battery and elevator circuit can only draw a constant current from the generator, and it follows that all of the fluctuations due to the elevator load must be taken by the battery. When the elevator current is greater or less than the average, the difference is given or absorbed by the battery. It is important to note that the battery voltage applied to the elevator motors is that of the battery alone and is therefore variable. Ordinarily this is not a disadvantage as the heavy load is caused by the starting of motors, in which case high voltage is not an object.

It will be noted that the scheme given in Fig. 7 shows end cells. These are used for regulating the voltage on the lights when the generator is shut down and the booster is out of circuit, the battery carrying the entire lighting and elevator load.

**Other Uses of Small Regulating Batteries.** — Electric-elevator service has been taken as an example, as this is the class of work usually encountered. This scheme may be used, however, for other fluctuating loads, such as are due to electric cranes, shop tramways, mine hoists, etc., and in general for any fluctuating load where the maximum load is greatly in excess of the average load and constant potential on the motor bus is not required.

For fluctuating loads where constant potential on the power bus is required, the scheme described above under *Large Regulating Batteries* and shown in Fig. 2 should be used.

**Number and Capacity of Cells.** — The number of cells in the main battery is usually determined by dividing the bus voltage by 2.1. The number of end cells necessary will be determined by the minimum allowable voltage and the final cell voltage at the end of discharge when the battery is carrying the entire load. The capacity of the battery will be determined by the amount of the fluctuations to be taken care of by the battery and the amount of load to be taken out of the battery when the generating apparatus is shut down.

**Booster.** — It will be noted in Fig. 7 that the diagram shows a differentially-wound booster. The desired regulation is obtained by means of the series field which carries the constant current between the lighting bus and the elevator bus, and which is designed to produce a booster voltage in the direction to oppose this current. The relation between the series field and the shunt field is adjusted for any given average load.

A straight shunt booster with the field controlled by the carbon regulator as shown in Fig. 2 can be utilized with this constant-current scheme, if the solenoid is connected between the lighting bus and the elevator bus and if the carbon regulator actuated by this solenoid is utilized to control the field of the exciter as shown in Fig. 2. In all other respects this carbon regulator constant-current scheme operates according to the same general principle as the scheme for the differentially-wound booster.

It will be noted also that with the scheme shown in Fig. 2 the booster is in series with the battery and carries only the battery current, whereas in the constant-current scheme shown in Fig. 7 the booster carries the average current of the fluctuating load. The relative magnitude of the fluctuations as compared with the average will determine which booster will be least expensive and may, therefore, be a factor in deciding between the two schemes.

**Two- and Three-wire Systems.** — The scheme shown in Fig. 7 is for a two-wire system. This same general scheme is utilized for a three-wire system where the motor load is connected across the outside wires and the lights are balanced on each side of the neutral. Where the three-wire system is used, the general principles of the scheme are exactly the same as shown in Fig. 7, except that it will be necessary to have one booster generator and one set of end cells on each side of the system.

**ELECTRIC-VEHICLE BATTERIES.** — The growth in the use of storage batteries for electric vehicle propulsion has been enormous during the past few years. This is especially true in case of street trucks, industrial trucks and tractors and mining and industrial locomotives. The voltage and capacity of the battery necessary to operate any given vehicle is usually specified by the manufacturer of the vehicle, as the design of the vehicle determines the number of watt hours per car mile under certain definite conditions. Unless the vehicle operator is a battery expert and a vehicle expert, it is not advisable that he specify either the number or capacity of cells to be used.

**Desirable Characteristics of Vehicle Batteries.** — The following are the chief characteristics of a good vehicle battery.

1. Low internal resistance, because of high current demand required for acceleration or for ascending grades.
2. Small capacity temperature coefficient, in order that the capacity of the battery shall not be unduly affected by chilling of the cells.
3. Voltage characteristic as nearly flat as possible under average conditions of discharge.
4. Construction of sufficient ruggedness to prevent breakage of parts in ordinary service.
5. Assembly such as to minimize possible labor and attention for flushing, cleaning, removing short-circuits, etc.
6. Ability to stand some abuse, as the average vehicle operator is not a battery expert.

The use of batteries for vehicle work is treated in greater detail in the article on *Automobiles, Electric*.

**DRAWBRIDGE BATTERIES.** — It is becoming standard practice to install storage batteries in connection with electrically-operated drawbridges, chiefly as an insurance against the interruption of power from the generating station. The voltage of drawbridge motors is usually 220 or 500. The number of cells and the capacity of the cells to meet the requirements will depend upon the maximum and minimum allowable voltages, and the total energy required from the battery before recharging.

**Size of Drawbridge Battery.** — Assume a 2000-ton bascule lift bridge with a 185-foot span. This bridge is to be operated with 220-volt motors. The time

required to open or close is  $1\frac{1}{2}$  minutes, or a total of 3 minutes for a complete opening and closing. Assume the following conditions: The battery will be required to open and close the bridge 40 times on one charge, the maximum allowable voltage during bridge operation will be 250 and the minimum allowable voltage 200; the average current demand over a complete cycle will be 100 amperes with a maximum momentary current demand of 320 amperes lasting a few seconds.

It is seen that the total energy in ampere hours required for the 40 complete openings and closings of the bridge would be equal to  $\frac{3 \times 100 \times 40}{60} = 200$  ampere hours during a total period of  $3 \times 40 = 120$  minutes or 2 hours. The battery, therefore, must have a capacity not less than 200 ampere hours at the 2-hour rate of discharge. Bearing in mind the voltage limits specified above, an inspection of Figs. 3 and 6 in the article on *Batteries, Storage, Lead Type*, will show that the battery capacity will be fixed by the voltage limits in this case and not by the ampere-hour requirements. In any case that may arise, if there is any doubt as to which requirement will fix the capacity of the battery, select a battery having the ampere-hour capacity required and then examine Fig. 6 to see if a battery having this ampere-hour capacity will meet the voltage requirements.

For a maximum allowable voltage of 250 and a floating voltage of 2.1 volts per cell, there would be required 120 cells. Referring to Fig. 6 and using the upper curves, for plates  $10\frac{1}{4}$  inches square, we will assume that the battery must not discharge at a higher rate than 4 times the normal rate. At 4 times the normal rate the voltage drops almost immediately to 1.9 volts per cell. With 120 cells the voltage would drop to 228 volts. It is noted that the normal rate of this battery will be 80 amperes, and the average discharge of 100 amperes will be  $1\frac{1}{4}$  times the normal rate. By interpolating a curve between the normal curve and four times the normal curve, it is seen that with an average discharge at this rate for 2 hours, the voltage per cell at the end of the two hours, with 100 amperes flowing, will be approximately 1.9 volts, or the voltage of the 120-cell battery will be 228 volts. If, now, the current were increased to 320 amperes (4 times the normal rate), and this current flow continued for an appreciable period of time, the voltage would drop further, by about 20 volts, leaving a voltage of 208 at the battery terminal. It is, therefore, evident that the voltage requirements will be met by a 120-cell battery having a capacity of 80 amperes at the normal rate.

A battery having a normal rate of 80 amperes could be discharged at  $1\frac{1}{4}$  times the normal rate for something over 4 hours. It is, therefore, seen that the battery which we selected has more than ample ampere-hour capacity to meet the requirements, its capacity being fixed by the momentary current demand.

It usually will be found that the capacity of cells required for drawbridge operation is fixed by the maximum discharge rate and not by the ampere-hour capacity at the average rate.

**Size of Charging Generator.**—If a separate power plant is installed for the operation of the drawbridge, it will be well to install an engine-generator set having an available voltage range of from 220 to 325 volts. There may be required 2.7 volts per cell for charge, which with 120 cells would call for 324 volts. If the battery installed is of sufficient capacity to carry the bridge complete day or more on one discharge, it is good practice to install a generator of only sufficient capacity to charge the battery at the normal rate and to

emergencies, the generator must have sufficient capacity to carry the maximum current required by the bridge motors.

**IGNITION BATTERIES FOR PORTABLE AND STATIONARY GAS ENGINES.** — Probably the largest single application of storage batteries to-day is for the starting, lighting and ignition of gasoline automobiles. There are now in service in this use storage batteries of the lead-acid type numbering approximately 15,000,000 cells with an aggregate capacity of approximately 3,000,000 kw-hr. Batteries of from three to twelve cells (6 to 24 volts) are used for this purpose, but the common standard to-day is a 6-volt (3-cell) battery with a capacity of from 80 ampere hours to 150 ampere hours. For this purpose the essential requirement is a battery of as low internal resistance as can be designed compatible with a reasonable life.

For further details in regard to automobile starting and lighting batteries the reader is referred to the various manufacturers of automobiles and starting and lighting equipment and also to the bulletins and catalogs of the various storage battery manufacturers. See also *Ignition, Electric and Starting and Lighting Systems for Automobiles*.

For stationary engines of large capacity it is customary to use a voltage ranging from 90 to 110 volts. Glass-jar batteries of sufficient ampere-hour capacity to meet the requirements are installed in a cabinet in the main engine room. The number of cells in the main battery necessary to float on the system will be equal to the bus voltage divided by 2.5. The capacity of the battery will depend upon the number of ampere-hours required on one charge and the minimum allowable voltage during a discharge. These requirements being known, the correct number and type of cells can be determined from the characteristics of the batteries (see *Batteries, Storage, Lead Type and Alkaline Type*), in connection with trade catalogues.

Occasionally, there is installed in addition to the cells in the main battery a group of end cells which can be cut in on discharge by means of a single switch and thus hold up the voltage of the battery. The number of cells in this end-cell group usually varies from 3 to 8, depending upon the voltage requirements.

Usually a large ignition battery is charged by placing the two halves in parallel, each half being connected to the bus through a fixed resistance somewhat after the fashion explained above and indicated in Fig. 6.

**BATTERIES FOR STEADY-VOLTAGE REQUIREMENTS.** — It is frequently required to obtain a source of direct current with a steady voltage, as for instance, in electroplating, instrument calibration, telephone work, laboratory work, etc. In such cases there should be chosen a battery that has more capacity at the normal rate than the ampere hours actually required before recharging, in order that the battery may be worked on the flat portion of the discharge curve.

For instance, to furnish 10 amperes continuously for 8 hours at about 20 volts, with a variation of 1 per cent between the beginning and the end of the discharge, the time of discharge must be limited to about 50 per cent of the total time. A cell having a capacity of 10 amperes for 16 hours should, therefore, be chosen.

**BIBLIOGRAPHY.** — See Bibliography in article on *Batteries, Storage, Lead Type*.

**TYPES OF LEAD CELLS.** — A secondary or storage cell is any voltaic couple which can be regenerated, after exhaustion, by passing a current through it in a direction opposite to the direction of current flow when the couple delivers energy to the external circuit. Three types of storage batteries are now in use in this country, the Planté type, the Faure type, and the alkaline or Edison type. The special features of the alkaline type are treated in a separate article, viz., *Batteries, Storage, Alkaline Type.*

**Planté Type.** — The principle of the storage battery was discovered in 1860 by Gautherot, a Frenchman. However, practically nothing further was done until 1860 when Gaston Planté constructed a storage cell consisting of two lead strips immersed in dilute sulphuric acid. Planté found that, by giving this cell a long charge by passing the current through in one direction, and then giving the cell a long charge in the opposite direction, and repeating this cycle many times, the capacity of the cell was considerably increased. Little improvement was made in the Planté cell until a number of years after Planté's discovery.

At present the Planté type of storage battery is made by preparing a porous lead plate with a large superficial area exposed and then oxidizing the surface electrolytically so that it is covered with lead peroxide. A plate formed thus is a positive plate. To form a negative plate the peroxide, after electrolytic formation, is reduced to metallic sponge lead by reversal of current. In this manner a thin layer of active material which is porous and which adheres firmly to the supporting lead plate is produced.

**Use of Planté Type.** — The Planté type is used chiefly where weight and space are of no great importance.

**Faure or Pasted Plate.** — In 1880 Camille A. Faure, in France, and Charles F. Brush, in America, simultaneously developed the "pasted" type of storage battery. In this type of storage battery the active material, on both the positive and negative plates, instead of being formed electrolytically, as was done by Planté, was applied, in the form of a paste, to a stiff lead-antimony alloy supporting grid. This type of plate is now commonly called the Faure type of plate, and it was the discovery of this type that gave the storage battery its first commercial impetus.

**Use of the Faure or Pasted Plate Type.** — The Faure type is used chiefly where it is desired to obtain the greatest possible capacity with a minimum of weight and space occupied. This type is used chiefly for vehicle propulsion and for central-station "stand-by service."

**THEORY.** — The electrochemical theories of the storage battery are quite complicated and the various authorities on these subjects do not agree on all details. In this outline no attempt will be made to cover the various theories in detail; only the simplest fundamental chemical actions will be described.

**Positive and Negative Plates.** — The terms positive and negative are employed throughout this article in accordance with engineering usage; that is, positive plate is the one from which the current flows on discharge and negative plate is the one into which current flows on discharge. In a lead battery the positive plate, on which the lead peroxide is formed, has a comparatively hard surface of a reddish-brown or chocolate color, while the negative plate, which carries the sponge lead, has a much softer surface of a grayish color.

**Chemical Reactions.** — The active elements of the lead-acid type battery consist of lead peroxide ( $PbO_2$ ) on the positive plate, sponge lead ( $Pb$ ) on the negative plate and dilute sulphuric acid ( $H_2SO_4$ ) for the electrolyte.

Whatever the secondary reactions may be, it is agreed that the final result on discharge is the formation of lead sulphate ( $PbSO_4$ ) on both the positive and negative plates, the  $SO_4$  radical of the sulphuric acid combining with the lead on both plates to form this compound, resulting in the formation of some water ( $H_2O$ ), with a consequent decrease in the specific gravity of the electrolyte. On charge the electric current splits up the lead sulphate ( $PbSO_4$ ), returning the  $SO_4$  radical to the electrolyte, oxidizes the positive plate to its original condition lead peroxide ( $PbO_2$ ) and reduces the negative plate to its original condition sponge lead ( $Pb$ ). This action may be represented as follows:

This equation read from left to right is the equation of discharge; if read from right to left, it is the equation of charge. In practice, on charge, towards the end of charge some of the water ( $H_2O$ ) is split up by the current into its component parts, hydrogen ( $H$ ) and oxygen ( $O$ ), the hydrogen being liberated at the negative plate and the oxygen at the positive plate. This occurs whenever the density of charging current is greater than can be utilized in decomposing the lead sulphate remaining in the plates.

**DESIGN.** — The capacity of a storage-battery plate depends not only upon the amount of active material but also upon the active surface exposed to the electrolyte. Plates should therefore be designed to expose a maximum amount of surface consistent with the strength of the supporting grid or lead base. In order that the active material of the plates can be acted upon by the electrolyte, it should be as porous as is consistent with its proper support by, and proper contact with, the grid or supporting lead base.

Sponge lead and lead peroxide possess little mechanical strength. Lead dioxide is a poor conductor. Since mechanical conditions require a certain amount of rigidity in the plates and since the current generated by the active materials must be carried away, a battery plate must necessarily consist of two parts, viz., the grid or supporting base and the active material which in the lead battery is finely-divided porous sponge lead or porous lead peroxide.

**Lead Plates.** — There are certain ideal requirements to be met by a lead storage-battery plate, among which may be mentioned:

1. The grid and active material should be so proportioned as to obtain, as far as possible, uniform current distribution over the entire surface.
2. The active material should be applied to, or formed on, the grid in such a manner that good electrical contact exists when the plate is new and this contact should be maintained during the life of the plate.
3. In pasted plates and pellet plates the grid should be of material that is not seriously affected by the electrolyte.

4. The material of the grid should be such as to insure a minimum of self-action between itself and the active material.

5. The surface of the active material exposed to the action of the electrolyte should be as great as is compatible with proper mechanical strength and suitable provision for the natural expansion of the active material in use.

6. The plates should be so made and assembled as to allow the maximum possible diffusion of the electrolyte through and around the plates and through the containing vessel.

7. The grid or lead base should be of ample cross section to carry the current generated under working conditions without undue loss.

8. The lugs which collect the current from the grids should be of ample cross section, and when designed for heavy currents they should be so arranged as to distribute the current uniformly through the grid.

9. The negative, sponge-lead plate should be constructed so that the sponge lead retains its porous character and does not grow hard and dense in service and thus lose its capacity.

10. The lead and the electrolyte should be pure; otherwise secondary reactions will be set up, with a consequent decrease in efficiency.

Of the many lead plates on the market to-day, the most commonly used are the "pasted," Planté and composite or "pellet" plates. Cuts showing the construction of the various types of plates may be found in manufacturers' catalogues; the essential features of design are briefly discussed below.

**Pasted Plates.** — The pasted plate is usually made by applying to a bar lead-antimony grid a paste made of some oxide of lead, usually litharge ( $PbO$ ) or red lead ( $Pb_2O_3$ ), and some liquid and other substances. In the so-called "Iron-clad" battery made by the Electric Storage Battery Co., the active material is held in perforated hard rubber tubes. Various substances are used to mix with the lead oxide, the idea being to increase the hardness, porosity, toughness and conductivity. Some of the substances used by different manufacturers include anthracene, glycerine, graphite, potassium silicate, asbestos ammonium-sulphate, etc.

**"Forming" of Pasted Plates.** — After the grid is filled with the paste the plate is dried. After being completely dried a number of plates are assembled in a forming bath of dilute sulphuric acid with dummy lead plates for the opposite electrode and the forming charge is given by passing the proper current through the voltaic couple thus formed. Positive plates are formed by connecting the plates to be formed as the anode; the current oxidizes the lead oxide further to lead peroxide ( $PbO_2$ ). Negative plates are formed by passing the current in the opposite direction, reducing the lead oxide to sponge lead. After the forming charge the plates are dried and are ready for the market.

**Planté Plates.** — Of the various types of Planté plates, among the most commonly in use may be mentioned the central-web type; the cast-les having no central web; and the composite or "pellet" type. The main idea in any of these methods of manufacture is to produce a large surface on which to form the active material.

**Central-web Type.** — In the central-web type there is a solid sheet or "web" of pure lead on which the ribs are formed. This web prevents the circulation of the electrolyte through the plate. The ribs are formed from the original lead plate, either by rolling, spinning or cutting. In the rolling and spinning processes the plate is formed from a lead blank by means of a number of steel disks placed side by side and separated by small spacers on a shaft. The lead blank is passed between two sets of disks by forward and backward movements. The disks gradually work deeper into the plate and squeeze it

lead into the spaces between the adjacent steel disks. In the cut type of plate the ribs are formed from the lead sheet by a tool, which at each stroke turns up one complete rib. The cutting edge works at an angle so that the finished ribs stand out from the surface. The ribs may incline upward from the central web and thus form pockets to hold the active material and prevent its falling away.

The disadvantage of the web type is the web itself. There is invariably a tendency towards unequal work on the two sides of the positive plate, this tendency being caused by difference in the plate spacing, unequal capacity of the negative plate on either side, inequality in the shape of the ribs, etc. Where the active material and the active surface of a plate are disposed in planes perpendicular to the face of the plate and extend through the plate, excessive action on one side simply works the plate a little further through from that side, the effect on the active material, however, being uniform throughout. With a plate provided with a central web, preventing such action, any inequality of work will charge or discharge one side more than the other, producing a tendency to buckle.

**Cast-lead Type.** — The type of plate which has no central web is made by casting pure soft lead in a mold, casting having the advantage of allowing for distributing metal in the plate without limitations in manufacturing process. The plate as it comes from the mold consists of a great number of short vertical ribs running entirely through the plate and bound together by transverse ribs to give strength to the plate. In this manner a large surface can be obtained and in a plate having no central web the electrolyte can circulate through the plate, and the active material will be uniformly worked throughout even though the amount of work on the two sides of the plate be unequal. The best-known form of this plate is the "Tudor" positive.

**Composite or "Pellet" Type.** — The composite or pellet-type plate is made by rolling up into pellets pure soft-lead corrugated ribbons. These pellets or buttons are then forced by pressure into circular openings in a grid composed of a hard-lead-antimony alloy. The openings in the grid are beveled towards the center so that when the pellets are formed the swelling action causes them to fit tightly into place. The corrugations on the lead ribbon allow the electrolyte to circulate through the plate and thus expose the full surface of the closed lead spiral to the action of the electrolyte. It will be noted that in this type of plate additional mechanical strength is obtained from the supporting grid. The best-known form of this plate is the "Manchester" positive.

**"Forming" of Planté Plates.** — In all Planté positives, after the ribs or corrugations have been formed on the lead blank or the pellets have been placed in the hard grid, the plates are assembled in a sulphuric-acid bath containing some corrosive chemical, called a "forming agent," together with dummy lead plates. The forming agents used by various manufacturers are usually kept as trade secrets; the nature and method of using such agents determines largely the quality of the battery. To form the positive plates the dummies are connected as the cathodes, and a current is passed through the couple thus formed. The electrolytic action of this current causes lead peroxide ( $PbO_2$ ) to be formed from the lead of the ribs. The strength and duration of the current produce the desired thickness of lead peroxide on the ribs or pellets.

Negative Planté plates are made from positive plates by electrolytically reducing the lead peroxide to sponge lead. In most types of Planté negatives, however, it is necessary to form them with an initial capacity considerably in excess of the capacity of the positive plate. This is due to the fact that in actual service the sponge lead shrinks and loses its spongy nature, thereby reducing its capacity, since insufficient surface is exposed to the action of the electrolyte.

**"Permanizing" Process.** — One of the large manufacturers of storage batteries has recently developed a process for making the Planté negative plate permanent. This method consists of injecting into the sponge lead a material which prevents the shrinking of the sponge lead and thus enables it to maintain its spongy character and its initial capacity. This permanizing process can be applied to the pasted negative plate as well as to the Planté negative plate. The most widely used form of the permanized negative plate is one in which the sponge lead, formed by reducing lead oxide electrolytically, is retained in boxes made by casting a soft-lead perforated sheet on a hard lead-antimony grid. This negative is known as the "Box negative."

**Applications of the Various Types of Plates.** — In stationary work requiring frequent discharges, where expert attention is available at all times and where the conditions of operation are properly suited to its use, the lead Planté type of plate with through-and-through circulation is the plate that should be used. Where the battery is to receive little attention and where the conditions of service are variable and uncertain, the composite or "pelt" type of plate is the safest plate to use, on account of its rugged structure and its ability to stand great abuse. As stated above, for stand-by service and for vehicle service and other service where high capacity with a minimum weight and space is desired, the pasted type of plate is more desirable.

**Electrolyte.** — The electrolyte used with the lead type of battery is always a dilute solution of sulphuric acid. The specific gravity of the electrolyte when the battery is fully charged, varies from about 1.210 for stationary batteries to 1.300 for automobile ignition batteries. These values have been adopted as standard by all the leading manufacturers.

The proper specific gravity to use varies with the conditions. Fig. 1, showing the variation with specific gravity of the resistance of one cubic centimeter of electrolyte, shows that the resistance of dilute sulphuric acid is least at a specific gravity of from 1.224 to 1.240, this resistance increasing if the specific gravity be either increased or decreased. There are numerous other conditions which influence the selection of the proper specific gravity.

The curves in Fig. 2 show the specific gravity of various mixtures, both by weight and by volume, of one part of 1.840 specific gravity acid with from 1 to 7 parts of water. There is also a curve showing the percentage, by weight, of 1.840 specific gravity acid in mixtures of various specific gravities. These curves are approximately correct at 60° F. Unless a compensating hydrometer is used in determining the specific gravity, allowance must be made for temperature variation, on the basis of an increase of one point (i.e., one one-thirtieth) in gravity for each 3 degrees Fahrenheit decrease in temperature, and vice versa; for instance, electrolyte that has a specific gravity of 1.210 at 70° F. will have a specific gravity of 1.213 at 61° F., and 1.207 at 79° F.

**Impurities in Electrolyte.** — The electrolyte should be free from organic substances, iron, chlorine, copper, arsenic, mercury, nitrates, acetates and the slightest possible trace of platinum. The various battery manufacturers issue exact specifications to the acid manufacturers, specifying the maximum amount of these injurious ingredients which the acid may contain. Electrolyte that is not approved by the company furnishing the battery should never be used.

Fig. 1.

**Preparation of Electrolyte.** — In preparing the electrolyte, sulphuric acid, approved by the battery manufacturers, should be diluted with sufficient pure distilled water to bring the mixture to the required specific gravity. The acid should be poured into the water; *never pour the water into the acid*. If the water is poured into the acid, the heat formed by the mixture is sufficient to cause sputtering and damage may ensue.

The sulphuric-acid manufacturing companies furnish electrolyte for battery work in such large quantities that they carry a stock of various standard mixtures. It will usually be found cheaper and more convenient to purchase the electrolyte ready-mixed than to purchase the concentrated sulphuric acid and prepare the mixture on the ground. The latter course, however, is sometimes adopted where the amount of acid used is considerable and where the item of freight saving is appreciable.

**Containers for Lead Batteries.** — The containing receptacles for holding the battery plates and electrolyte are usually rubber jars, glass jars or lead-lined wooden tanks.

**Rubber Jars.** — Hard-rubber jars are used exclusively in vehicle and portable batteries. In these batteries the plates are supported on ribs at the bottom of the jars. To reduce cleaning to a minimum, these ribs should be of sufficient height to leave ample space in the bottom of the jar for the reception of the active material which falls away from the plate. If the sediment in the bottom of the jars is allowed to reach the plates and short-circuit them, serious damage will result. The jars themselves should be made of the very best hard rubber which is not affected by sulphuric acid.

**Glass Jars** are ideal containers for small batteries when they are properly installed. The glass jar has the advantage that the plates and electrolyte can always be seen. The use of the glass jars is limited to the smaller sizes on account of their liability to break, due to strains left in the glass after annealing, temporary strains set up by unequal temperatures between the inside and outside of the jars, and to strains due to weight of the plates and electrolyte. Glass-jar manufacturers have, up to the present time, been unable to produce a thoroughly reliable jar larger than 21 by 13 by 18 inches.

**Lead-lined Tanks.** — In the larger sizes of batteries lead-lined tanks are standard. Tanks are generally made from specially selected yellow pine, dovetailed together without the use of nails or other metallic fastenings. The upper edges should be slightly beveled inward so that the moisture will drain into the tank. The bottoms under the linings should be drained and venti-

Fig. 2.

lated; these bottoms are usually constructed of slats across the tanks, separated by a small spacing to provide drainage. To further facilitate drainage under the lining, the upper surface of these slats should be grooved crosswise. Before the tanks are lined they should be coated inside and outside with two coats of acid-resisting paint, and a third coat should be added outside during installation. The tanks should be lined with lead of 3 to 4 pounds per square foot, depending on their size. The lining should extend over the upper edge of the tank and a short distance down the sides. The outer edge of the lining should be provided with drip points projecting clear of the tank, so that any drip from the lining will clear the wood of the tank and the tank supports. Especial attention should be paid to the seaming of the linings. All seams should be burned with the hydrogen flame with pure lead, without the use of any flux. The lower corners of the lining should be reinforced by puddling with lead. The upper corner should be reinforced by burning on an additional thickness of sheet lead. Each tank should be so built that it is self-supporting without the use of any braces or reinforcements. If this is done, any tank in the battery can be removed and replaced without affecting the remaining tanks in any way. A poorly constructed wood tank is bound to cause trouble. Special attention should be paid to this detail in preparing specifications.

**Covers.**—While covers are not absolutely necessary for stationary batteries, it is considered good practice to cover all cells. Covers should preferably be made of glass of sufficient weight to prevent excessive breakage in handling. Covers will more than pay for themselves in reducing evaporation and keeping out dirt. They are absolutely necessary in situations, such as steel mills, where the air is liable to contain particles of foreign matter injurious to the battery.

**Support of Plates in Container.**—As stated above, in the portable and vehicle types of batteries, the plates are supported on ribs at the bottom of the jar.

In stationary types, using glass jars or lead-lined tanks, it is preferable to support the elements from the top. In glass jars, plates are supported on the top edges of the jars by means of lugs cast or burned on to the plates. In lead-lined tanks it is, of course, necessary to insulate the plates from the lead lining. The plates are, therefore, supported in the tanks by vertical sheets of glass resting on the bottoms of the tanks. The bottom of the tank lining, under the glass sheets, should be heavily reinforced. These glass sheets should be ground top and bottom and the lower corners should be cut off at an angle of about 45°, to avoid injury to the lead lining during installation by sharp corners.

**Separation and Separators.**—Since the positive and negative groups, forming the complete element in a cell, are assembled with positive and negative plates alternating, it is necessary that some means be provided to prevent contact between adjacent positive and negative plates. Such contact would mean a short-circuit and might result in injury to the element. Various forms of separators have been used for keeping the plates apart. The most common practice to-day, and the one considered the best for stationary work, is to use wooden diaphragms. Each wooden diaphragm should consist of a thin sheet of porous wood mounted in slotted dowels which will allow free passage of the electrolyte between the plates. The wood should be specially treated to insure the absence of elements which in conjunction with the electrolyte might form acids injurious to the plates.

In vehicle batteries rubber separators are generally used in addition to the wood separator. That is, a rubber separator is placed on each side of each positive plate and one wood separator between each positive plate and the adjacent negative plate. In the so-called "iron-clad" battery, made by the

Electric Storage Battery Co., the active material of the positive plate is contained in rubber tubes, and therefore additional rubber separators are not necessary. Ignition batteries use wood separators only. Portable batteries use rubber only. Car-lighting batteries use wood only or rubber only. Yacht-lighting batteries use rubber only.

**Sediment Space.**—In all types of batteries, no matter what container is used, there should be a certain amount of free space between the bottoms of plates and the bottoms of jars. This space is designed to receive the sediment or active material which falls away from the plates. The amount of sediment space required will depend upon the service, and no fixed rule can be given to cover this point. If not prohibitive from space or expense limitations it would be well to have this sediment space great enough to take all of the active material which will be shed from the plates during their useful life.

**Assembly of Parts.**—All portable, automobile, car-lighting and other batteries that will be subject to jar or vibration should be assembled in the containing vessel in such a manner that the plates cannot move. They should be packed in as tightly as is possible with due consideration to the amount of electrolyte necessary and the avoidance of injury to the plates when being put into or taken out of the jars. Hard-rubber covers should be used and these covers should be so sealed as to avoid any splashing of the electrolyte. The cases containing the jars should be constructed, as far as possible, without the use of metallic fasteners and they should be thoroughly painted with acid-resisting paint. In portable batteries that will receive rough handling, if several jars are assembled in a single crate, they should be imbedded thoroughly in an acid-proof elastic compound.

Cells assembled in crates should be connected by burning together the adjacent positive and negative terminals. Cell connections should never be soldered. The main terminals of the series in one crate should be brought out and fastened in such a manner that these terminals will not be attacked by the acid.

The methods of assembling and connecting stationary types of cells are described below in the section on *Installation*.

**METHODS OF TESTING.**—The tests described below are intended to cover only those tests that are of interest in the commercial operation of batteries.

**Test of Specific Gravity.**—The specific gravity of the electrolyte is the most accurate guide as to the state of charge of a lead-type storage battery. Specific instructions furnished by the manufacturer of the battery are given, showing the range in specific gravity over a given amount of charge and discharge and the operator should be guided by the instructions of the manufacturer. The test of the specific gravity is made by means of a hydrometer having a suitable scale for the type of cell to be tested. In stationary types of batteries the hydrometer has a scale reading of 1150 to 1250 and is left floating in one cell. In all portable types of batteries, and ordinarily in vehicle- and car-lighting batteries, it is usually necessary to draw some of the electrolyte from the cell in order to test its specific gravity with the hydrometer, which should have a scale reading of 1150 to 1300. Hydrometer syringes, with hydrometer contained in a glass barrel, can be obtained on the market for this purpose. There is also on the market a regular acid-testing set consisting of a syringe for withdrawing the acid and a test tube into which the acid is poured from the syringe, in order that the hydrometer may be floated for reading.

**Test for Impurities in Electrolyte.**—The proper testing of electrolyte for impurities requires not only some knowledge of chemistry, but also experience in such work, in order to correctly interpret results; it is therefore inadvisable

for the ordinary user to attempt it. Furthermore, it is usually entirely unnecessary that he should, since the leading battery manufacturers make analyses for their customers free of charge. The harmful impurities most likely to be present are iron, hydrochloric acid, oxides of nitrogen, sulphurous acid, arsenic, organic matter and platinum. In order to insure freedom from the latter, it is advisable to specify acid which has not been concentrated in platinum.

**Test of Internal Resistance.** — The most accurate method of determining the internal resistance of a cell is to subject it to a discharge current of a certain amount, and after the voltage has become sufficiently constant to permit accurate reading with the discharge current flowing, the current is instantly interrupted and the rise of voltage noted. This rise of voltage divided by the current will give the internal resistance. If this test is made on a battery of more than one cell in series the result shows the internal resistance of the entire battery, including the cell connections.

**Test of Capacity.** — The capacity of a storage cell depends on various conditions, such as the temperature, the rate of discharge, the strength of the electrolyte, the character of service to which it has previously been subjected, and the attention it has received. The "normal capacity" of a storage cell is usually expressed in ampere hours at the 8-hour rate at 70° F., down to a certain definite voltage per cell. For instance, when it is said that a cell has a capacity of 100 ampere hours, it is usually meant that this cell can be discharged at a rate of 12½ amperes continuously for 8 hours at 70° F., down to the limiting voltage specified by the battery manufacturer. In lead cells this limiting voltage is usually taken at 1.75 volts per cell. The "watt-hour" capacity of a battery is equal to the ampere-hour capacity multiplied by the average voltage during discharge.

The "available" ampere-hour and watt-hour capacity of a battery varies with the rate of discharge, the available capacity decreasing with increase of rate. The higher the rate of discharge the lower the limiting voltage at end of discharge. Therefore, to test the capacity at any given rate of discharge, the limiting voltage at that rate as specified by the manufacturer should be known.

Bearing in mind the above facts, to test the capacity of a storage battery at any given rate, the battery should be first charged at the normal rate, as specified by the manufacturer, until the voltage and gravity in all of the cells will rise no further and until all cells gas freely at both the positive and negative plates. The capacity of the battery, as a whole, will be limited by the capacity of the lowest cell and all cells should be as nearly as possible in a condition of full charge before the discharge is started to test the capacity of the battery. Individual cell readings should be taken of the voltage and gravity while the charging current is flowing.

When it is certain that the battery is fully charged, discharge the battery at a constant current at the desired rate, down to the limiting voltage at this rate. The ampere-hour capacity will be equal to the constant current in amperes, multiplied by the time of the discharge in hours; and the watt-hour capacity of the battery will be the ampere-hour capacity multiplied by the average voltage during discharge.

In order to be sure that the battery is in good condition it is well to take several complete discharges before making the final charge, preceding the final test discharge.

On each charge and discharge observations should be taken of the voltage, the current, the temperature and the specific gravity. The temperature of the room should be held as nearly constant as possible throughout the test. In order to facilitate the plotting of curves, the readings should be taken at intervals of time which are even factors of an hour.

**Standard Test.** — When a strip of cadmium is placed across the top of the plates in a cell, and properly insulated from them, there will be a difference in potential, as measured by a voltmeter, between the cadmium and the positive plates and between the cadmium and the negative plates; the sum or difference (depending on the relative directions of the two potential differences) between two readings being equal to the internal voltage of the cell.

This test, when properly interpreted, is a valuable guide to the capacity condition of the positive and negative plates separately. The results are, however, very apt to be misleading to one who has not had a wide experience in storage-battery work. See *Tech. Paper No. 146*, Bureau of Standards.

**Test of Efficiency.** — The ampere-hour efficiency of a battery is the ratio of the output on discharge in ampere-hours to the input on charge in ampere-hours; the watt-hour efficiency of a battery is the ratio of the output on discharge in watt-hours to the input on charge in watt-hours.

The efficiency of a battery depends upon numerous conditions, chief among which are the charge and discharge rates and the temperature.

It has been noted above that the available capacity of a battery depends upon the discharge rate. For instance, if a battery is discharged at the one-hour rate to its allowable final voltage limit, the energy taken out at this rate is approximately only fifty per cent of the energy that could be taken out at the normal rate.

However, if, at the end of one hour's discharge at the one-hour rate, the rate of discharge be reduced to the normal rate, much of the available normal capacity of the battery can be obtained.

It is thus seen that any statement of the true efficiency of a battery should include the charge and discharge rates. It is also seen that in order to make an efficiency test an average of several charges and discharges should be taken, the battery should be given several discharges and charges before the actual test is begun. Failure to observe these conditions may result in figures that are misleading. The writer has seen test figures showing an efficiency of more than one hundred per cent; he has also seen figures showing efficiencies far below actual efficiency.

To determine the efficiency of the battery, get all the cells in satisfactory condition by preliminary charge and discharge, as outlined above under the capacity test, and then take a preliminary discharge down to the final voltage specified by the manufacturer for this rate of discharge. The first test charge should then be made at the normal rate until the cells are fully charged. The test discharge should then be taken at the specified rate down to the same final voltage used in the preliminary discharge. The watt-hour efficiency of the battery will then be the ratio of the total watt-hours discharged to the total watt-hours charged. If greater accuracy is desired, this cycle should be repeated several times (say, from four to six times) and the watt-hour efficiency will then be the ratio of the total watt-hours of all the discharges to the total watt-hours of all the charges.

**RATING AND PERFORMANCE.** — The capacity of a storage-battery of a given size varies somewhat with the conditions, chief among which are the specific gravity of electrolyte, the temperature of electrolyte, the amount of electrolyte, the original formation of the plate, the design of the cell, the age of the plate, the length of time between charge and discharge and the final voltage limit specified.

**Rating of Stationary Batteries.** — The rate of discharge of a storage battery is the number of amperes that it will supply continuously for 8 hours, for 3 hours or for 1 hour. The 8-hour rate is the so-called "normal" rating, the 3-hour rate is approximately twice the normal rating and the 1-hour rate is approximately three times the normal rating. The capacity of a storage battery is usually

stated in ampere hours. Since the capacity varies with the rate of discharge it is necessary to specify the rate of discharge in stating the capacity in ampere-hours. If the rate is not specified, the normal rate is assumed.

Certain plates especially designed for high rates of discharge are rated in terms of the amperes they will supply for 6 hours, this rating being designated as "normal." The corresponding 1-hour rate is 4 times this 6-hour rate.

While the above is standard for ordinary batteries, plates for certain class of service are designed to give the normal rate for from 7 to 7½ hours.

The capacity of a storage battery is sometimes expressed in kilowatts, but this is ambiguous unless the rate of discharge is specified.

**Rating of Vehicle and Ignition Batteries.** — It is standard practice to rate a vehicle battery in terms of the amperes it will give continuously for 4½ or 5 hours, specifying the battery to have a capacity of so many ampere hours at one of these rates. In most portable types of ignition batteries the batteries are rated at so many ampere-hours at the "service rate," i.e., the rate of discharge (amperes) corresponding to the service for which they are designed.

Fig. 3.

**Variation of Rate of Discharge with Time of Discharge.** — Fig. 3 shows an average capacity curve for a Planté plate, the time for a complete discharge at any rate being shown as a fractional part of the normal time and the rate of discharge for any given time being shown as a multiple of the normal rate.

From these curves it will be noted that a cell which will give its normal rate for 8 hours will give 4 times that rate for about 1½ hours; and a cell which will give 4 times the normal rate for 1 hour will give the normal rate for only 7 hours. These are approximately correct relations for the average Planté cell. Trade catalogues usually specify the normal rate for 8 hours and 4 times the normal rate for 1 hour. This is due to the fact that a cell which regularly worked at the normal rate will tend to hold its 8-hour capacity while a cell which is regularly worked at 4 times the normal rate will tend to lose some of its 8-hour capacity and finally give only 1 hour at 4 times the normal rate.

**Variation of Capacity with Rate of Discharge.** — It will be noted from the capacity curves that the available capacity in ampere-hours decreases with increase of rate of discharge. This is largely due to the time required for fresh electrolyte to penetrate into the pores of the active material of the plate. At the higher rates of discharge the diffusion of electrolyte is not sufficient

he battery, the battery be allowed to rest or the rate of discharge be decreased, additional capacity can be obtained from the battery.

Fig. 4.

**Variation of Capacity with Temperature.** — Fig. 4 shows the variation of capacity with temperature at various rates of discharge. This change of capacity is temporary and the capacity will be restored to its original value as the temperature is restored to its original value.

**Voltage and Specific-gravity Characteristics.** — The charge and discharge characteristics of a battery vary with the conditions. Fig. 5 shows

the charging characteristics of a battery vary with the conditions. Fig. 5 shows the charging characteristics of a Planté type of cell designed for stationary service. It will be noted that the specific gravity increases gradually until all of the lead sulphate in the plates has been reduced, the  $(SO_4)$  radical having returned to the electrolyte to form sulphuric acid, which accounts for the steady increase in specific gravity and for the fact that the specific gravity will rise further after the battery is completely charged.

Fig. 5.

**Final Charging Voltage (Fig. 5).** — The scale of volts on the upper

curve has been purposely omitted, but this curve shows the general shape of charging curve for any type of lead battery. The final charging voltage of any lead type battery varies over a considerable range, according to the type of cell, age of plates, temperature of electrolyte, strength of electrolyte, etc. The final charging voltage may vary anywhere from 1.4 to 2.8 volts per cell. It will be noted that the voltage rises rapidly at the beginning and at the end of charge.

Fig. 6.

**Discharge Voltage.** — Fig. 6 shows discharge curves at the

normal, four times the normal and eight times the normal rates, respectively, for two different sizes of Planté plates. The upper set of curves are for plates 10% inches square and the lower set of curves are for plates 15% inches square.

These curves, used in conjunction with the capacity curves shown in Fig. 3, will enable anyone to determine the approximate performance of any lead battery when the capacity at any given rate is known.

The voltage readings at the very beginning of the discharge are liable to vary more or less from those shown on the curves depending upon the length of time the cell has been allowed to stand on open circuit after the completion of the charge.

**Open-circuit Voltage.** — The open-circuit voltage of a lead cell is of no value as an indication of its state of charge. A healthy cell will regain its full voltage on open circuit, even though fully discharged, if sufficient time is allowed for depolarization.

**Internal Resistance.** — The true internal resistance of a cell may be determined by the method explained above in the paragraph on *Test of Internal Resistance*. This internal resistance determines the *immediate* change of voltage at the cell terminals with any sudden change of discharge rate. In the ordinary commercial types of lead cells at 70° F. the internal resistance is such as to cause an immediate drop in terminal voltage of between 5 per cent and 7 per cent, with a sudden increase of current equal to four times the normal rate of discharge, the drop being proportional to the change in current. If this change in current is not strictly momentary, the change in terminal voltage will be greater, due to the effect of polarization. The internal resistance of a cell increases with reduction of temperature; at 0° F. the internal resistance is twice as great as at 70° F.

**DIMENSIONS AND WEIGHTS.** — In determining the dimensions and weights of a storage battery to meet the requirements, it is suggested that the proper type of battery be determined in accordance with the curves and examples given above and a battery be selected from trade catalogues to meet the specifications. When the battery has been thus chosen, the dimensions and weights of individual cells can be obtained from the trade catalogues. In order to determine the total installed dimensions and weights, it will be necessary to make a layout according to standard practice. The distances between adjacent cells and the dimensions of aisles are given below in the section on *Installation*.

**SPECIFICATIONS, CONTRACTS AND PROPOSALS.** — (*See also article on Specifications.*) In preparing specifications for a storage-battery plant and accessories, special care should be taken to avoid drawing up specifications in such a manner as needlessly to embarrass the manufacturers who are requested to bid.

**Preliminary Specifications.** — It is recommended that preliminary specifications of a very general nature be prepared. These specifications should contain complete detailed data of the conditions to be met, so that the manufacturers who are requested to bid can readily determine the number and capacity of cells, the proper scheme of operation, the correct design of booster, switchboard and other accessories recommended by them to meet the requirements in hand. That is, the preliminary specifications should state plainly just what the battery is intended to accomplish. These preliminary specifications should be sent to the manufacturer with a request for a complete proposal.

**Manufacturer's Proposal.** — This proposal should give detail specifications covering the apparatus recommended by the manufacturer. In order to obtain the best results, it is recommended that after these proposals are received, the prospective purchaser confer with the bidders that are to be considered, and that complete final specifications be prepared, covering all details of the necessary equipment. These final specifications can then be sent to the manufacturer for their final bids.

**Final Specifications.**—As a guide in preparing the final specifications the items enumerated below should be thoroughly covered:

Number of cells;	Detailed specifications for booster and exciter apparatus according to the A.I.E.E. Standardization Rules.
Number of plates in elements initially installed;	Foundation for booster and switch-board;
Material of plates;	Testing instruments;
Capacity of the elements initially installed;	Battery room;
Charging rate of the elements initially installed;	Erection;
Material of the containing vessels expressed in the number of plates which the vessel can contain;	Skilled and unskilled labor;
Connectors and supports;	First charge;
Electrolyte;	Operation;
Material of plates;	Test;
Smelting and lead burning;	Freight, cartage;
Reinforcing bars, both plain and reinforced;	Delivery;
6-cell switches;	General scheme of operation;
Copper work and cables;	Temporary work;
Control board in detail;	Cutting of walls, etc.;
	Access, storage and hoisting;
	Acceptance.

If specifications are drawn, covering all of these points clearly and if the specifications are attached to, and form part of, the contract, no trouble should arise in the future from misunderstandings.

**Contract.**—The contract should cover the price, time of payments, guarantee, protection from patent litigation and insurance of the material during construction.

**INSTALLATION AND ERECTION.**—*Never install any battery without being explicitly the detailed instructions furnished by the manufacturer who makes the battery.*

If the battery is of considerable capacity, detail drawings showing the method of installation should be obtained from the battery manufacturer. The leading manufacturers issue printed instructions and detail drawings describing the method of installation. Much time and money can be saved by obtaining these drawings from the battery manufacturers.

**Spacing of Glass Jars.**—The spacing between cells along rows varies from 1/2 inches with the smaller types of multiple plate-glass cell batteries to 3/4 inches for the largest size multiple plate-glass cell batteries. This space is the distance from jar to jar. It is standard practice to place the jars on wood or glass sand trays filled with sand; the distance between the sand trays along the rows varies from 1/2 inch to 2 1/2 inches, depending upon the size of the glass jars. As the outside dimensions of the sand trays are not usually given in trade catalogues, it would be well in figuring the length of the rows to use the spacing between glass jars as given above, for the outside dimensions of the glass jars as usually stated.

With glass-jar batteries the aisle space between the rows should never be less than 24 inches, and aisles of 36 inches are recommended. In the case of multiple rows or where a row is installed near a wall or partition, the distance between rows, or the distance between a row and the wall, should not be less than 6 inches.

All batteries should be installed in one tier, if space is available, though glass-jar batteries (and occasionally lead-lined wood-tank batteries) can be installed

in two or three tiers, if more space is not available. In installing batteries more than one tier, sufficient headroom should be allowed in each tier to permit the removal of the elements from the jars without displacing the jars. The minimum headroom for a single-tier glass-jar battery varies from  $4\frac{1}{2}$  feet to 5 feet; for two tiers from 5 feet to  $7\frac{1}{2}$  feet and for three tiers from 7 feet to 8 feet, depending upon the size of the battery. In all cases the ceiling of the battery room should be of sufficient height to allow for the passage of a man without stooping.

**Spacing of Lead-lined Tanks.** — Lead-lined tank batteries should always be installed in one tier, if space is available. More than one tier should not be installed without consulting with the battery manufacturer. With lead-lined tanks the distance between tanks along rows is from 2 to  $2\frac{1}{4}$  inches. The aisle space between rows should never be less than 30 inches and should always be sufficient to allow the tank to be pulled out into the aisle for repairs. Where space will not allow the tank to be pulled out its full length the aisle should have at least sufficient width to allow the tank to be stood on end in the aisle. In double rows or in rows next to the wall, at least 18 inches should be allowed between rows or between the tanks and the walls so that a man can get in for examination. The battery room should have sufficient headroom for a man to walk upright. With large-sized batteries where the amount of gases liberated on overcharge is considerable, sufficient headroom should be allowed for proper ventilation.

**Dimensions of Containers.** — For any given type of plate, either in glass jars or lead-lined wood tanks, there is one dimension for all jars or tanks which is practically constant, independent of the number of plates in the cell. This is the dimension parallel to the horizontal edge of the plates. This dimension is usually specified in trade catalogues as the "width." The other dimension is the dimension across the row and is usually specified in trade catalogues as the "length."

**Dimensions of Battery Room.** — Keeping in mind these definitions one can determine from trade catalogues the approximate inside dimensions of a battery room necessary to house the battery in question. Note, however, that any manufacturer will gladly furnish a sketch showing an ideal layout for a given battery and such a layout should always be obtained from the manufacturer, if there is sufficient time. If there is available space in a building already built, the battery manufacturer will gladly prepare a sketch showing the layout of any given battery in the available space.

**Insulation of Cells.** — Cells in stationary batteries, whether in glass jars or in wood tanks, must be insulated from the ground and from each other.

Glass jars are usually mounted in glass or wooden sand trays which rest on glass insulators. The glass insulators, in turn, rest on wooden racks or stringers, these racks or stringers being mounted on vitrified brick set on the battery room floor.

For lead-lined wood-tank cells the standard practice at present is to mount each tank on a sufficient number of oil insulators. These insulators consist of a glass insulator provided with a circular trough partly filled with oil, the oil surrounding a central section which supports the tank. Over the insulator is placed a lead-alloy cap, designed to exclude spray or other foreign matter from the oil. This cap rests on the central section of the glass insulator, the being no connection between the tank and the glass except at this section. The oil around this central section of glass is for the purpose of preventing a spill of acid from collecting thereon; if, by any chance, acid or water should get into the trough, it would sink to the bottom, the oil would float on top, and a perfect insulation would be maintained.

The glass insulator rests upon a heavy earthenware truncated cone, having a feet. Between this cone and the glass is a Y-shaped lead washer. Thus a point support is obtained between the floor and the earthenware, and between the earthenware and the glass. This form of support is not necessary between the glass and the tank, because the wood and lead cap take up any face inequalities.

**Connections between Cells.** — In glass-jar batteries of small size, elements adjacent cells are usually bolted together. In the larger-sized glass-jar batteries and in all lead-lined wood-tank batteries the positive plates in one cell are burned to the negative plates in the adjacent cell through the medium of end bus bar. The bus bars at the ends of rows, and wherever current taps are made, are reinforced by a bar of copper embedded in the lead.

**Battery-room Design.** — Though no battery should be installed without specific instructions from the manufacturer, the following points should receive special attention.

**Floor.** — The floor of the battery room should be made acidproof and should be graded to drain. A wood floor should never be used, as it is bound to become acid soaked and eventually be destroyed. For small batteries a cement floor can be used, but, unless it is kept thoroughly washed, acid will eat holes in it. A glazed tile floor is preferable.

**Ventilation.** — All battery rooms should be well ventilated. With small stores natural ventilation is usually sufficient; with large-capacity batteries, however, the gassing during overcharge is considerable, artificial ventilation should be provided. Exhaust ventilation is preferable to compression ventilation.

**Temperature.** — The temperature of the battery room should be kept near 70° F. as possible.

**Exposed Metal.** — The amount of exposed iron or metal work in the battery room should be reduced to a minimum on account of the action of acid upon it. Any iron or metal work that must be in the battery room should be protected with an acid-resisting paint.

**OPERATION.** — *Never operate any battery in any manner except in accordance with the instructions of the battery manufacturer furnishing the battery.*

With all large battery plants there should be supplied by the manufacturer proper testing instruments and detail instructions for the operation of the battery under the conditions obtaining. The blank forms furnished by the manufacturer should be filled in at regular intervals and mailed to the manufacturer for analysis and recommendations.

No general instructions for the proper operation of a battery are given in this article, since the different manufacturers differ in their opinions on certain points of operation.

Practical instructions for operating any type of battery can be obtained free of charge from the manufacturer.

**Attention from Operator.** — The successful operation of a battery plant does not require much time from the operator, but attention given the battery should be systematic and absolutely in accordance with the instructions furnished by the manufacturer. If the manufacturer's instructions are followed explicitly and systematically, it will be found that the battery can be kept in good condition with a small amount of labor and time. If the operator neglects to follow the regular instructions and does not appeal to the manufacturer until he gets into trouble, the usual result will be considerable loss in time and money.

**Addition of Water.** — Pure distilled water, or natural water that has been analyzed and approved by the battery manufacturer, should be added to the cells from time to time to replace evaporation. If there is not available a source

of pure, natural water, and if distilled water cannot be purchased cheaply, a distilling outfit will usually be found necessary with large sizes of batteries. Standard water stills, for this purpose, can be purchased on the market.

**Addition of Acid.** — *Acid should never be added to a battery except upon the recommendation of the battery manufacturer.* The manufacturer should specify the specific gravity and the proper amount of acid.

**REPAIRS.** — Very few repairs, other than battery plates, should be required. For replacing the plates in the larger sizes of batteries, a lead-burning outfit and the necessary lead-burning material will usually be required. No one but a skilled lead burner should attempt to burn in plates.

Smaller sizes of batteries, with bolted connections between adjacent cells can be purchased from the manufacturer with each element assembled.

**Leaky Tanks.** — A leaky tank should be repaired immediately. No one but an expert sheet-lead burner should be allowed to repair a leaky lead-lined tank. To repair the leaky lead-lined tank it will be necessary to cut loose from the bus bars all of the plates in the leaky tank and remove the tank into the air. If it is necessary to keep the rest of the battery in commission while it repairs are being made, the cell or cells cut out should be jumped by jumper of sufficient current-carrying capacity.

**FIRST COST.** — It is impossible to give exact figures for the total cost of installation of a complete battery plant of any size. An analysis of the first costs of a great many plants now in operation shows that the first cost per kilowatt for the entire battery installation, exclusive of building, varies from \$80.20 per kilowatt to \$250.00 per kilowatt. The kilowatt rating as used here and elsewhere in this article is an arbitrary rating determined by multiplying the one-hour discharge rate in amperes (four times the normal rate) by double the number of cells.

**ANNUAL COST.** — The total annual cost includes operation, maintenance, depreciation and interest.

**Operating Cost.** — The operating cost will consist largely of labor. All material except necessary water should be included under maintenance.

**Maintenance and Depreciation.** — The cost of maintenance of a battery varies with the conditions. Other things being equal, the life of a battery is dependent upon the work done. The maintenance cost of a battery varies from 4 per cent to 10 per cent per annum. When the battery is used only for strictly emergency service the maintenance cost may be less than 4 per cent.

These figures cover not only maintenance, but also what is commonly included under the term depreciation. The plate being the essential component of the battery, plate renewals, which are made from time to time, involve improvements that have been made in design and construction and serve to bring the battery up to date. An increase of voltage or capacity to meet changing conditions may be effected by the addition of cells or by increasing the number of plates in each cell, without sacrifice of the original investment. In the opinion of the writer there is, therefore, little, if any, true depreciation in battery installation which is properly maintained.

**BIBLIOGRAPHY.** — Lyndon, L., *Storage Battery Engineering*; Wac E. J., *Secondary Batteries*.

**BEARINGS.** — (See also *Friction; Lubricants and Lubrication; Shafting.*) The common types of shaft bearings may be classified as follows:

**Plain Cylindrical Bearings.** — The usual form of bearing is a metal cylinder of cast iron, brass, bronze or gun-metal, mounted in a pedestal, bracket or frame, which serves as a support for the shaft. The portion of the shaft within the bearing is called the journal. Plain bearings are usually lined with some soft metal, such as babbitt metal or other white metal. In a self-aligning bearing the seating of the bearing in the pedestal is made a portion of a sphere, so that the bush may automatically align itself with the shaft. Cylindrical bearings are sometimes provided with an oil bath within the pedestal just below the bearing proper; rings or chains running loosely over the journal through slots in the bearing and dipping into this bath supply a steady stream of oil to the rubbing surfaces.

T. D. Lynch (*Amer. Soc. Test. Mat.*, June, 1913) gives the following data in regard to plain Babbitt bearings: (1) The constituent metals of the alloy (see *Alloys*) must be of superior grade. (2) A temperature of 500° C. or less has been found sufficient for satisfactory alloying. (3) A pouring temperature of 460° C. has been found to give excellent results. (4) The shell should be heated to 100–155° C. before the bearing metal is poured in. (5) Babbitted bearings must not be jarred during the solidification of the metal. (6) A Brinell hardness of 25 for lead-base and 30 for tin-base babbitts have been found to give excellent results.

**Roller Bearings.** — In this type of bearing the journal is supported on rollers which are in turn supported by smaller shafts in smaller bearings. The rollers support the journal of the main shaft.

**Step Bearing.** — A step bearing is essentially a large pivot bearing used at the end of vertical shafts carrying a heavy load. The end of the shaft is provided with a steel plate or "step," which rests on a second plate or bearing. The bearing proper may be either of the ball or roller type, or may be a plane surface with one or more grooves into which oil can be forced under pressure. The stationary plate is sometimes supported on short helical springs and is held against rotation by dowel pins (*H. G. Reist, A.S.M.E. Journ.* 40, p. 303, May, 1918).

**Thrust Bearings.** — Thrust bearings are used on horizontal shafts when the shaft is subjected to a horizontal thrust. They are similar to step bearings for vertical shafts, except that a collar fitting around the shaft is used instead of a plate at the end of the shaft. Steamship shaft bearings have numerous collars on the shaft, with thrust blocks between them. Roller or ball bearings may be used instead of collars.

**Ball Bearings.** — A ball bearing consists essentially of a track of curved cross-section which is filled with a set of balls. For a discussion of the use of ball bearings in electric machinery see H. N. Turnbull (*Elec. Rev. and West Lic.* 70, p. 1054, 1917).

**Pivot Bearings.** — Various types of pivot bearings are used. The pivot may be either a flat surface, a pointed cone, a truncated cone, a hemisphere or a surface of special form, such as Shiele's "tractrix."

**ALLOWABLE LOADS AND SPEEDS.** — If the pressure on a bearing is too great the oil film between journal and bearing surface will be destroyed and the bearing will overheat and "seize." Various formulas have been developed for the allowable pressure in terms of the speed and type of bearing.

**Safe Loads, Line Shaft and Mill Bearings.** — F. W. Taylor (*Trans. A.S.M.E.*, 1905), as the result of an investigation of line shaft and mill bearings

that were running near the limit of durability and heating, yet not dangerously heating, gives the formula

$$p = \frac{400}{v},$$

where  $p$  = pressure in pounds per square inch of projected area (i.e., product of diameter of the journal by its length) and  $v$  = peripheral velocity of journal in feet per second.

The formula is applicable to bearings in ordinary shop or mill use on shafting which is intended to run with the care and attention which such bearings usually receive, and gives the maximum or most severe duty to which it is safe to subject ordinary *cast-iron* or *oiled* ball- and socket-bearings which are *babbitted*. It is not safe for ordinary shafting to use *cast-iron* boxes, with either sight feed, wick feed or grease-cup oiling, under as severe conditions as  $p \times v = 200$ .

**Safe Loads, Miscellaneous Bearings.** — Alford in *Bearings and their Lubrication*, gives the following allowable bearing pressures in pounds per square inch of projected area.

Kind of bearing and condition of operation	Allowable bearing pressure in lb. per sq. in. of projected area	
<b>UNITED STATES NAVAL PRACTICE</b>		
Main engine bearings.....	275- 400	} For weight alone.
Main engine crank pin bearings.....	400- 500	
Steam turbine bearings.....	85	
Thrust bearings for torpedo boats.....	50	
<b>MERCHANT MARINE PRACTICE</b>		
Main engine bearings.....	400- 500	
Main engine crank pin bearings.....	400- 500	
<b>HIGH-SPEED STATIONARY ENGINE PRACTICE</b>		
Main bearings.....	60- 120	For dead load.
Main bearings.....	150- 250	For steam load.
Crank pin bearings, overhung crank.....	900-1500	
Crank pin bearings, center crank.....	400- 600	
Cross-head pin bearings.....	1000-1800	
<b>SLOW SPEED STATIONARY ENGINE PRACTICE</b>		
Main bearings.....	80- 140	For dead load.
Main bearings.....	200- 400	For steam load.
Crank pin bearings.....	800-1300	
Cross-head pin bearings.....	1000-1500	
<b>GAS ENGINE PRACTICE</b>		
Main bearings.....	500- 700	
Crank pin bearings.....	1500-1800	
Cross-head pin bearings.....	1500-2000	
<b>ELECTRICAL MACHINERY PRACTICE</b>		
Generator and motor bearings.....	30- 80	
Main engine bearings, driving generators..	40- 80	
Horizontal steam turbine bearings.....	60- 400	
Vertical steam turbine steps.....	100-1000	

Kind of bearing and condition of operation

Allowable bearing pressure in lb. per sq. in. of projected area

## MISCELLANEOUS PRACTICE

Bearings for slow speed and intermittent load as in punch presses, shears and the like.....	3000-4000
Main bearings of slow speed pumping engines.....	600
Heavy line-shaft bearings, bronze or bab-bitt lined.....	100-150
Light line-shaft bearings, cast-iron.....	15-25
Heavy slow-speed step bearings.....	2000
Drill-press thrust collars.....	325
Angular-thrust bearing for boring mill tables.....	75

**Safe Loads, Roller Bearings.**—The following table gives the safe load in pounds for Mossberg roller bearings (*Trans. A.S.M.E., 1905*).  $D$  = diameter of journal, in inches;  $d$  = diameter of roll, in inches;  $N$  = number of rolls;  $P$  = safe load on journals, in pounds. The rolls are enclosed in a bronze supporting cage.

$D$	$d$	$N$	$P$	$D$	$d$	$N$	$P$	$D$	$d$	$N$	$P$
3	$\frac{1}{2}$	20	3,500	6	$1\frac{1}{8}$	24	50,000	15	$1\frac{1}{2}$	28	255,000
$3\frac{1}{2}$	$\frac{5}{8}$	22	7,000	7	$1\frac{3}{8}$	22	70,000	18	$1\frac{3}{4}$	32	325,000
4	$\frac{3}{4}$	22	13,000	8	$\frac{7}{8}$	22	90,000	20	$1\frac{3}{4}$	34	400,000
4	$\frac{7}{8}$	24	24,000	9	1	24	115,000	24	$1\frac{3}{4}$	36	576,000
5	$\frac{7}{8}$	24	37,000	12	$1\frac{1}{4}$	26	175,000	..	...	..	.....

Surface speed of journal from 0 to 50 feet per minute. Length of journal  $1\frac{1}{2}$  diameters. The rolls are made of tool steel not too high in carbon, and of spring temper. The journal or shaft should be made not above a medium spring temper. The box should be made of high-carbon steel and tempered as hard as possible.

Marks in his "Mechanical Engineers' Handbook" gives the following formulas for load capacities of roller bearings.

"For rollers such as are used on bridge turn tables and in similar places where the speeds of rotation are slow, the safe load in pounds is  $P = cnd$ , in which  $n$  = number of rollers in the bearing,  $l$  and  $d$  the length and diameter of each roller, in.,  $c = 360$  for hard cast-iron rollers running on hard cast-iron tracks, and  $c = 850$  for hard steel rollers on hard steel tracks. Where  $l > 5d$ , smaller values of  $c$  should be used. In case conical rollers are used,  $d$  is the mean diameter.

"The Standard Roller Bearing Company determines load capacities of roller bearings by the formula  $P = 130,000s^2 nd/3s$ , in which  $P$  = load on bearing, lb.;  $d$  = diam. of roller, in.;  $n$  = number of rollers;  $l$  = length of each roller, in.; and  $s$  = circumferential speed of each roller, ft. per min. In bearings with conical rollers  $d$  is the diameter of the roller at its mid-length. The safe load per inch of length of a solid roller is taken at 2000 lb., with the assumption that one-third the number of rollers take the whole load on the journal.

"Another formula for the safe load on a roller bearing is  $P = knd^2/(ND + 2000d)$  in which  $N =$  r.p.m. of the shaft;  $D =$  diam. of the sleeve or roller path, in.; and  $k = 1,200,000$  to  $2,000,000$  for first class workmanship, hardened steel rollers with  $i = d$ , running on hardened ground surfaces;  $k = 400,000$  for ordinary workmanship and soft steel rollers running on a soft steel shaft."

**Safe Loads, Ball Bearings.**—The following formula is given by Mr. Henry Hess, 1910. See also paper by Mr. Hess in *Trans. A.S.M.E.*, 1907.

Let

$W =$  total safe load on bearing in pounds,

$n =$  number of balls,

$d =$  diameter of balls in eighths of an inch.

Then for *radial* (cylindrical) bearings

$$W = Knd^2,$$

where  $K$  ranges from 0.9 to 9 depending upon the condition and type of bearing and the hardness of the balls, but for ordinary speeds is practically independent of the speed. (See *Keul's Mechanical Engineers' Pocket-Book*.)

For *thrust* bearings

$$W = \frac{K_1 nd^2}{\sqrt{N}},$$

where  $N$  is the number of revolutions per minute, which may range from 3000 down to 1 revolution per minute, as for crane hooks and similar elements. For high quality ball  $K_1$  ranges from 25 to 40 for a race having a cross section of radius  $1.66 \times$  (radius of balls). For unhardened steel, occasionally used for very large races,  $K_1 = 0.5$ .

In both types of bearings the balls must be carefully selected to make sure that all that are used in the same bearing do not vary among one another by more than 0.0001 inch. A ball that is more than that larger than its fellows will sustain more than its proportion of the load, and may therefore be overloaded and will in turn overload the races.

**FRICTION OF BEARINGS.**—The coefficient of friction of a well-lubricated plain cylindrical bearing is practically independent of the projected area of the journal, the pressure per unit area remaining constant, and in the case of plain bearings is also practically independent of the nature of the rubbing surfaces, provided these are smooth.

**Friction of Plain Bearings.**—The coefficient of friction of plain bearings however, does depend to a very great extent upon the following factors:

1. The method of lubrication.
2. The nature of the lubricant.
3. The temperature of the lubricant.
4. The peripheral velocity of the journal.
5. The pressure of the journal on the bearing surface.

1. The more perfectly the bearing is bathed in oil the less will be the coefficient of friction. The friction coefficient of a scantily lubricated bearing may be from 6 to 10 times the coefficient when an oil bath is used.

2. As a rule the lower the viscosity of an oil the less will be the coefficient of friction. There are other factors, however, which must be taken into account in selecting the proper lubricant for any service (see article on *Lubricants and Lubrication*).

3, 4 and 5. The variation of the friction coefficient with temperature, speed and pressure is shown by the curves in Fig. 1. The pressures are nominal

Fig. 1. Numbers at end of curves are pressures in lb. per sq. in.

pressure, i.e., pounds per square inch of projected area of journal. These curves are taken from a paper by Stribeck (*Zeit. Ver. Deutsch. Ing.*, 1902, Vol. 46, p. 132), and are test results on a Sellers bearing with oil rings; journal 1.3 inches long, 1.75 inches in diameter, lubricated with "gas motor oil." These curves are typical of ordinary bearings.

#### POWER LOST IN BEARINGS. — Let

- $f$  = coefficient of friction,  
 $W$  = weight on journal or pivot in pounds,  
 $r$  = radius in inches,  
 $d$  = diameter in inches,  
 $s$  = space in feet through which sliding takes place per minute,  
 $r_1$  = inner radius in inches,  
 $r_2$  = outer radius in inches,  
 $n$  = number of revolutions per minute,  
 $\alpha$  = the half-angle of the cone, i.e., the angle of the slope with the axis.

Type of bearing	Friction torque in in.-lb.	Power loss ft.-lb. per min.
Flat surfaces	.....	$fWS$
Shafts and journals	$\frac{1}{2} fWd$	$0.2618 fW dn$
Flat pivots	$\frac{1}{2} fWr$	$0.349 fWr n$
Collar-bearing	$\frac{1}{2} fW \frac{r_2^2 - r_1^2}{r_2 - r_1}$	$0.349 fW n \frac{r_2^2 - r_1^2}{r_2 - r_1}$
Conical pivot	$\frac{1}{2} fWr \operatorname{cosec} \alpha$	$0.349 fWr n \operatorname{cosec} \alpha$
Conical journal	$\frac{1}{2} fWr \sec \alpha$	$0.349 fWr n \sec \alpha$
Truncated-cone pivot	$\frac{1}{2} fW \frac{r_2^2 - r_1^2}{r_2 \sin \alpha}$	$0.349 fW n \frac{r_2^2 - r_1^2}{r_2 \sin \alpha}$
Hemispherical pivot	$fWr$	$0.5236 fWr n$
Turnix, or Schiele's "anti-friction" pivot	$fWr$	$0.5236 fWr n$

It should be noted that for peripheral speeds of 100 feet and over the coefficient of friction is approximately proportional to the square root of the peripheral velocity of the journal. These particular curves also indicate that the coefficient of friction is approximately inversely proportional to the square root of the pressure. Other experimenters, however, have found that this variation is merely as the first power of the pressure.

**Friction of Roller and Ball Bearings.** — The friction coefficient of a well-made annular ball bearing is 0.001 and 0.002 of the total load on the journal

and is independent of the speed and load. The friction coefficient of a good roller bearing under normal loads and speed is from 0.0035 to 0.014; it rises very much if the load is light. It increases also when the speeds are very low, though not so much as with plain bearings. (*Henry Hess.*)

Lubrication is absolutely necessary with ball-and-roller bearings, although the contrary claim is often advanced. Under favorable conditions an almost imperceptible film is sufficient; a sufficient quantity to immerse half the lower ball should always be provided as a rust preventive. Rust and grit must be kept out of ball-and-roller bearings. Acid or rancid lubricants are as destructive as rust. (*Henry Hess.*)

**Comparison of Plain, Roller and Ball Bearings.** — Thomas, Maurer and Kelso (*A.S.M.E. Journ.* 36, p. 89, March, 1914), give the following relative power consumption, based on tests of 20 bearings of each type:

Bearings	100 ft. per min.		300 ft. per min.	
	77° F.	100° F.	77° F.	100° F.
Ball	1.0	1.0	1.0	1.0
Roller	2.2	2.5	2.7	3.0
Plain Babbitt	3.0	3.6	4.5	4.0

Co., *Ball Bearing Engineering*; Phillips, *Kent's Mechanical Engineers' Pocket-Book*; Halsey's *Handbook for Machine Designers*; Allford's *Bearings and their Lubrication*; Wallis-Tawler, *Bearing and Lubrication*; Hersey, *Laws of Lubrication of Journal Bearings*, A.S.M.E. Trans., Vol. 37, p. 167.

**BELTS AND BELTING.** — (See also *Ropes and Rope Drive*.) Belts are usually made of tanned leather, though rubber belts are frequently employed, as well as various woven fabrics. Rubber belts are made of two or more layers of canvas connected together with a rubber composition, and then heated until the rubber vulcanizes. The "ply" of a rubber belt is the number of layers of canvas. Leather belts are referred to as single, light-double, medium-double, standard-double and 3-ply. Wire belts with paper driving surface have recently been developed in Germany (*Zeits. Vereines Deutsch. Ing.* 63, p. 1057, Oct. 1909).

**Thickness of Belts.** — The following figures are from a paper by Samuel Webber (*Am. Mach.*, May 11, 1909). The thickness of leather belts, however, is variable, depending on the hide and process of manufacture.

BELT THICKNESS, INCHES

Leather		Rubber	
		30-oz. duck, new rubber vulcanized	
Single thickness.....	$\frac{3}{16}$	3-ply	0.18
Light-double.....	$\frac{1}{4}$	4-ply	0.24
Medium-double.....	$\frac{5}{16}$	5-ply	0.30
Standard-double.....	$\frac{3}{8}$	6-ply	0.35
3-ply.....	$\frac{7}{16}$	7-ply	0.40
		8-ply	0.45

**Weight.** — The average weight of leather per cubic inch is  $\frac{3}{60}$  pound (*Bark*). The average weight of rubber belting made of 30-ounce duck is about 0.045 pound per cubic inch.

**Strength.** — The strength of the solid leather in belts is from 2000 to 5000 pounds per square inch; at the lacings, even if well put together, only from 1000 to 1500. If riveted, the joint should have half the strength of the solid belt. Rubber belts have approximately the same tensile strength as leather belts. The working tension on the driving side is generally taken at not over one-third of the strength of the lacing, or from one-eighth to one-sixteenth of the strength of the solid belt.

#### Belt Tension. — Let

$T_1$  = actual, or "total," tension in pounds per square inch on driving side of belt,

$T_2$  = actual tension in pounds per square inch on slack side of belt,

$T_0$  = "initial" tension in belt, i.e., the tension in each side when the belt is at rest,

$T$  =  $T_1 - T_2$  = effective tension in pounds per square inch, i.e.,  $T$  corresponds to the force actually driving the driven pulley,

$T_c$  = the tension produced in the belt due to centrifugal action as it goes around the pulleys,

$w$  = weight of belt per cubic inch in pounds,

$f$  = coefficient of friction between belt and pulley,

- $\pi$  = ratio of arc of contact between belt and pulley to an arc of  $180^\circ$ , i.e., if the arc of contact is  $180^\circ$ ,  $\pi = 1$ ,  
 $C = 1 - e^{-\pi f \pi}$ . The value of  $e^{-\pi f \pi}$  may be found directly from the table in the article on *Exponential Functions*, putting  $\pi f \pi = x$ ,  
 $V$  = velocity of belt in feet per minute.

Then

$$T_c = \frac{mV^2}{9660} \quad (1)$$

$$T = C(T_1 - T_c) \quad (2)$$

$$T_2 = T_1 - C(T_1 - T_c) \quad (3)$$

$$T_0 = \left( \frac{\sqrt{T_1} + \sqrt{T_2}}{2} \right)^2 \text{ approximately.}^* \quad (4)$$

Barth recommends that for belts running at various speeds the initial tension  $T_0$  should not be the same in all belts, but that the belts should be tightened initially to such a tension that under load the sum

$$A = T_1 + \frac{1}{2} T_2 \quad (5)$$

is a constant. Barth also states, basing his conclusion in part on the studies of the economics of belting made by F. W. Taylor (*Trans. A.S.M.E.*, Vol. 27, p. 204), that the best values of  $A$  for greatest economy are the following:

	Machine belts	Counter-shaft belts
Maximum value of $A$ , belt first put on.....	320	240
Minimum value of $A$ , belt to be retightened.....	240	160

These values of  $A$  are for full-load conditions. The corresponding values of the various tensions are given below.

**Belt Friction and Belt Slip.**—The value of the factor  $C$  depends upon the coefficient of belt friction, which is subject to considerable variation, depending upon the condition of the belt and pulleys. Barth gives the following formula for  $f$  for leather belts on cast-iron pulleys

$$f = 0.54 - \frac{140}{500 + V}$$

Barth also gives a formula for the belt slip which may be written

$$s = \frac{V_1 - V_2}{V} = \frac{320}{V} \left( \frac{1 + 0.0055 V}{85 + 0.03 V} \right),$$

where  $V_1$  and  $V_2$  are the peripheral velocities of the driving and driven pulley respectively.

\* See paper by C. G. Barth, *Trans. A.S.M.E.*, 1909, Vol. 31, p. 29. In this paper Barth also gives a more exact formula, and takes into consideration the difference in the relation between  $T_1$ ,  $T_2$  and  $T_0$  for vertical and horizontal belts.

**Power Lost Due to Belt Slip** is proportional to the slip, i.e., if the slip is 0.03 the power lost is 3 per cent of the power transmitted by the belt. Under normal conditions the power loss due to belt slip is from 2 to 4 per cent. The power loss in mill shafting due to the friction of the shaft bearings ranges from 10 to 60 per cent, depending upon the type of bearing, belt tension, etc., See article on *Bearings*.

**Power Transmitted by Belt.** — Let

$V$  = velocity of belt in feet per minute,

$w$  = width of belt, in inches,

$t$  = thickness of belt, in inches,

$w$  = weight, in pounds, of 1 cubic inch of belt,

$T_1$  = actual tension in driving side of belt in pounds per square inch of belt cross-section,

$s$  = slip of belt as a fraction of belt speed.

Then the horse-power transmitted by the belt is

$$P = \frac{wCVT_1}{33,000} \left( 1 - \frac{mV^2}{9660 T_1} \right),$$

where  $C$ , defined above, depends on the belt friction and arc of contact between belt and pulley.

As a rough approximation  $C$  may be taken equal to 0.6, and the second term in the bracket zero, at least for low speeds, and the formula then becomes

$$P = \frac{wVT_1}{55,000},$$

or the horse-power transmitted per square inch of belt cross-section is

$$p = \frac{VT_1}{55,000}.$$

The power lost in the transmission from one pulley to the other, excluding the loss due to shaft friction, is  $sP$ , the driving pulley absorbing approximately  $(P + 0.5 sP)$  horse-power and the driven pulley receiving  $(P - 0.5 sP)$  horse-power.

The following tables are derived from curves in the paper by Barth above referred to.

#### HORSE-POWER TRANSMITTED BY BELTS DRIVING MACHINES

(For  $\Delta = T_1 + 0.5 T_2 = 240$ )

Velocity, ft. per min.	500	1000	2000	3000	4000	5000	6000
Initial tension, $T_0$	124	130	121	128	136	144	152
Centrifugal tension $T_c$ . . . . .	0+	3	13	31	56	86	124
Difference, $T_0 - T_c$ . . . . .	123	117	108	97	80	58	28
Tension on tight side, $T_1$ . . . . .	210	212	211	207	198	187	173
Tension on slack side, $T_2$ . . . . .	60	54	57	68	84	107	134
Effective pull, $T_1 - T_2$ . . . . .	150	158	154	139	114	80	39
Sum of tensions $T_1 + T_2$ . . . . .	270	266	268	274	282	294	307
H. p. per sq. in. of section . . . . .	2.27	4.79	9.33	12.64	13.82	12.12	7.09

## HORSE-POWER TRANSMITTED BY BELTS DRIVING COUNTER-SHAFTS

(For  $A = T_1 + 0.5 T_2 = 160$ .)

Velocity of belt, ft. per min.	500	1000	2000	3000	4000	5000
Initial tension, $T_0$ .....	82	81	83	89	96	102
Tension on tight side, $T_1$ ...	140	141	140	134	125	114
Tension on slack side, $T_2$ ...	40	38	41	53	69	90
Effective pull, $T_1 - T_2$ .....	100	103	99	81	56	23
Sum of tensions .....	180	179	181	187	194	206
H.p. per sq. in. of section...	1.51	3.12	6.04	7.36	6.79	3.31

Proper Size of Belt to Transmit a Given Amount of Power. — Using the same notation as in the preceding paragraph, the proper cross-section of the belt in square inches is approximately

$$w = \frac{55,000 P}{VT_1}$$

or exactly

$$w = \frac{33,000 P}{CVT_1 \left( 1 - \frac{\pi V^2}{9660 T_1} \right)}$$

The various "handy formulas" for determining the proper cross-section of belt are all of the form of the approximate formula, and differ only in regard to the proper value to assign to the tension  $T_1$ . A working tension, that is the difference between the tensions on the tight and slack sides of the belt, of 45 pounds for a single (thickness) belt 1 inch wide is commonly used, giving a nominal tension of  $6 \times 45 = 270$  pounds per square inch. Taking the coefficient  $C$  at 0.6, the actual tension in a belt designed in accordance with this rule is 450 pounds per square inch. The value of  $C$  varies through a wide range, say from 0.25 to 0.90, chiefly due to the variability of the coefficient of friction.

The following table, deduced from Barth's curves, may be considered as representative of modern practice.

## CROSS-SECTION OF LEATHER BELT PER HORSE-POWER TRANSMITTED, IN SQUARE INCHES

Speed, ft. per min.	500	1000	2000	3000	4000	5000	6000
Machine belts .....	0.44	0.209	0.107	0.079	0.072	0.082	0.111
Countershaft belts.....	0.662	0.320	0.166	0.136	0.147	0.300	.....

All belts should have a contact area with the smaller pulley of at least 165 degrees. If this is not possible to obtain under normal conditions an idler should be provided to increase the belt contact.

**Pulley Face and Belt Speed.**—The following table may be used for determining the pulley face and best belt speed for moderate-speed machines or slow-speed machines the pulley sizes are the same as those used with moderate machines of the same frame dimensions.

PULLEY FACE AND BELT SPEED

Horse-power		Kilowatts		Belt width in inches	Pulley face in inches	Belt speed in feet per minute for moderate- speed ma- chines
1 to under	5	1 to under	4	2	2½	2000

**Relations of Driving and Driven Pulleys.**—The maximum ratio between the diameters of the driving and driven pulleys should not exceed 6 : 1. The ratio will determine the distance between the pulley centers, and good proportions are given in the accompanying table.

**CARE AND OPERATION OF BELTS.** — The following is taken from an article by F. W. Taylor (*Trans. A.S.M.E.*, Vol. 15, p. 203). See also an excellent article by C. J. Morrean (*Eng. Mag.* 51, p. 567, July, 1916).

The best distance from center to center of shafts is from 20 to 25 feet.

Idler pulleys work most satisfactorily when located on the slack side of the belt about one-quarter way from the driving pulley.

Belts are more durable and work more satisfactorily made narrow and thick, rather than wide and thin.

It is safe and advisable to use a double belt on a pulley 12 inches diameter or larger; a triple belt on a pulley 20 inches diameter or larger; a quadruple belt on a pulley 30 inches diameter or larger. As belts increase in width they should also be made thicker.

The ends of the belt should be fastened together by splicing and cementing instead of lacing, wiring or using hooks or clamps of any kind.

Belts should be cleaned and greased every five to six months.

Belt-clamps having spring-balances between the two pairs of clamps should be used for weighing the tension of the belt accurately each time it is tightened.

Double leather belts, when treated with great care and run night and day at moderate speed, should last for 18 years (the tension being adjusted in accordance with Barth's rules).

In figuring the total expense of belting, and the manufacturing cost chargeable to this account, by far the largest item is the time lost on the machines while belts are being relaced and repaired.

The total stretch of leather belting exceeds 6 per cent of the original length.

The stretch during the first six months of the life of belts is 15 per cent of their entire stretch (the tension being adjusted in accordance with Barth's rules).

A double belt will stretch 0.81 per cent of its length before requiring to be tightened (the tension being adjusted in accordance with Barth's rules).

The most important consideration in making up tables and rules for the use and care of belting is how to secure the minimum of interruptions to manufacture from this source.

The average double belt when running night and day in a machine shop will cause an interruption to manufacture not oftener than once in sixteen months (the tension being adjusted in accordance with Barth's rules).

The oak-tanned and fullled belts showed themselves to be superior in all respects except the coefficient of friction to either the oak-tanned not fullled, the semi-rawhide, or rawhide with tanned face.

Belts of any width can be successfully shifted backward and forward on tight and loose pulleys. Belts running between 5000 and 6000 feet per minute and driving 300 h.p. are now being daily shifted on tight and loose pulleys to three lines of shafting in and out of use.

The best form of belt-shifter for wide belts is a pair of rollers twice the width of belt, either of which can be pressed onto the flat surface of the belt on its slack side close to the driven pulley, the axis of the roller making an angle of 75° with the center line of the belt.

**Dressings for Leather Belts.** — We advise that no belt dressing should be used except when the belt becomes dry and husky, and in such instances we recommend the use of a dressing. Where this is not used beef tallow at blood

Approximate Ratio	Minimum Distance Between Centers in Feet
2:1	8
3:1	10
4:1	12
5:1	15
6:1	20

warm temperature should be applied and then dried either by artificial heat or the sun. The addition of beeswax to the tallow will be of some service if the belts are used in wet or damp places. Our experience convinces us that resin should never be used on leather belting. (*Feyerweather and Ledet.*)

Some forms of belt dressing, the compositions of which have not been published, appear to have the property of increasing the coefficient of friction between the belt and the pulley, enabling a given power to be transmitted with a lower belt tension than with undressed belts. C. W. Evans (*Power, Dec., 1905*) gives a diagram, plotted from tests, which shows that three of these compositions gave increased transmission for a given tension, ranging from about 10 per cent for 50 pounds tension per inch of width to 100 per cent increase with 20 pounds tension.

**Dressings for Rubber Belts.** — Rubber belts will be improved, and their durability increased, by putting on with a painter's brush, and letting it dry, a composition made of equal parts of red lead, black lead, French yellow and litharge, mixed with boiled linseed oil and japan enough to make it dry quickly. The effect of this will be to produce a finely polished surface. If, from dust or other cause, the belt should slip, it should be lightly moistened on the side next the pulley with boiled linseed oil. (*From circulars of manufacturers.*)

**Lacing of Belts.** — In punching a belt for lacing, use an oval punch, the larger diameter of the punch being parallel with the sides of the belt. Punch two rows of holes in each end, placed zigzag. In a 3-inch belt there should be four holes in each end — two in each row. In a 6-inch belt, seven holes — four in the row nearest the end. A 10-inch belt should have nine holes. The edge of the holes should not come nearer than  $\frac{1}{4}$  inch from the sides, nor  $\frac{1}{8}$  inch from the ends of the belt. The second row should be at least  $1\frac{1}{4}$  inches from the end. On wide belts these distances should be even a little greater.

Begin to lace in the center of the belt and take care to keep the ends exactly in line, and to lace both sides with equal tightness. The lacing should not be crossed on the side of the belt that runs next the pulley. In taking up belts observe the same rules as in putting on new ones.

**Setting a Belt on Quarter-twist.** — A belt must run squarely on to the pulley. To connect with a belt two horizontal shafts at right angles with each other, say an engine-shaft near the floor with a line attached to the ceiling, will require a quarter-turn. First, ascertain the central point on the face of each pulley at the extremity of the horizontal diameter where the belt will leave the pulley, and then set that point on the driven pulley plumb over the corresponding point on the driver. This will cause the belt to run squarely on to each pulley, and it will leave at an angle greater or less, according to the size of the pulleys and their distance from each other.

In quarter-twist belts, in order that the belt may remain on the pulleys, the central plane on each pulley must pass through the point of delivery of the other pulley. This arrangement does not admit of reversed motion.

**BLOCKS AND TACKLE.** — (See also *Ropes and Rope Drive; Chains and Chain Drive.*) A simple block used with rope tackle consists of one or more pulleys mounted in a casing or shell. They may be single, double, triple, etc., depending upon the number of sheaves or pulleys. In chain blocks, instead of simple pulleys, spur or worm and wheel gearing (see *Gears and Gearing*) or differential pulleys are used. In the triplex block, made by the Yale and Towne Co., the power is transmitted to the hoisting-chain wheel by means of a train of spur gearing operated by the hand chain. In the duplex block the power is transmitted through a worm wheel and screw.

Fig. 1 shows schematically a differential pulley. The two upper pulleys are rigidly fastened together and rotate as one piece. The rims of these pulleys are shaped to mesh with the links of the chain and prevent the latter from slipping. Let  $D_1$  and  $D_2$  be the respective diameters of the larger and smaller upper pulleys. Then if the diameter of the lower pulley is  $(D_1 + D_2)/2$ , the pull  $P'$  required to raise a load  $W$ , neglecting friction, is

$$P' = \frac{D_1 - D_2}{2D_1} \cdot W.$$

**ACTUAL PULL REQUIRED; EFFICIENCY OF BLOCK AND TACKLE.** —

In the case of a simple block and tackle the pull  $P'$  required to raise a load  $W$  is, neglecting friction,

$$P' = \frac{W}{N},$$

where  $N$  is the number of lengths of rope shortened when the lower block rises (in Fig. 2  $N=6$ ). The actual pull required is this theoretical pull  $P'$  divided by the efficiency expressed as a fraction, or

$$P = \frac{100 W}{N e},$$

where  $e$  = the per cent efficiency. The distance in feet through which the pulling rope must be pulled to raise the load 1 foot is equal to the number ( $N$ ) of lengths of rope shortened.

In the case of a differential pulley the actual pull is

$$P = \frac{100 (D_1 - D_2) W}{2 D_1 e},$$

where  $e$  is the per cent efficiency and the other symbols as above. The distance through which the hand chain must be pulled to raise the load 1 foot is

$$\frac{2 D_1}{D_1 - D_2}.$$

In any case, if the rope or chain pulls on the lower block at an angle, the block will be pulled out of the line drawn between the load and the upper block, and the effective pull will be less than the actual pull on the rope in the ratio of the cosine of the angle the pulling rope makes with the vertical, or line of action of the resistance, to unity.

Fig. 1.

Fig. 2.

Efficiency of Rope Blocks. — S. L. Woson, *Eng. News*, June 11, 1903, is the following:

Number of rope lengths abtorted, <i>N</i>	Manila rope, 1¼ to 3 in.		¾-inch wire rope	
	Ratio of load to pull	Efficiency, per cent, $\phi$	Ratio of load to pull	Efficiency, per cent, $\phi$
2	1.91	96	....	..
3	2.64	88	2.73	91
4	3.30	83	3.47	87

10	....	..	6.46	65
12	....	..	7.08	59

Pull Required with Chain Blocks. — The following table is taken from catalogue of the Yale and Towne Co.

Capacity in tons, (see lb.)	Pull in pounds required on hand-chain to lift full loads			Feet of hand-chain to be pulled by operator to lift load one foot high		
	Triplex	Duplex	Differential	Triplex	Duplex	Differential
¼	...	...	72	...	...	18
½	62	68	122	21	40	24
1	82	87	216	31	59	30
1½	110	94	246	35	80	36
2	120	115	308	42	93	42
3	114	123	357	69	126	38
4	124	142	...	84	155	..
5	110	145	...	126	195	..
6	130	145	...	126	252	..
8	135	160	...	168	310	..
10	140	160	...	210	390	..

For loads from 10 to 20 tons two hand-chains are provided.

**SAFE LOAD.** — Blocks are usually designed to carry a load as great as that of the rope or chain which fits the grooves in the sheaves (*see Ropes and Rope Drives; Chains and Chain Drives*).

**BIBLIOGRAPHY.** — See the works on *Machine Design* given in the Bibliography in article on *Bearings*; also circulars of Yale & Towne Mfg. Co., N. Y., and Boston & Lockport Block Co.

**BLOWERS AND COMPRESSORS.** — (See also *Draft, Mechanical; Fans.*) A blower is any kind of apparatus that is used for blowing or forcing air or other gas into or out of a room or other receptacle. When it is used to draw air from a room or vessel and discharge it into another vessel or into the external atmosphere it is commonly called an "exhauster." A fan is a blower in which motion is given to the air by means of thin blades or vanes (see *Fans*). A blowing engine is a large machine in which air is compressed in and discharged from a cylinder which is fitted with a reciprocating piston. When a blowing engine delivers air at high pressures, say 30 pounds per square inch and upwards, it is called an air compressor. Following is a brief description of the several kinds of blowers.

**Displacement Blowers.** — Into a closed tank containing air a stream of water is caused to flow, displacing the air and blowing it out through an opening provided for it. By using two tanks with suitable valves, the action may be made continuous.

**Hydraulic Blowers.** — A large tank is surmounted by a vertical pipe into the top of which water enters in such a way as to "entrain" or drag air along with it, which is separated from the water when it reaches the tank and is blown out through an air pipe while the water escapes through another opening. Tests of a compressor of this kind at Magog, P. Q., Canada, showed a capacity of from 967 to 1165 cubic feet of air per minute at a pressure of 53 pounds per square inch, and an efficiency of from 60 to 76 per cent. See paper by W. O. Webber, *Trans. A.S.M.E.*, Vol. 22, p. 599.

**Jet Blowers.** — A jet of water, compressed air, or steam flowing into a short pipe of a diameter greater than that of the jet will induce a current of air to flow through the pipe, which may thus be used as a blower or exhauster. The steam jet is in common use for blowing air into furnaces and gas producers, and is used as an exhauster to increase the draft of chimneys. It is usually very wasteful of steam, and should be used only in emergencies, when blowing machines are not available, or when the steam used to drive the jet is also used for other purposes, as for combining with the carbon of the fuel in gas producers.

**Positive Rotary Blowers.** — These are built like rotary pumps, with two rotating shafts, geared together so as to turn in opposite directions, each carrying an "impeller," a casting approximating a figure 8 in section; the curve of the two impellers is so shaped that they touch or nearly touch on lines parallel to the shafts during the whole period of rotation, and also nearly touch the casing which surrounds them. A blower thus built delivers a constant quantity of air at each revolution, differing in this respect from centrifugal fans which deliver a varying quantity according to the resistance the air meets at the outlet. The economical range of these blowers is between 8 ounces and 1 pound pressure per square inch. For higher pressures than 8 pounds the blowing engine is more economical.

**Blowing Engines.** — A cylinder with a reciprocating piston when used for blowing air is called a blowing engine, whether it is driven by a steam engine, a water wheel or an electric motor. Blowing engines are commonly used to furnish air to blast furnaces and Bessemer converters, at pressures of from 4 to 30 pounds per square inch. They are simple in construction, but are usually large, heavy and costly relative to the quantity and pressure of air furnished by them, on account of their moderate speeds, and there is a tendency to supplant them by

**High-speed Centrifugal Compressors.** — These are built on the principle of steam turbines or high-pressure centrifugal pumps and are driven at very high

speeds, 1800 to 3500 r.p.m. The General Electric Co. makes a line of these compressors for pressures ranging from 1 to 3.25 pounds per square inch, and for delivering 800 to 28,000 cubic feet of free air per minute. By using several such compressors in series, one delivering into another, pressures of 100 pounds per square inch may be obtained.

**POWER AND EFFICIENCY.**—The useful work done by a blower is that equivalent to the isothermal compression of the air to the pressure in the receiver (or to the static plus the velocity pressure in the delivery main if the air were cooled to the atmospheric temperature) plus the work of delivering it against that pressure. If  $P_1$  = absolute pressure at inlet in pounds per square foot;  $P_2$  = pressure in the receiver;  $V_1$  = volume of entering air at the pressure  $P_1$ , in cubic feet per minute, then useful work in foot-pounds per minute =

$P_1 V_1 \ln \frac{P_2}{P_1}$ . The useful or "air horse-power" is this quantity divided by 33,000.

When  $P_2$  is but slightly in excess of  $P_1$  the work per minute is  $(P_2 - P_1)V_1$  nearly, the error being less than 5 per cent when  $P_2 = 1.1 P_1$ , and less than 1 per cent when  $P_2 = 1.01 P_1$ .

When the air is compressed adiabatically, that is, without cooling during compression, the useful work is the same as in isothermal compression, but the actual work done in the cylinder (not including work lost by friction and leakage) is greater, or

$$3.463 P_1 V_1 \left\{ \left( \frac{P_2}{P_1} \right)^{0.287} - 1 \right\}.$$

The efficiency of blowing machines (i.e., the ratio of the air horse-power to the horse-power required to drive the machine) ranges from 95 per cent in the case of a slow-moving engine with large inlet and outlet valves, down to almost zero in poorly designed rotating machines. Centrifugal compressors have an efficiency under normal load of from 40 to 60 per cent (see *Fans*). A 39 by 84-inch positive blower, made by the Connersville Blower Co., is reported to have given an efficiency ranging from 68.5 per cent at an air pressure of 0.5 pound per square inch to 86 per cent at a pressure of 3.5 pounds per square inch, the displacement of air in each case being approximately 18,000 cubic feet per minute. The efficiency of steam-jet blowers is very low.

**SPECIFICATION FOR BLOWER.**—The following memoranda are intended to assist in writing specifications. See also under *Fans* and article on *Specifications*.

**Principal Characteristics and Conditions of Service.**—Purpose of blower.

**Style and Description; Details of Construction.**—Shall have horizontal, upward or downward discharge. Location of air outlet with reference to rotating parts. Hand or automatic closing of dampers when blower stops. How coupled to motor or engine, i.e., direct or belted. If direct driven, give details of coupler to disconnect blower from motor. Lubrication. Tools. Enclosure of moving parts to reduce danger.

**Performance and Tests.**—Cubic feet of air per minute. Air pressure, ounces or inches of water column at stated temperature.

**ELECTRIC DRIVE OF COMPRESSORS.**—(See also *Motors, Industrial Applications of*.) As compressors of the reciprocating type must be driven at a low speed, the synchronous motor is well adapted for driving them, chiefly because this motor operates normally at unity power factor and can be efficiently operated at leading power factors to counteract the lagging power factor

due to induction motors driving other apparatus on the system. Slow-speed induction motors must be built with a large number of poles and will then operate at very low power factors with a comparatively low efficiency. Other reasons favoring the synchronous motor drive for this service are the steady load and the new torque required in starting, as a by-pass is generally provided so that the compressor works only against atmospheric pressure when starting. The motor should be able to be started from the alternating-current side and should for this reason be provided with the usual "squirrel-cage" winding. There is usually sufficient flywheel effect in the machine itself to keep within a reasonable angle of displacement, so that no trouble is experienced from "hunting."

The centrifugal type of compressor operates at a comparatively high speed. For driving the smaller size compressors the squirrel cage induction motor is used, but for larger units where a low starting current is desirable the phase wound type of motor should preferably be selected. When design difficulties prevent the use of the induction motor for driving the larger size centrifugal compressors it has been the recent practice to use two-pole, 60-cycle synchronous motors built along the line of the turbo-alternator.

For direct-current installations compound-wound motors are generally used for driving reciprocating compressors and shunt-wound motors for the centrifugal type.

**DIMENSIONS, WEIGHTS AND COSTS.**—There is so great a variety of blowers and compressors that it is impossible in the space available to give a representative table of dimensions, weights and costs. The reader is referred to the manufacturers' catalogues and price lists. Representative manufacturers are the Ingersoll-Rand Co., the American Blower Co., the Sturtevant Co., and the Connersville Blower Co. (See also *Kent's Mechanical Engineers' Pocket-book*.)

**BIBLIOGRAPHY.**—Ennis, W. D., *Applied Thermodynamics*; Innes, C. H., *Air Compressors and Blowing Engines*; Richards, Frank, *Compressed Air*; Peole, Robt., *Compressed Air Plant*; Ivens, E. M., *Pumping of Compressed Air*, catalogues of manufacturers.

**BOILERS, STEAM.** — (See also *Chimneys; Condensers, Steam; Conveyors; Lift, Mechanical; Feed-water Heaters; Fuels; Pipes and Piping; Power Stations; Pumps; Separators, Steam; Steam.*) The simplest form of boiler is a closed cylindrical vessel partly filled with water, with a pipe for the introduction of feed water, another pipe for the escape of steam and means for maintaining fire under the boiler. Modifications of this elementary form are made: (1) for the purpose of insuring that as large a fraction as possible of the heat energy generated by the burning fuel shall be absorbed by the water and as small a fraction as possible shall be lost in the escaping hot gases and by radiation; and (2) for the purpose of increasing the heating surface and therefore the evaporative capacity of the boiler, with as great an economy of space occupied and of cost as possible, without at the same time endangering the safety of the boiler, or decreasing its durability, facility for cleaning or other desirable qualities.

**DEFINITIONS.** — Certain special terms used in reference to boilers are defined below.

**Boiler Horse-power.** — This term was originally introduced to indicate the size of boiler required for an average reciprocating engine, the boiler being sized to have the same horse-power as that of the engine. Due to improvements in the design of steam engines a boiler of a given horse-power rating may be capable of supplying an engine (e.g., a compound condensing engine) of 3 times the rating of the boiler. The American Society of Mechanical Engineers has adopted the following definition:

A boiler horse-power is equivalent to the evaporation of 34.5 pounds of water per hour from feed water at 212° F. to saturated steam at the same temperature. Adopting Marks and Davis's figures for the properties of steam (see *Steam*) 34.5 pounds of steam from and at 212° F. is equivalent to 33,479 B.t.u. per hour, or to an evaporation of 30.018 pounds from 100° F. feed-water temperature to steam at 70 pounds gage pressure.

It is customary in the trade to consider 10 square feet of heating surface as equivalent to a boiler horse-power, for stationary boilers. The term boiler horse-power is not used in connection with locomotive or marine boilers, and there is a tendency to discontinue its use for stationary boilers, expressing their size in square feet of heating surface, and their evaporative capacity in pounds of water evaporated from and at 212° F. per hour.

**Equivalent Evaporation.** — **Factor of Evaporation.** — For the purpose of reducing the results of a boiler test made under certain conditions of feed-water temperature and steam pressure and quality to a common standard, it is customary to use the equivalent evaporation from and at 212° F. as that standard. The pounds evaporated under actual conditions are multiplied by a factor of evaporation,  $F$ , which is determined by the formula

$$F = \frac{H - h}{970.4}$$

in which  $H$  = total B.t.u. above 32° F. in 1 pound of steam at the actual pressure and degree of superheat, and  $h$  = total B.t.u. above 32° F. of 1 pound of the feed water. The values of  $H$  and  $h$  are given in steam tables (see *Steam*). If the steam contains  $x$  per cent of moisture, use for  $H$  in the above formula

$$H = H' \left( 1 - \frac{x}{100} \right) + \frac{h'x}{100}$$

where  $H'$  is the total heat of saturated steam at the given pressure and  $h'$  is the heat of the liquid at the given pressure, as given in steam tables.

**Boiler Efficiency.**—The efficiency of the boiler alone is usually defined as the ratio of the number of B.t.u. absorbed by the water per pound of combustible *actually* burnt, to the number of B.t.u. in one pound of the combustible. The over-all efficiency of the boiler and grate is the ratio of the B.t.u. absorbed by the water per pound of coal *as fired* to the number of B.t.u. in one pound of this coal. This over-all efficiency differs from the efficiency of the boiler alone according to the amount of coal lost through the grates.

**"Economy" or Water Rate.**—Boiler efficiency is also frequently expressed in terms of the number of pounds of water evaporated from and at 212° F. per pound of combustible in the coal actually burnt (this corresponds to the efficiency of the boiler alone), or per pound of coal as fired (this corresponds to the efficiency of boiler and grate). The number of pounds of water evaporated from and at 212° F. per pound of coal is frequently referred to as the "economy" of the boiler, or its "water rate."

The relation between efficiency and economy may be expressed as follows:

Let  $e$  = boiler efficiency, in per cent,

$B$  = B.t.u. per pound of coal,

$w$  = economy, i.e., the equivalent number of pounds water evaporated per pound of coal.

Then

$$w = \frac{Be}{97,040}$$

For example, if the coal contains 10,000 B.t.u. per pound and the boiler efficiency is 70 per cent, then the economy is  $10,000 \times 70/97,040 = 7.2$  pounds water per pound coal.

**CLASSIFICATION OF BOILERS.**—Boilers may be classified as *externally* and *internally fired*, *water tube* and *fire tube*, *through tube* and *return tube*, *horizontal* and *vertical*. An *internally fired* boiler is one in which the furnace is built inside of the boiler, and its roof and sides form a part of the heating surface of the boiler; the locomotive and Scotch marine, the Lancashire and the vertical-tubular boiler are of this type. An *externally fired* boiler is one in which the furnace is separate from the boiler itself and is usually placed underneath it, but sometimes at the side of it in a structure lined with fire-brick. A *fire tube* boiler is one in which the hot gases pass through the tubes, whereas the water is contained in an external shell through which the tubes pass. A *water tube* boiler is one in which the water is contained in the tubes and the hot gases pass around them. A *through tube* boiler is one in which the hot gases pass directly through the tubes from the fire to the smoke flue, whereas in a *return tube* boiler the gases are caused to pass under the shell containing the tubes to the farther end, thence upward through the "back connection," at rear of the setting and return through the tubes to the "breaching" or flue connection to the chimney. The term "return tubular" is applied only to fire tube boilers.

**APPLICATIONS OF VARIOUS TYPES.**—Externally fired *return tube* boilers in sizes up to 200 horse-power and for pressures up to 150 pounds per square inch are very commonly used. Boilers of this type are comparatively cheap and do not require expensive setting. In large power stations externally-fired *water tube* boilers are almost invariably used in this country. These boilers are built in sizes up to 2300 horse-power and for all practicable pressures. Babcock and Wilcox, Heine, Sterling and Wickes boilers are of the water tube type. In the first two makes the tubes are slightly inclined, in the third they are quite steeply inclined, and in the last they are vertical.

**Selection of Type of Boiler.** — In selecting the type of boiler to be used in any particular case the following points should be taken into consideration: (1) steam pressure desired; (2) space available; (3) danger of explosion; (4) liability to minor troubles which cause temporary stoppage; (5) durability; (6) ease of making repairs; (7) facilities for cleaning and removing scale and for inspection; (8) water-storage capacity; (9) rapidity at which steam can be raised; (10) steadiness of water level; (11) dryness of steam; (12) cost, including setting.

The question of economy of fuel is not generally dependent on the type of boiler as the same economy may be obtained with all types provided each is so designed that (1) there is sufficient heating surface; (2) the fuel can be thoroughly burned in the furnace, so that no unburned gases are allowed to reach the heating surface, and (3) the path of the gases through the boiler is properly baffled so that they are not "short-circuited," leaving part of the heating surface out of the current.

**DESIGN AND CONSTRUCTION.** — The essential parts of the boiler in the case of a water tube boiler are the tubes, steam drums and mud drums, grates and setting. The tubes are usually 4 inches in diameter in large stationary boilers, and are usually more or less inclined. The steam drums are large cylindrical vessels which serve as a reservoir for the water and steam. The mud drums are arranged to collect a considerable part of the sediment formed by evaporation of the water. Suitable blowpipes are provided for draining of the water and for discharging the sediment and scale-forming material. The water level in the boiler is usually indicated by a gauge glass or try cocks, or both, connected either directly to the boiler shell or to a water column. Suitable manholes and handholes are provided to give access to the various parts of the boiler.

**Heating Surface.** — For maximum fuel economy with any kind of boiler it should be proportioned so that at least one square foot of heating surface should be given for every 3 pounds of water to be evaporated from and at 212° F. per hour. Still more liberal proportions are required if a portion of the heating surface has its efficiency reduced by: (1) tendency of the heated gases to short-circuit, that is, to select passages of least resistance and flow through them with high velocity, to the neglect of other passages; (2) deposition of soot from smoky fuel; (3) incrustation. If the heating surface is clean, and the heated gases pass over it uniformly, little if any increase in economy can be obtained by increasing the heating surface beyond the proportion of 1 square foot to every 3 pounds of water to be evaporated, and with all conditions favorable but little decrease of economy will take place if the proportion is 1 square foot to every 4 pounds evaporated; but in order to provide for driving of the boiler beyond its rated capacity, and for possible decrease of efficiency due to the causes above named, it is better to adopt 1 square foot to 3 pounds evaporation per hour as the minimum standard proportion.

For maximum commercial economy, taking into consideration not only the cost of fuel but also the interest, depreciation and taxes on the cost of the plant, a higher rate of driving may be required, even as high as 6 or 8 pounds per square foot of heating surface per hour at the time of maximum or peak load, if the high loads last only a few hours each day.

**Measurement of Heating Surface.** — The usual rule is to consider as heating surface all the surfaces that are surrounded by water on one side and by flame or heated gases on the other, using the external diameter for water tube boilers and the internal diameter for fire tube boilers.

**Grates.** — Three kinds of grates are employed, the stationary, the rocking or shaking, and the traveling grate. The grate bars are made of cast iron. Rock-

ing grates have the advantage of permitting clearing the fire-bed of ash and clinker without opening the fire door and require less manual labor than the stationary grate. A traveling grate is one form of a mechanical stoker (*see Stokers, Mechanical*).

**Grate Surface.**—The amount of grate surface required per horsepower and the proper ratio of heating surface to grate surface are extremely variable, depending chiefly upon the character of the coal and upon the rate of draft. With good coal, low in ash, approximately equal results may be obtained with large grate surface and light draft, and with small grate surface and strong draft, the total amount of coal burned per hour being the same in both cases. With good bituminous coal, like Pittsburgh, low in ash, the best results apparently are obtained with strong draft and high rates of combustion, provided the grate surfaces are cut down so that the total coal burned per hour is not too great for the capacity of the heating surface to absorb the heat produced.

With coals high in ash, especially if the ash is easily fusible, tending to choke the grates, large grate surface and a slow rate of combustion are required, unless means, such as shaking grates, are provided to get rid of the ash as fast as it is made.

The following table is adapted from a more extensive one given in Gebhardt's *Steam Power Plant Engineering*.

Nature of plant	Number of plants	Character of fuel	Average ratio of heating surface to grate surface
Central stations	10	Illinois screenings, 15 to 20% ash	65
Central stations	14	Bituminous	60
Central stations	1	Bituminous	31
Central stations	9	Anthracite	40
Mfg. plants	20	Anthracite	35
Office building	6	Bituminous	48

**Calculation of Required Heating Surface and Grate Area.**—From the data given above the proper grate area and heating surface may be calculated as follows:

**Example 1.**—Steam required per hour at the "peak of the load," 6000 pounds; 3000 pounds ordinarily. Steam per pound of the poorest coal under the given conditions of feed-water temperature and steam pressure at maximum rate of driving, 6 pounds. This corresponds to  $6000/6 = 1000$  pounds of coal per hour. Maximum rate of combustion under worst conditions 25 pounds of coal per square foot of grate per hour. The required grate surface is then  $1000/25 = 40$  square feet. Heating surface for maximum economy at ordinary driving will be  $3000/3 = 1000$  square feet, requiring  $6000 \times 3/3000 = 6$  pounds of steam per square foot of heating surface per hour at highest rate. Ratio of heating to grate surface,  $1000/40 = 25$  to 1.

**Example 2.** Let 3000 pounds of steam be required per hour uniformly. The coal is of good quality so that 9 pounds of water will be evaporated per pound

of coal when the rate of driving does not exceed 3 pounds of evaporation per square foot of heating surface per hour. The rate of combustion of this coal may be as high as 30 pounds per square foot of grate per hour, but to have easy firing, 20 pounds is chosen. Then,

Heating surface =  $3000/3 = 1000$  square feet;

Coal per hour =  $3000/9 = 333$  pounds;

Grate surface =  $333/20 = 16.7$  square feet;

Ratio of heating to grate surface =  $1000/16.7 = 60$  to 1.

**Air Passages through Grates.** — The usual practice is to make the air opening 30 to 50 per cent of the total grate area. With coal free from fines much smaller openings may be used.

**Flues and Other Gas Passages.** — Rules are usually given making the area of gas passages bear a certain ratio to the area of the grate surface; thus a common rule for horizontal tubular boilers is to make the area over the bridge flue  $\frac{1}{4}$  of the grate surface, the flue area  $\frac{1}{6}$ , and the chimney area  $\frac{1}{6}$ .

For average conditions with anthracite coal and moderate draft, say a rate of combustion of 12 pounds of coal per square foot of grate per hour, and a ratio of heating to grate surface of 30 to 1, this rule is as good as any, but it is evident that if the draft were increased so as to cause a rate of combustion of 24 pounds, requiring the grate surface to be cut down to a ratio of 60 to 1, the area of gas passages should not be reduced in proportion. The amount of coal burned per hour being the same under the changed conditions, and there being no reason why the gases should travel at a higher velocity, the actual area of the passages should remain as before, but the ratio of the area to the grate surface would in that case be doubled.

Mr. Barrus states that the highest efficiency with anthracite coal is obtained when the tube area is  $\frac{1}{6}$  to  $\frac{1}{10}$  of the grate surface, and with bituminous coal when it is  $\frac{1}{6}$  to  $\frac{1}{4}$ , for the conditions of medium rates of combustion, such as 10 to 12 pounds per square foot of grate per hour, and 12 square feet of heating surface allowed to the horse-power.

**Boiler Settings.** — The boiler proper is usually mounted in a brick setting with suitable iron buckstays. The setting also forms the walls of the furnace. Common red brick is usually employed for the setting except for those parts which are exposed to a sufficiently high temperature to require the use of fire brick. Sometimes a separate furnace, or "Dutch oven," directly in front of the boiler, is used.

**OIL BURNERS AND FURNACES.** — In burning liquid fuel in steam-boilers or other furnaces it is of the utmost importance that the fuel be completely atomized and that each minute particle be surrounded by sufficient air for its complete combustion. Failure in this results in the formation of smoke and soot. The following methods of injecting the oil and air into the furnace are used in connection with steam boilers:

(1) *Steam injection.* A fine jet of steam at high pressure is employed to inject both oil and air into the furnace. Furnaces fired by this method are very successful in burning oil without smoke, if the oil is not fed to the furnace at a rate faster than that for which the burner is designed. (2) *Air injection.* Air at about 40 pounds pressure per square inch is used to inject and atomize the oil. Burners of this type are very successful, and they give higher temperatures than steam injectors. The objection to them is the cost of the air-compressing machinery. (3) *Mechanical injectors.* The oil under pressure operates a revolving device in the nozzle of the burner which causes the oil to be delivered in a very fine spray. Some burners of this type have given excellent results. With these burners it is necessary to supply the oil under a high pres-

sure, say from 50 to 80 pounds per square inch and to heat it before reaching the burner to a temperature of from 120° to 180° F. in order to reduce its viscosity.

More important than the burner is the furnace. It must be of sufficient size to give ample room for complete combustion of the gases formed by decomposition of the oil before these gases are allowed to be chilled by contact with the heating surfaces of the boiler. For economy of oil the air supply should be regulated so that the excess of air is not more than 50 per cent above that theoretically required for complete combustion.

**POWDERED FUEL BURNERS AND FURNACES.**— In burning powdered fuel, it is necessary that the coal be dried to a moisture of 1 per cent or less. The coal must be ground to such fineness that 95 per cent will pass through a 100-mesh screen and 80 to 85 per cent through a 200-mesh screen. Reliable regulation of the coal and air supply seems to be the principal requirement of a good burner. John V. Cullney specifies the essentials as: (a) uniform feed; (b) proper mixture of coal and air; (c) proper control and ability to vary coal supply; (d) simplicity; (e) compactness. The life of furnaces using pulverized coal varies with the type of furnace. Information available at the present time indicates that the life of such furnaces is about the same as for furnaces using oil. The working temperatures of powdered fuel furnaces seem to range from 1800 to 3000° F.

**Cost of Grinding and Handling, including Upkeep (Pre-war figures).**— These items vary considerably with plants of different size and under different operating conditions. The cost of grinding, drying, handling, etc., per ton of fuel, as reported by four companies is as follows:

For Plant (a) about 45 cts. per ton, subdivided as follows:

Labor.....	15 cts.
Power.....	10
Repairs.....	14.5
Coal for drying.....	5.5
	<hr/>
	45 cts.

For Plant (b), based on 200 tons in 24 hours, excluding overhead charges, interest, and depreciation.

Price of coal	Cost of grinding, handling, etc.
\$1.....	17.6 cts.
2.....	21.8
3.....	23.9

For Plant (c), 140 tons per 24 hours in plant built 16 years ago.

	Cost per ton.
Labor, operating.....	15.64 cts.
Labor, repairs.....	1.70
Supplies, fuel, power, etc.	14.71
Oil and waste.....	1.25
Repairs.....	4.54
	<hr/>
	37.84 cts.
Interest, depreciation and obsolescence.....	1.35
	<hr/>
	39.19 cts.

For Plant (d), from 11.4 cts. per ton to 49.7 cts., depending upon the degree of pulverization, amount of coal consumed, etc.

**SUPERHEATERS.** — To obtain the advantages of superheated steam (*see* *art.*), various forms of superheaters are employed. A superheater consists essentially of a number of small tubes, through which the steam is passed, and is heated by the hot gases in the boiler or from some external source. In this country the superheater is nearly always placed within the boiler setting. Frequent cleaning of the exterior walls of the superheater tubes is necessary to prevent the accumulation of soot. It is customary to provide for the flooding of the superheaters when the boiler is banked and no steam is being raised; this procedure may be undesirable when the feed water contains much scale-forming impurity, as superheater tubes are not readily cleaned internally.

**PERFORMANCE OF BOILERS.** — The number of boiler horse-power (i. e., the number of pounds of steam from and at 212° F. divided by 34.5) which can be obtained from a boiler depends upon the heating surface of the boiler, the grate area of the furnace, the quality of coal used, the method of firing, etc. Consequently the horse-power rating of a boiler is at best but an exceedingly rough indication of its capacity, and therefore the modern tendency is to rate a boiler in terms of the number of square feet of heating surface. If the horse-power rating is also given, this is usually taken arbitrarily for water tube boilers as the number of square feet of heating surface divided by 10; that is, 1 boiler horse-power is taken as equivalent to 10 square feet of heating surface. Some of the modern boilers, however, are operated normally under conditions such that the boiler horse-power actually developed is twice the rating on this basis. Holders of fire tube boilers usually rate them on the basis of 11 to 12 square feet per boiler horse-power.

**Boiler Capacity.** — The capacity of a boiler may be expressed in terms of the boiler horse-power which may be obtained from it, or, more definitely, in terms of the number of pounds of water which can be evaporated in it. The capacity of a boiler, by which is meant the quantity of steam it will make in a given time, depends (1) upon the quantity of heat that can be generated in the furnace, and (2) upon the percentage of this heat that is absorbed by the boiler and not wasted in the chimney gases or by radiation.

The first essential of boiler capacity for a given heating surface is furnace capacity, and this depends chiefly upon three things, area of grate surface, quality of fuel and force of draft. It may also depend upon the kind of grate, plain or shaking grate, or mechanical stoker; upon the roof of the furnace, whether formed of the heating surface of the boiler, or of fire brick; and upon the introduction of air above the fire in addition to that which passes through the grate. The second essential of boiler capacity is boiler efficiency. Other things being equal, anything that increases the efficiency of a boiler increases its capacity in the same ratio.

**Factors Affecting the Efficiency of a Boiler.** — Boiler efficiency depends: (1) on the quality of the coal (or other fuel) as regards its content of moisture and volatile matter (*see* *article on Fuels*); (2) on the completeness with which the coal is burned in the furnace, before the gases of combustion reach the heating surface; (3) on the combustion being effected with the least possible excess of air, above 20 per cent excess being necessary to avoid imperfect combustion; (4) on the cleanness of the heating surface, inside and out; (5) on the proper baffling of the gases, so as to avoid short-circuiting; (6) on the heat lost by radiation; and (7) on the extent of the heating surface relative to the quantity of heat generated, or to the rate of driving of the boiler, as measured by the heat absorbed in a given time per square foot of heating surface (*see* *article on Heating Surface, below*). In general the efficiency of a boiler may be represented approximately by the equation

$$\epsilon = \frac{T_1 - T_2}{T_1}$$

in which  $T_1$  is the temperature of the fire and  $T_2$  the temperature of the chimney gases. The temperature  $T_1$  is proportional to the heat generated in the furnace assuming the specific heat of the gases to be constant, and  $T_2$  to the heat in the chimney. The loss by radiation is not considered in the formula, this is generally not over 2 to 3 per cent when a boiler is driven at a normal rate.

**Values of Boiler Efficiency.** — The *highest* efficiency that is obtainable with ordinary boilers and furnaces, fired by hand, is about 79 per cent with anthracite and 76 per cent with bituminous coal. As high as 81 per cent is possibly be obtained with bituminous coal with very large boilers, provided with mechanical stokers, and 82 per cent with oil fuel. With economizer heating the feed water by the waste heat of the gases from the boiler, the combined efficiency of boiler and economizer may be as high as 90 per cent.

The necessary conditions for obtaining these high figures of efficiency are: (1) that the coal is of good quality, low in moisture; (2) that the coal is burned uniformly and with uniform conditions of air supply, so that the grate is not obstructed by clinker or imperfectly covered by coal; (3) that the rate of driving does not exceed 3 pounds evaporation per square foot of heating surface per hour; (4) that the air supply does not exceed 20 pounds per pound of coal burned; (5) that the combustion of the gases is completed in the furnace so that no unburned gases touch the heating surface of the boiler and be chilled below the point of ignition; (6) that the path of the gases through the boiler is so baffled as to cause them to traverse uniformly all parts of the heating surface; (7) that the heating surface is free from soot and dust on the outside and from scale or grease on the inside.

The conditions of high efficiency above described are obtained only in the best-managed plants, where the chimney gases are constantly analyzed and a check on the air supply (see below under *Tests of Boilers*). In the average practice in everyday practice the efficiency may be anywhere from 10 to 30 per cent below the best possible.

Boiler efficiencies are usually graded as follows: 50 to 60 per cent, poor; 60 to 70 per cent, fair; 70 to 75 per cent, good; over 75 per cent, excellent.

**Effect of Rate of Evaporation on Efficiency.** — On the basis of 10 square feet of heating surface per boiler horse-power (34.5 pounds of steam per hour and at 212° F.) approximately 3 pounds of steam are evaporated per square foot of heating surface when the boiler is developing its rating at normal steam pressure and temperature. If there is sufficient grate surface and draft the evaporation may be increased to 6 or in emergency to 15 pounds of steam per square foot of heating surface. The efficiency, however, falls off with increased rate of driving. The following figures are taken from a test by D. S. Jacobus (*Trans. A.S.M.E., 1911*) on a large Stirling boiler (23,650 square feet of heating surface).

**Equivalent evaporation**

per square foot =	3.24	3.40	3.72	4.18	5.22	5.62	6.40	6.67	6.75
Over-all efficiency =	81.2	81.0	80.3	79.2	77.1	77.9	76.4	76.7	75.6

Still higher rates of driving and the corresponding efficiencies are given by these figures being taken from a test of Babcock & Wilcox boilers designed for the United States warships "Cincinnati" and "Wyoming" (*Industrial Engineering, March, 1911*). The results are as follows:

**Equivalent evaporation per square**

foot =	8.42	8.75	9.03	9.58	10.1	10.5	13.7
Over-all efficiency =	70.4	70.6	72.2	68.2	70.2	71.0	64.5

These efficiencies are all exceptionally high for the given rates of driving, and the relative efficiencies for the different rates are representative of good stoke practice.

**Thickness of Fire and Efficiency.** — Too thin a fire results in excess air and too thick a fire in a deficiency, unless sufficient draft is provided by fans or tall chimneys (*see Draft, Mechanical*). There are so many factors to be considered that the proper thickness for maximum economy in any particular case can be determined only from actual test. Under ordinary conditions of hand-firing the thickness of fire for best efficiency ranges from 6 to 12 lbs.

**Air Supply and Efficiency.** — The air supply for maximum efficiency, other conditions remaining constant, is about 17 or 18 pounds per pound of fuel.

With an air supply lower than 17 pounds the efficiency is likely to fall off, on account of imperfect combustion. If the air supply is greater than 20 pounds the efficiency falls off very rapidly, the excess air supply causing a reduction in temperature in the furnace and an increase of heat carried into the chimney.

**Heat Balance and Distribution of Losses.** — By the "heat balance" is meant a statement accounting for ultimate distribution of the B.t.u. in the fuel supplied to the boiler. Such a statement is usually made up as follows. The figures given illustrate the ordinary range for the various items.

#### HEAT BALANCE PER POUND OF COMBUSTIBLE

Item	B.t.u.	Per cent
1. Heat absorbed by the boiler.....	.....	80-90
2. Loss due to heating moisture in coal.....	.....	0.2-2.0
3. Loss due to heating moisture formed by the burning of hydrogen.....	.....	0.5-4.0
4. Loss due to heat carried away in the dry chimney gases.....	.....	12-30
5. Loss due to incomplete combustion of carbon (CO in flue gas).....	.....	0.0-3.0
6. Loss due to		
a. Unconsumed hydrogen and hydrocarbons (smoke and soot).....	.....	0.0-1.5
b. To heating the moisture in the air.....	.....	0.2-1.5
c. To carbon lost through grate.....	.....	0.5-3.0
d. To radiation.....	.....	1.0-3.0
e. Unaccounted for.....	.....	1.0-10.0
Total.....	11,000 to 15,500	100

The five items under 6 are frequently given as a single item.

**TESTING OF BOILERS.** — The principal observations made during an "evaporation" test of a boiler are pounds of water evaporated, pounds of coal fired, steam pressure and feed-water temperature. Records of the water evaporated and the coal fired should be made for each hour of the test if possible. The steam pressures and feed-water temperatures are recorded every half-hour or oftener, and averaged for the whole test. All conditions should as nearly as possible be the same at the end as at the beginning of the test. When the boilers are hand fired, tests of 8 to 10 hours duration are usually sufficient, but when mechanical stokers are used it is difficult to obtain an equal quantity and condition of the coal in the furnace at the beginning and end of the test, and a

large error in the results may be made if the test is much shorter than 24 hours. The average moisture in the coal should be determined and the ash and refuse should be weighed.

In all important tests the code of the American Society of Mechanical Engineers (new code to be published shortly, 1922) should be followed. The principal data and results given in this code are as follows:

#### PRINCIPAL DATA AND RESULTS OF BOILER TEST.

- |   |                  |
|---|------------------|
| 1. Grate surface (width . . . . , length . . . . ) . . . . .                                  | sq. ft.          |
| 2. Total heating surface . . . . .  | sq. ft.          |
| 3. Date . . . . .   |                  |
| 4. Duration . . . . .   | hr.              |
| 5. Kind and size of coal . . . . .  |                  |
| 6. Steam pressure by gauge . . . . .  | lb.              |
| 7. Temperature of feed water entering boiler . . . . .  | ° F.             |
| 8. Percentage of moisture in steam or number of degrees of superheating . . . . .             | per cent or ° F. |
| 9. Percentage of moisture in coal . . . . .   | per cent         |
| 10. Dry coal consumed per hour . . . . .  | lb.              |
| 11. Dry coal consumed per sq. ft. of grate surface per hour . . . . .                         | lb.              |
| 12. Equivalent evaporation per hour from and at 212° . . . . .                                | lb.              |
| 13. Equivalent evaporation per hour from and at 212° per sq. ft. of heating surface . . . . . | lb.              |
| 14. Rated capacity per hour, from and at 212° . . . . .                                       | lb.              |
| 15. Percentage of rated capacity developed . . . . .  | per cent         |
| 16. Equivalent evaporation from and at 212° per lb. of dry coal . . . . .                     | lb.              |
| 17. Equivalent evaporation from and at 212° per lb. of combustible . . . . .                  | lb.              |
| 18. Calorific value of 1 lb. of dry coal by calorimeter . . . . .                             | B.t.u.           |
| 19. Calorific value of 1 lb. of combustible by calorimeter . . . . .                          | B.t.u.           |
| 20. Efficiency of boiler, furnace and grate:  |                  |

$$100 \times \left( \frac{\text{Item 16} \times 970.4}{\text{Item 18}} \right) \dots\dots\dots \text{per cent}$$

21. Efficiency of boiler and furnace:

$$100 \times \left( \frac{\text{Item 17} \times 970.4}{\text{Item 19}} \right) \dots\dots\dots \text{per cent}$$

**Flue Gas Analysis and Heat Balance.** — See Kent's *Mechanical Engineer Pocket-Book* and Gebhardt's *Steam Power Plant Engineering*.

**SPECIFICATIONS FOR STEAM BOILERS.** — As nearly all steam boilers are now made by large manufacturing concerns who have their own specifications as to details of construction, quality of material, etc., it is rare the case that an engineer of a power plant or a consulting engineer is called on to make an original design of a boiler or to furnish detailed specifications for one. What is usually done is to call for bids on general specifications, naming the quality of coal to be used, the kind of furnace or stoker, the horse-power to be developed (34.5 pounds of water evaporated from and at 212° F. = 1 h.p.; when the boiler is driven at a rate not to exceed 3.5 pounds per square foot of heating surface per hour, evaporated from and at 212° F., and the overload cap-

desired for higher rates of driving, or "the peak of the load." The bids received are then tabulated as to the details, such as heating surface, grate surface, size of combustion chamber, size of tubes, diameter of shell, quality of steel, size of riveting, factor of safety, space occupied, guarantees of capacity and economy, etc., and a selection made of the boiler that appears to be the most suitable for the location. Of two boilers that have the same heating surface one that has the largest grate surface is the one that has the greatest overload capacity, if the draft is the same in both cases. Guarantees of capacity and economy may be disregarded when bids are for ordinary forms of boilers and furnaces, for the capacity and economy of two boilers of the same size of grate and heating surface will be practically the same whatever the type or form of the boiler, but they will vary greatly from causes independent of the boilers themselves, such as quality of coal, method of firing, kind of furnace, size of combustion chamber, etc.

**OPERATION OF BOILERS.** — To obtain the best results from boilers, considerable care must be paid to the firing and regulation of air supply.

**Firing.** — There are three common methods of hand firing: (1) the alternate, in which fresh coal is fired on one side of the grate at a time, the combustion of volatile matter being assisted by the heated air passing through the other side; (2) the spread-firing, in which small amounts are spread thinly over the entire grate bed; and (3) the coking, in which a thick bed of fresh coal is fired directly in front of the door and allowed to coke, after which it is pushed back into the furnace. The best method for any particular kind of fuel, style of furnace and rate of driving should be determined by experiment.

Mechanical stokers (*see Stokers, Mechanical*) afford the following advantages: (1) the uniform feeding of coal, the close regulation of the air supply at all times, and consequently smokeless and efficient combustion with a wide range of loads, and a great reduction of labor cost in handling and firing fuel. In small plants with poor load factors the expense of installation is generally considered prohibitive, but in plants of 1500 kilowatts or more a considerable net annual saving can usually be obtained.

**Air Supply.** — (*See also Chimneys; Draft, Mechanical.*) The extent of the heat losses is determined by the amount of gas discharged, the temperature at which it is discharged, the amount of incompletely burned gas discharged and the amount of latent heat carried away in water vapor. The minimum economic amount of flue gas would obtain with the amount of air supplied to the fire exactly equal to the theoretical requirements of complete combustion. The admission of less air tends to the production of CO. More air dilutes the flue gas, increases the total amount of gas rejected and, in the same ratio, increases the amount of heat rejected, the stack temperature remaining the same. The theoretical air supply per pound of combustible (*see Fuels*) is approximately 15 pounds, but since the air and fuel cannot be mixed with perfect intimacy it is necessary to considerably increase this amount to prevent the formation of CO. *See above under Air Supply and Efficiency.*

**CO<sub>2</sub> Recorders.** — The per cent of CO<sub>2</sub> in the flue gas is an index of the air excess, provided combustion is complete. With perfect combustion and no excess air 20.9 per cent CO<sub>2</sub> should be obtained with pure carbon as fuel, or 18.6 per cent with a fuel composed of 95 parts C and 5 parts H. In practice more air must be supplied and 14 per cent CO<sub>2</sub> represents about the upper limit which should be attempted. 17 per cent CO<sub>2</sub> is good, 10 per cent fair and 5 per cent poor. Several types of CO<sub>2</sub> recorders have been devised. If properly maintained and interpreted they form a valuable check on the regulation of the air supply. Their indications, however, give no clue to the presence of CO, and are directly significant only when the formation of CO is prevented.

**Flue-gas Temperature.**— Because of the great heating surface which would be required it is not practicable to reduce flue-gas temperature to less than 75 degrees above the feed water. Economizers or flue-gas feed-water heaters (see *Feed-water Heaters*) assist in lowering the temperature of discharge but add considerably to the space required, increase the cost of installation and maintenance and increase the total draft required. Without economizers it is seldom economical to attempt to reduce the gas temperature below 450° F.

**Smoke** represents a minor element of loss *per se*, seldom exceeding 1 per cent but it is generally an index of inefficient combustion. Smoke is usually due to a poorly regulated air supply, an imperfect mixture of air and fuel, or the rapid volatilization of hydrocarbons and their premature chilling in a half-burned state. The absence of smoke, however, is not a final index of efficiency for the air supply may be excessive. See also article on *Smoke Prevention*.

**Feed Water.**— (See *Feed-water Heaters; Pumps and Pumping Engines*.)

**Cleaning Tubes.**— The tubes of a boiler should be kept clean, both internally and externally. For blowing the soot off the external surface the use of water tube boilers or off the internal surface of the tubes of fire tube boiler a steam jet blower is ordinarily used. For removing scale from the interior of water tubes different forms of scrapers or chippers are used, also rotary cutting devices driven at a high speed by steam, water or other power. For removing scale from the water side of fire tubes of horizontal tubular boilers the usual method is the operation of chipping and hammering by a man working inside of the boiler. Sometimes the scale is softened by the use of soda or other chemicals, before chipping, and a strong jet of water from a hose assists in detaching the scale. In locomotive practice it is often necessary to cut the tubes out of the boiler and run them through a cleaning machine, and then to weld a piece of each tube on one end to restore its original length, and to reset the tubes in the boiler.

**DIMENSIONS OF BOILERS.**— An ordinary fire tube boiler occupies a floor space of from 1.5 to 2.0 square feet per boiler horse-power (on the basis of 12 square feet of heating surface per horse-power). A water-tube boiler occupies from 0.5 to 1.0 square foot of floor space per boiler horse-power (on the basis of 10 square feet of heating surface per horse-power). With either type the height ranges from as low as 7 to as high as 30 feet depending not only on the horse-power but also on the style, whether horizontal or vertical. One boiler is sometimes placed directly on top of another, making "double-deck" arrangement. For complete dimensions see the manufacturer catalogues.

**COST OF BOILERS (Pre-war figures).**— The selling price of boilers per rated horse-power (10 square feet of heating surface = 1 horse-power) ranges from about \$8 to \$25, depending upon the size, the pressure they are to sustain, the style and design, etc. The lowest prices named are for large-sized ordinary horizontal tubular boilers (fire tube) for low pressures. For power plants of 1000 horse-power and over the price will range usually between \$10 and \$15 per horse-power at pressures not over 150 pounds per square inch. For higher pressures and for boilers provided with superheaters the prices will be higher. For boilers of less than 100 horse-power the price per horse-power increases as the size decreases. The prices named are for the boilers with the usual fittings of grates, steam and water gauges, blow-off and stop valves, on board cars at the boiler works, and do not include the cost of erection nor of brickwork, flues or chimneys. (See also *Power Station*.)

The following approximate rules, in which  $P$  = boiler horse-power, may be used for determining the cost of boilers:

- ) Horizontal return tubular boilers.  
 Cost f.o.b. factory (\$) =  $180 + 6.4P$   
 Cost of setting (\$) =  $140 + 2P$ .
- ) Horizontal water-tube boilers, 125 lb. pressure.  
 Cost f.o.b. factory (\$) =  $425 + 9P$ .  
 Cost of setting (\$) =  $140 + 2P$ .
- ) High grade water-tube boiler, 160 lb. pressure.  
 Cost f.o.b. factory (\$) =  $1000 + 10P$ .
- ) High grade water-tube boiler, 200 lb. pressure.  
 Cost f.o.b. factory (\$) =  $1300 + 12P$ .

**BONDS, RAILWAY TRACK.** — (See also *Third Rail Systems; Trolley Systems; Wires and Cables.*) Rail bonds are electrical conductors for bridging the joints of rails. They consist either of a series of thin strips of annealed copper, or of one or more cables of copper wire, the ends of which are usually pressed or cast into solid copper terminals. Ribbon is more compact, but stranded wire is more flexible; the latter should always be used if space permits. Sometimes the terminals are made by upsetting the ends of a stranded conductor, so as to form a crude bond head. The terminals of the headed bond are then heated to a welding heat in furnaces, and pressed to the proper size and shape, the separate wires in the terminals becoming a solid mass of homogeneous copper. After being cleansed of all foreign substances the terminals are shaved to the proper size.

**TYPES OF BONDS.** — Bonds may be classified, according to the method of fastening them to the rail, as soldered bonds, brazed bonds and bonds applied by mechanical pressure.

**Soldered Bonds** (Figs. 1 and 2) usually consist of a series of thin strips of annealed copper with tinned terminals as shown in Figs. 1 and 2. They are

Fig. 1.

Fig. 2.

soldered direct to the head, foot or web of the rail. One or more bonds per joint may be used. A few companies employing well-trained workmen continue to install bonds of this type, but they have generally been abandoned.

**Brazed Bonds** resemble soldered bonds except that the terminals are encased in brass. They are brazed or welded to the rail by heat generated electrically in a carbon which constitutes one jaw of a clamp holding the bond against the rail. These are sometimes known as "electrically welded" bonds.

**Expanded and Compressed Terminal Bonds.** — Bonds fastened to the rail by mechanical pressure may be divided into two general classes, expanded terminal and compressed terminal bonds. Both kinds are called "stud terminal" bonds. The number of stud terminal bonds in use greatly exceeds that of any other kind, brazed bonds being second.

Fig. 3.

**Pin-expanded Terminal Bonds** (Fig. 3) have their heads drilled with an axial hole, through which a tapered steel pin *d* is driven, forcing the copper

## Bonds, Railway Track

tward and against the steel. This type of bond is fastened to the web of the rail.

**Compressed Terminal Bonds** (Figs. 4 and 5). — There are two kinds of compressed terminal bonds, in one of which direct pressure is applied at both ends of the head, and in the other, at one end only. The first type of bond is usually applied to the web of the rail by means of a heavy screw or hydraulic press (Fig. 6) which engages the bond head and causes it to compress longitudinally and expand laterally as the pressure is applied, bringing the copper into

Fig. 4.

Fig. 5.

contact with the steel and spreading the projecting end of the terminal into a button-shaped rivet-head, as shown in Fig. 4. The second type of bond (Fig. 5) is applied only to the head of the rail, the terminal lugs being set in holes therein and expanded into contact by means of hammer blows.

**Compressed Terminal Soldered Bond.** — A type of bond which has been found very successful at the Detroit River Tunnel for third-rail work is a compressed terminal head bond soldered to the rail. The combination of mechanical adhesion and soldering has resulted in a bond of unusual durability. (F. B. P. Wren.)

**Exposed Versus Concealed Bonds.** — Whether soldered, brazed, expanded or compressed, bonds may be either exposed or concealed (Fig. 6) under the fish-plates. The former condition is preferable, if there is no likelihood of theft, as it permits inspection to be easily made. Where the bonds are exposed to theft, as, for example, on track rails unprotected by paving, concealed bonds are almost a necessity.

Fig. 6.

While concealed bonds are necessarily applied to the web of the rail, exposed bonds may be applied to the foot or head. Head bonds have the advantage of greater contact surface at the terminal studs, while foot bonds are less exposed to mechanical violence. Web bonds, unless concealed, have to be excessively long in order to span the fish-plates.

**USES OF VARIOUS TYPES OF BONDS.** — Bonds are used for track rails, third rails and girders of elevated and subway lines. Soldered bonds and compressed terminal head bonds find their best application in third-rail work, where good electrical contact is of greater importance than mechanical strength. Expanded terminal web bonds, especially of the concealed type with two stranded conductors, are regarded as the best for heavy track work, where mechanical strength and ease of installation are of the utmost importance.

**SUBSTITUTES FOR BONDING.** — Several efficient substitutes for bonding are now in use, such as electrical welding, cast welding and Thermit welding.

**Electrical Welding** is performed by clamping an iron bar to the web of the rails, and bringing the bar and the neighboring part of the rail to a white heat by

means of an electric current. Another process accomplishes the welding by means of a carbon electrode. A modification of the latter process makes use of a composition bar which is clamped against the fish-plate. A soft steel is placed in a groove between the rail and composition bar supplies the weld material.

Cast Welding is accomplished by setting a mold around the rail joint and pouring molten iron around it. The Thermit process is a modification of this the iron being liberated at a white heat from a mixture of iron oxide and aluminum, which is ignited in a crucible.

**SELECTION OF TYPE AND SIZE OF BOND.** — Considerations determining the choice between concealed and exposed bonds are liability of theft, electrolytic corrosion, facility of inspection and injury to fish-plate bolts of old rails.

The choice between mechanical adhesion and soldering depends largely upon the importance of rapid installation, the mechanical stresses to be withstood in service, the type of labor available and the facilities for the use of drills, presses, etc.

**Single vs. Double Bonding.** — Joints are sometimes bonded with one and sometimes with two bonds. Double bonding has the advantages of less chance of complete failure and greater carrying capacity for a given cross-section of copper. It, however, has the disadvantages of being more expensive and giving uncertain results in testing.

**Selection of Cross-sectional Area of Bond.** — The cross-sectional area of a rail bond should, as a rule, be not greater than is necessary to keep its temperature at a safe working amount, unless greater area is required for mechanical strength. The resistance of the bonded joint is of secondary importance unless very high, because the resistance of the joints is usually a mere fraction of the total track-rail resistance (see below).

**Carrying Capacity of Bonds.** — The carrying capacity of rail bonds is not very well known as the manufacturers do not supply any data on this subject for their various products. The excellent heat conductivity of copper and the large heat storage capacity of steel rails tend to make the carrying capacity of bonds in cold weather considerably greater than that of free wire of the same size, especially if the bonds are short. In hot weather, however, the rails and consequently the bonds are likely to become hot from exposure to the sun's rays, thereby reducing the effective carrying capacity of the bonds.

Tests to determine the ultimate carrying capacity of soldered bonds indicate that a 500,000 circular mil bond of the type shown in Fig. 1 will carry 350 amperes continuously without injury, but will melt off in 5 or 10 minutes at 10,000 amperes. On the basis of this test assuming the cooling surface per unit length of a bond to be proportional to the square root of its cross-section, the safe carrying capacity of a bond of  $A$  circular mils cross-section is

$$I = \frac{A}{5.6 \sqrt{A}}$$

Or, the cross-section required for a given current is

$$A = 10 I \sqrt{I}$$

**Resistance of Bonds.** — The total resistance of a bond is the sum of the resistances of the copper in the bond and the contact resistance between the body of the bond and the terminals and the contact resistance between the

minals and the rail. The following table gives the resistance of a well-bonded joint at 75° F., including the body resistance and the two contact resistances at each end.

RESISTANCE OF BONDED JOINT IN MICROHMS ( $10^{-6}$  OHMS)

Size L. W. G. or B. & S. and C. M.	Diameter of termi- nals, inches	Length of bond in inches, between centers of terminals							
		9	12	15	18	24	30	36	42
500,000	1	28	33	39	44	55	65	76	87
400,000	1	32	39	46	52	66	80	93	106
300,000	1	38	46	55	63	80	97	114	131
250,000	$\frac{3}{4}$	44	54	65	75	95	116	136	157
200,000	$\frac{3}{4}$	50	62	75	87	111	136	160	185
150,000	$\frac{3}{4}$	60	75	91	107	137	169	200	230
100,000	$\frac{3}{4}$	72	91	112	131	171	210	250	290
75,000	$\frac{3}{4}$	87	112	137	162	211	260	310	360

**Bonding Efficiency and "Equivalent" Length of Joint.**—The bonding efficiency\* of a bonded rail system (having one bonded joint to each rail length) is the ratio of its conductance to that of an equal length of perfectly continuous rail without any breaks or joints. By "equivalent" length of a joint is meant the length of continuous rail having a resistance equal to that of the bonded joint. Let

$B$  = bonding efficiency,

$l$  = distance in feet measured along the rail between centers of bond terminals,

$l'$  = equivalent length of bonded joint in feet,

$L$  = length in feet of a full rail section,

$r$  = resistance of rail per foot,

$R_j$  = resistance of bonded joint.

then

$$r = \frac{R_j}{l'}$$

$$B = \frac{1}{1 + \frac{l'}{L}}$$

For values of  $r$  see article on *Rails*. The equivalent length of a properly bonded joint ranges from 1 foot to 6 feet, depending upon the size of rail, number and cross-section of bonds, length of bond, etc. (See also section on *Rebonding*, this work.)

It is common practice to bond a joint with a bond having one-half the conductance of the rail. Hence for a 12-inch bond, and 30-foot rail section, assuming 12 inches between terminals measured along the rail,  $l = 0.75$  and  $l' = 2$ , giving a bonding efficiency of 96 per cent.

**Selection of Length of Bond.**—The length of concealed bonds is necessarily determined by the dimensions of the rail and fish-plate, and by the bolt-hole drilling. The length should never be less than ten inches for single bonding

\*The efficiency of individual bonds is sometimes stated as the ratio of the distance along the rail between centers of bond terminals to the equivalent length =  $l/l'$ .

and should generally be greater, it being usual practice to place the terminal between the first and second bolt holes. In double bonding it is customary to place one terminal of each bond between the first and second bolt holes on each rail, and the other terminals beyond the second bolt holes. It is unusual to use concealed bonds 2 feet long for double-bonded rails on electrified steam roads. Exposed bonds are usually made as short as is consistent with the flexibility requisite to withstand vibration and other rail movements.

Tests by H. H. George (E.R.J., 1914, Vol. 44, p. 487) on No. 0000 strands wire bonds showed the following relative number of vibrations to produce fracture.

Length of Bond inches	Relative number of vibrations
7	1.0
8	5.2
10	31.2
14	194.0

**Effect of Vibration and Expansion of Rails.**—The continuous bending of a copper wire or ribbon will cause local hardening and crystallization of the metal, and eventually lead to fracture. It is, therefore, important to save track bonds from vibration as much as possible, and they should be initially designed to withstand the vibration they are likely to experience in use. The best way to accomplish this is to use long thin wires of soft annealed copper entirely free from surface imperfections.

According to the A. S. W. Co., Cut. No. 3, wires of from 0.040 to 0.045 in diameter give the best general service for short bonds.

Concealed ribbon bonds, and to a less extent wire bonds, frequently break at the loop between rail bolts, first, because the operation of crimping slightly hardens the copper in the loop, and second, because the travel of the rails, due to their expansion and contraction, is wholly taken up in the loops, causing the copper to crystallize and break at this point. Of course this action is aggravated by any severe jarring or vibration of the joint.

**SPECIFICATIONS.**—(See also article on *Specifications and Contract*.) Specifications for rail bonds should state the exact service conditions under which the bond is to be used, the style of adhesion desired, the part of the rail they are to be applied to, the style of conductor (ribbon, solid wire or cable), the cross-sectional area, the contact area of the stud, the formed length between centers of terminals, and the fish-plate and bolt layout, if the bonds are to be concealed.

**INSTALLATION.**—The foremost consideration in the installation of bonds is the cleanliness of the bonds and bond holes, or other adhesion surfaces. Unless this is secured the bonds will be electrically defective whatever their mechanical strength may be.

**Soldered Bonds.**—The rail surface is brightened by means of a carbonyl or emery wheel, then tinned, using an acid flux. The bond is then clamped in place and the rail and bond heated by means of a blow-torch, to a temperature at which the solder will melt and cause the bond to adhere firmly to the rail.

**Brazed Bonds.**—The preliminary processes are the same as for soldered bonds except that a special clamp is used, the terminals of which are the electrodes of an electrical circuit, one being of copper and the other of carbon.

The surface of the rail being previously ground bright at the point where the weld is to be made, the brass-enveloped bond terminal is placed in position against the rail at this point, held there and pressed against the rail by the carbonyl

electrode, the copper electrode being in contact with the opposite side of the rail. The current, on passing from one electrode to the other, traverses the bond terminal and rail, the carbon becoming incandescent. The incandescent carbon pressing the copper against the rail quickly transmits sufficient heat exactly the point where it is required, to produce the weld. To make a weld, the current is applied for a period of from 45 seconds to two minutes, depending on conditions.

**Welding Outfit.** — It is claimed by the manufacturers of one type of welding outfit that an average of over 100 bonds per day is readily installed by their car operating with four men, a bonder and three helpers. This car is about 6 feet, 10 inches long by 5 feet, 10 inches wide, and carries an 18-kilowatt motor converter and transformer, with the necessary apparatus for their safe operation. To weld an average-size rail bond to the rail, an alternating current of about 2000 amperes at 5 volts is employed. On d-c. railways this is obtained by converting and transforming about 20 amperes at 500 volts taken from the trolley wire.

**Pin-expanded Bonds.** — The rail is drilled, usually through the web, with a diamond without lubricant, using some form of drill especially adapted to this service.

Fig. 8.

Drilling without lubricant has the advantage of giving a perfectly clean hole, and is now generally preferred. Holes are drilled to the same diameter as the bond studs, and rust or scale on the web of the rail is removed around the hole. The bond head is then inserted into the hole, and a long taper punch lubricated with grease is driven entirely through the terminal. Then a short drift pin is driven home, as shown in Fig. 3. The diameter of the hole is usually increased

about  $\frac{1}{8}$  inch by the expansion process. From 100 to 200 bonds may be installed with one taper punch before it is worn down to an appreciable extent.

This type of bond requires a smaller equipment in tools and materials than most other types and does not necessitate the use of any apparatus which obstructs the track and thereby endangers traffic.

**Compressed-terminal Web and Foot Bonds.**— The drilling and cleaning having been performed as for a pin-expanded bond, and the bond being inserted into their respective holes, a screw or hydraulic compressor, as shown in Fig. 8, is applied at both ends of the bond head, the conical point of the press fitting into the conical depression of the bond. Pressure is applied, either until the collar on the ram touches the rail, or until the head of the bond acquires its proper shape. Where no collar is used the point of the press (if of the screw type) sometimes cuts into the bond head; this may be avoided by placing a small amount of flake graphite mixed with oil in the depression of the bond head.

**Compressed-terminal Head Bonds.**— A four-spindle drill is used to drill four holes simultaneously in the rail heads. It is important to avoid drilling the holes too deep lest the copper should not touch bottom and therefore be unable to expand laterally. If, on the other hand, the hole is too shallow expansion will occur too soon.

**Pressure and Contact Resistance.**— It has been found by P. M. B. P. C. Smith and C. B. Starbird (*St. Ry. Jour.*, Sept. 14, 1907) that the pressure of a compressed-terminal rail bond against the steel rail, which gives a reasonable low-resistance value, is from 25,000 to 30,000 pounds per square inch of contact surface. To obtain this pressure a compressor giving a direct pressure of 1500 psi per square inch of terminal steel section is required. This pressure being well below the elastic limit of steel, the metal of the rail does not take a permanent set. Furthermore, if the contact surface of the bond terminal be increased, no appreciable decrease of resistance will occur unless the pressure is correspondingly increased. The contact resistance between annealed cast copper and steel is from 30 to 60 per cent higher than the resistance between annealed rolled copper and steel.

The copper of a bond head is hardened by the pressure it is subjected to, and like the steel, is distorted within its elastic limit, causing the surfaces to adhere even if the pressure is reduced to one-third its original value, say 10,000 pounds per square inch. Between these two pressures, the electrical resistance does not vary. Expansion due to heat, therefore, has no effect upon the resistance of bonds.

**TESTS AFTER INSTALLATION.**— Out of 42 companies 15 do not inspect regularly, 6 test only by inspection, and melted snow. Twenty-one companies which inspect, test at the following intervals

Interval, months	Number of companies
3	2
6	10
12	12
18	1

Twenty-three of these companies use portable bond testers; four use automatic graphic test cars.

**Resistance Test.**— The usual method of testing is to measure the drop potential across the bonded joint and find simultaneously the length of a continuous rail in which the same drop occurs, i. e., the "equivalent" length of the

led joint. Several ingenious instruments have been devised for making comparison with ease and accuracy.

**Differential Voltmeter Method.** — The most accurate type consists differential voltmeter and three contact pieces for attachment to the rail. winding of the differential voltmeter is connected to a pair of contact

as *A* and *B*, which are placed contact with the rail just over centers of the bond termi- see Fig. 9, and the other ling to a pair of contact es *B* and *C*, which span a able length of continuous . The distance *BC* is varied moving the contact *C* until voltmeter shows no deflec- . This indicates that the ntial drop between *A* and *B* equal to that between *B* and *C*, or in other words, that a length of continuous

has been found which has the same resistance as the bonded joint. The er should make sure that there is current in the rail while he is making test.

**Conant Bond Tester.** — R. W. Conant (Cambridge, Mass.) makes a d tester in which the balancing is done by sound. A clockwork interrupter, induction coil, and a telephone receiver is connected across a Wheatstone lge (see *Bridges, for Electric Measurements*). The interrupted current causes nds in the telephone receiver, which sounds diminish and disappear when drop in the rail is balanced, by the bridge adjustment, to equal the drop os the joint. This type of apparatus has the advantage of being inde- dent of the traction current in the rails, and is, therefore, constant in its itiveness.

**Herrick Test Car.** — A. B. Herrick has devised a recording instrum- nt, which being placed on a car, is able to test the bonding of a railroad while ing the car over it. The Herrick test car carries autographic recording uratos, which measures by means of millivoltmeters, the potential drop os each joint, recording on sensitized paper by an electric spark, the scale the record being usually about 1 inch to 60 feet of track. Wire-brush con- ts made of steel of composition similar to that of the rail measure the drop os joints through which low-voltage current iculated from a small motor generator set on ar. The car trucks are insulated from each r. current passing through the rail from one ct to the other, while the bond is under urement. The apparatus can also automati- ly mark bad bonds by squirting paint on the

The advantages of this method of testing are follows: 1. Uniform impressed low-voltage rent through joints while testing; 2. Heavy passing over joint breaks any transient on- tion made by fish-plate; 3. Autographic record h- ued by the bonds themselves of their con- io.

**Mechanical Strength.** — The mechanical adhesion of soldered bonds may tested by means of a lever as shown in Fig. 10. It may be used as soon

Fig. 9.

Fig. 10.

as the terminals are cool. The operation of testing consists simply in admitting each bond terminal to a predetermined pull. A properly soldered bond should stand a shearing force of 1200 pounds per square inch of contact. Calling  $S$  this shearing force per square inch,  $A$  the square inch of contact and  $P$  the pull, as registered on the balance, then

$$P = \frac{ASl}{L}$$

**REBONDING.**—The resistance at which a joint should be rebonded depends upon how much potential drop is permissible in the tracks, and upon the relative cost of the energy loss and the cost of rebonding. The latter, in turn, depends upon the probable life of a new bond. If the energy loss is of primary consideration, the resistance at which rebonding becomes economical is given by the formula below.

Let

$R$  = amount by which the resistance of the existing bond has increased over that of a new bond, ohms,

$B$  = cost of rebonding once, dollars, allowing credit for scrap material,

$I$  = root-mean-square current in the bond, amperes,

$C$  = cost of an increment of energy, dollars per kw. hour,

$T$  = expected life of the bond in days, i.e., the number of days in which its resistance is expected to increase  $R$  ohms, or in which it is to be removed for any reason whatsoever. This may be estimated from previous experience on the railway under consideration, the usual limitations being the life of the rails to which they are attached, corrosion by electrolysis, fracture due to crystallization and loosening of the terminals.

Then it is economical to rebond if  $R$  is equal to or greater than

$$\frac{B}{0.024 I^2 C T}$$

It is usual to state the resistance of bonds in terms of the number of feet of rail having the same resistance. Let  $r$  be the resistance of the rail in ohms per foot; then the increased resistance  $R$  will be represented by an increased length expressed in feet, equal to  $\frac{R}{r}$ .

It should also be noted that bonds in different parts of a railway system carry different amounts of current, those nearer the station bus carrying more than those at comparatively remote points. Hence, the economical resistance at which to rebond is less the nearer the bond is to the bus, a consideration that complicates the use of the above formula. Furthermore, as the economical resistance is inversely proportional to the square of the current, a slight error in the estimation of the root-mean-square current will lead to a considerable error in the resistance. Such errors are unavoidable, a circumstance that, taken in conjunction with the probable error in the estimated life, renders the above formula a mere approximation. It is, therefore, usual for railway companies to select some arbitrary total resistance at which to replace their bonds, this resistance being expressed in terms of equivalent length of rail. For urban lines this length varies from 3½ feet to 20 feet with an average of about 8 feet for suburban lines, a length of 12 feet or more is common.

**REPAIRS.**—If a soldered bond becomes loose, it may often be resoldered but defective bonds of other types are usually scrapped, unless the defect is of a very trivial nature. Pin-expanded bonds may, however, be reexpanded into

per holes, but with some loss in efficiency. Soldered bonds entail a comparatively large and increasing expense for repairs when applied to track rails, in spite of the fact that no failures may occur for several months after installation. Most bond failures are due to loose rail joints.

**COSTS.**—The cost of bonding is extremely variable, depending upon the type and size of bond, cost of labor, etc. The following cost data should therefore be used with caution.

## COST OF BONDING

	Cost per joint		
	Labor	Material	Total
a. 2-500,000 C.M. bonds soldered to head of third rail . . . . .	\$0.66	\$1.23	\$1.89
b. 2-500,000 C.M. pin-expanded concealed bonds applied to track rail . . . . .	0.69	2.05	2.74
c. 2-400,000 C.M. compressed terminal concealed bonds applied to track rail . . . . .	.....	.....	1.90
d. 2-000 bonds of same type as c . . . . .	0.50	1.00	1.50

Note.—In c and d the item for material includes inspection and the labor item includes primary; solder, acids and tools, not included.

**BIBLIOGRAPHY.**—(See also bibliographies in the articles on *Rails, Track and Third Rail; Railways, Systems of Electric Traction for.*) Richey, A. S., *Electric Railway Handbook*, New York, 1915; Rickett, C. W., *Track Bonding*, Trans. A.I.E.E., 1905, Vol. 24, p. 81; Shepard, E. R., *Modern Practice in the Construction and Maintenance of Rail Joints and Bonds in Electric Railways*, Tech. Paper No. 62 of Bureau of Standards, 1920. (The last of these is the most complete work on the subject.)

**BRAKES AND BRAKING SYSTEMS.** — (*See also Cars, Electric; Railways, Energy Requirements for.*) In order to stop a car or train a torque must be applied to the wheels in a direction opposite to the direction of motion of the car. This may be accomplished by applying a frictional retarding force to the wheel rims, by applying a retarding force to the axle by means of a magnetically operated friction clutch, by applying a reverse torque to the axles by operating the motors as generators, or by applying a frictional force to the rails directly by a "track brake." The method of applying a retarding frictional force to the wheel rims is the most general one and lends itself most readily to the system of manipulating the brakes by compressed air. This system has done much to improve the safety of travel on railroads. The other methods have all been tried and some have been put into practical operation, but only to meet special local conditions.

**FRICTIONAL RESISTANCES IN BRAKE-SHOE SYSTEM.** — The application of the usual brake-shoe system makes use of the frictional adhesion between the wheels and the track and between the brake shoes and the wheels. Both these quantities vary throughout a considerable range and it is therefore necessary to adjust the pressure between the various members so that it is possible to rely on a definite minimum value.

**Adhesion between Wheel Rim and Rails.** — The coefficient of adhesion between the wheel rims and rails varies from less than 15 per cent to over 30 per cent depending upon the condition of the track and the relative motion between the track and wheel rim. (*See Railways, Energy Requirements for.*) An adhesion of 15 per cent can usually be depended upon with normal track, and this can be increased to 25 per cent by the use of sand. But these values only obtain while the wheels are rolling on the track. If they begin to slide the coefficient decreases considerably. For this reason the braking effort must always be controlled so that the wheels do not slip.

**Adhesion between Brake Shoe and Wheel Rim.** — When the brakes are applied, the retarding force is applied below the center of gravity of the car body. The latter is therefore subjected to a couple and tends to press downward at the forward end and upward at the rear end, thus changing the distribution of weight on the axles and decreasing the adhesion on some axles or trucks. It is therefore not possible to figure on using for braking purposes the same weight per axle as exists at standstill. For this reason the brake-shoe adhesion must be less than the track adhesion. The coefficient of adhesion between the customary cast-iron brake shoe and the steel tire of the wheel varies with the speed, and decreases as the time of application increases. As the speed increases the coefficient drops off, being a maximum of from 30 to 25 per cent at speeds from 0 to 5 mi. per hr., 20 per cent at 20 mi. per hr., 14 per cent at 40 mi. per hr., and 7.5 per cent at 60 mi. per hr. Thus at high speeds a heavy pressure may be applied without stopping the wheels, while as the speed of the car diminishes the pressure on the brake shoes must be decreased in order to prevent gripping the wheels and causing them to slide on the track.

**Effect of Angular Momentum.** — In addition to overcoming the linear momentum of the cars the brakes must overcome the angular momentum of the gears and motor armatures. The effect of the latter is to introduce a tendency of the whole motor to rotate around the car axle and introduce additional strains on the gears and on the trucks. For this reason brake shoes hung between the wheels of a truck are better than those hung on the outside of the wheels.

**HAND BRAKES** are always provided on cars and locomotives whether power brakes are employed or not, as they are necessary to hold a car left out of service on a grade, because the air brakes will not hold a car standing idle for any

ngth of time. When a car is descending a very steep grade it is customary to set the hand brakes to hold the speed of the car and reserve the power brakes for emergency or for stopping the car. In hand braking equipment the "foundation" brakes (see next paragraph) are actuated through a drum or lever system which is hand operated.

**POWER BRAKES.** — The "foundation" brakes are that part of the brake equipment usually furnished separately from the power-braking equipment, and consist of the brake shoes, hangers, equalizers, levers, etc., back to the brake cylinder. To this is attached the desired form or make of power brake. Of the various forms of power brakes in use, viz., air, electric, regenerative and electro-pneumatic, the air-brake is the most generally used.

**Air-Brakes.** — In electric railway practice there are three systems of air-brakes in use, each of which is best suited to a definite type of service and has its particular field, as follows: (1) straight air-brake system for cars always operated singly; (2) emergency straight air-brake system for cars operated in trains of two or three but never more than three cars; (3) automatic air-brake system for cars operated in trains of any number of cars.

**Straight Air-brake System.** — The equipment for the straight air-brake system consists essentially of a motor-driven compressor, a reservoir, a brake cylinder, a motorman's valve, a train pipe, and the foundation brakes. The brakes are applied by direct pressure, that is by admitting air from the reservoir directly to the cylinder. The advantages of the system are that it is quick-acting and the braking effort is easily controlled to any value desired. Its disadvantage is that in trains a leak in the train pipe renders the brakes ineffective so that there is no means of applying the brakes on the trail-cars if the train should break apart. Sometimes instead of a compressor the motor-car carries a large reservoir which is charged at stations.

**Emergency Straight Air-brake System.** — This system involves a special valve and an extra pipe on each car so arranged that if the air pressure in the train pipe drops, due to cars breaking apart, this valve automatically turns the pressure of the reservoir into the brake cylinders and applies the brakes. The equipment of the motor car includes an extra pipe and each trail car has a reservoir, two pipes, automatic valve, brake cylinder and foundation brakes. The usual operation in service is like that of the straight air-brake.

**Automatic Air-brake System.** — This system involves the use of an auxiliary reservoir and a "triple valve" on each car. Whenever the air pressure in the train pipe is reduced, either intentionally or accidentally, this triple valve turns the air pressure of the auxiliary reservoir on each car into the brake cylinders. The brakes are applied by the motorman by opening the service pipe to the air by means of the engineer's valve. The engineer's valve has three positions, "off," "lap," and "on." By turning the handle to the "on" position the train pipe is opened to the atmosphere and the air continuously escapes. This applies the brakes with a continuously increasing pressure. When the desired pressure has been reached the handle is turned to the "lap" position, when the pressure of air in the train pipe and the pressure of the brakes on the wheels remains constant. By turning the handle to the "off" position pressure is restored in the train pipe, the brakes are released, and the reservoirs recharged.

**Quick-action Triple Valve.** — In any air-brake system an appreciable time elapses between the action of turning the engineer's valve and the actual application of the brakes. If there are many cars in a train the brakes may be applied on the leading cars sometime before they are applied on the rear cars and the result is that the rear cars bump into the forward cars, and may cause a derailment, particularly if this happens on a curve. To guard against this, the

"quick-action triple valve" is used on long trains. This consists of a special form of valve which causes a local intensification of the change in pressure in the train pipe on each car. The action is somewhat similar to a relay which is affected by slight changes in pressure and causes greater changes, and thus applies or releases the brakes more quickly.

**Electromagnetic Brakes.** — Any braking system making use of the electric current is not as reliable as the air system since if either the trolley comes off or the motors fail to pick up as generators the brakes are inoperative. Electromagnetic braking may be applied either to the axles or directly to the track.

**Disc Brakes.** — This system comprises two cast-iron discs mounted concentrically on the car axle. One is keyed to the axle and the other anchored to the truck frames. A coil is placed in one of these discs and when a current flows in the coil the two discs are attracted to each other by the magnetism and the friction between them retards the car. The current for the coils may be taken from the trolley or from the motors operating as generators. In the latter case the motors supply an additional retarding force. The braking effort is controlled by resistance in series with the magnet coils.

**Track Brakes.** — The principle of electromagnetic braking may also be applied to a track brake in which a magnet coil when energized draws a shoe against the rail, the pressure being regulated by a resistance in series with the magnet coil.

**Regenerative Braking.** — By supplying the field circuits of the motors with a current of proper value and direction by means of separate excitation they may be operated as generators and made to exert a strong retarding effort on the car axles. This separate excitation may be obtained by connecting the field windings of all the motors on a car in series with themselves and with a regulating resistance to the trolley, or by means of a motor generator set (on a locomotive) supplying a low potential of the proper value. The energy developed by the motors when acting as generators may be dissipated in rheostats or may be returned to the distributing system. In the latter case the voltage generated by the motors must be accurately controlled. Ordinarily, if the energy is returned to the line, the braking effort can only be obtained at speeds in the proximity of full speed. Very special means must be provided to make it possible to return energy to the line at low speeds.

This system has had its most elaborate application in the locomotives of the C. M. & St. P. Ry. of U. S. A., where experience over a considerable period of time shows a saving of approximately 15 per cent in the energy consumption with grades varying from 0.7 per cent to 2 per cent. Of greater importance than the saving of energy, is the saving in wear on wheel tires, brake shoes and track and the ease of control, as these features have reduced the number of derailments to a marked extent. In the early St. Paul locomotives, a special motor generator was provided to serve as an exciter. In the later locomotives, two of the main traction motors are used to supply the exciting currents for the rest of the motors when they act as generators.

Three-phase induction motors will provide regenerative braking at rated speed without auxiliary devices.

**Electro-pneumatic Brakes.** — This system has been proposed as an improvement over the quick-acting air-brake system. It involves controlling the application of the brakes on each car by means of an electromagnet receiving current from the locomotive cab. By energizing this circuit the motorman can set the air brakes on all cars practically simultaneously. Each car would be equipped with the usual brake cylinders and reservoir and merely the application of the brakes would be controlled electrically.

C., *Recent Developments in Air Brakes*, *El Jour.*, 1915, Vol. 12, p. 467; Harding, C. F., *Electric Railway Engineering*, N. Y., 1916; Jackson, W., *Electric Car Maintenance*, N. Y., 1914; Master Car Builders' Association, *Car Builders' Dictionary*, N. Y., 1916; Turner, W. V., *Regenerative Braking*, *El. Jour.*, 1917, Vol. 14, p. 386.

**BRICKS AND BRICK MASONRY.** — (See also *Buildings, Allowable Unit Stresses in; Cement; Concrete.*) Brick construction may be made more ornamental than concrete, but is generally more expensive to place on account of the necessity of handling each brick as an individual unit. The properties of building and engineering construction in which bricks are used, although still extensive, has been falling off in recent years with the increasing use of plain and reinforced concrete.

**Kinds of Bricks.** — Ordinary or clay bricks are made by moulding a rectangular block of nearly pure clay, or clay and clean sand, and subsequently burning it in a kiln for from one to two weeks. Pressed bricks are machine moulded dry bricks used for facing work in high-class construction. Sand lime bricks are also used to some extent. They are made from sand cemented by lime and are hardened by being subjected to steam pressure at from 100 to 150 pounds per square inch for about one-half a day. Fire bricks are a special kind of dry bricks, which are made to stand high temperatures. The refractory properties of fire bricks depend chiefly upon the amount of silicon contained. The amount of iron oxide in fire bricks should not exceed 6 per cent. Vitrified bricks are very hard burned clay bricks which have been annealed by slow cooling; used in pavement work.

**Physical Properties.** — A common, practical test for a good brick is that it will give a clear, ringing sound when struck with a hammer. The color of a brick is not a reliable indication of its strength or properties. The water absorbed in a specified time by a number of bricks is sometimes considered to indicate their relative strengths, as water acts as a lubricant on the material and causes crushing to occur more readily than when dry, but there is considerable difference of opinion as to the value of this test.

The compressive strength of dry bricks ranges from 500 pounds per square inch for soft bricks to over 10,000 pounds per square inch for pressed bricks. The strength of the individual bricks, however, is of little importance except for comparing various kinds, as the strength of brick masonry is usually limited by the strength of the mortar used.

The specific gravity of bricks ranges from 1.6 to 2.6. See also paragraph below on *Brick Masonry* and article on *Weights of Materials*.

Several foreign countries have adopted legal standard sizes for brick, but the only standard sizes in the United States are those specified by the National Brick Mfg. Assoc. as follows:

Common brick.....	8¼ by 4 by 2¼ inches
Pressed brick.....	8½ by 4 by 2½ inches
Paving brick.....	8½ by 4 by 2½ inches

**BRICK MASONRY.** — Bricks are laid in lime or cement mortar, the mortar forming a cushion which fills the interstices and keeps out water. Joints, i. e., the spaces between adjacent bricks which are filled with mortar, are usually made from ¼ to ¾ inch thick in outside walls, and from ⅝ to ½ inch thick in inner walls. In ordinary building work, where the weight of the wall itself is the greater part of the load, lime mortar is usually used because it is cheap. Where strength is required of brickwork, a rich Portland cement mortar should be used; see article on *Cement*. Tests upon the ultimate compressive strength of brick piers are quoted in detail in Johnson's *Materials of Construction*, and Baker's *Masonry Construction*. The values of loads allowed upon brick masonry in various localities range from 100 to 300 pounds per square inch; see *Buildings, Allowable Unit Stresses in*. A brick wall itself weighs from 100 to 145 pounds per cubic foot, depending somewhat upon the quality of the brick and the thickness of joints.

**Measurement of Brickwork.** — Bricks are usually sold by the thousand. Brickwork is commonly measured by the cubic yard in place, but the units of per thousand brick and per square yard of surface area are also used. The relation between the number of bricks used and the volume of finished brickwork depends upon the size of brick, thickness of joints and shape of the structure. For solid brick walls the number of bricks per cubic yard ranges from about 400 with  $\frac{3}{4}$ -inch joints to about 500 with  $\frac{1}{4}$ -inch joints. An allowance of 3 or 4 per cent excess should be made in estimating to provide for waste and leakage.

**Cost of Brickwork (Pre-war figures).** — Hudson River common bricks cost prior to the war about \$6.00 per thousand. Lime for mortar was quoted at \$0.97 to \$1.10 per 200-pound barrel. The total cost of brick masonry including labor and materials was from \$6.00 to \$15.00 per cubic yard, depending upon the locality, type of construction and quality of brick and mortar. An average figure for ordinary brick walls was from \$8.00 to \$10.00 per cubic yard.

**BRIDGES FOR ELECTRICAL MEASUREMENTS.** — (See also *Inductance and Inductive Reactance; Resistance and Conductance, Electric; Resistors, Standard; Wires and Cables, Insulated.*) Numerous arrangements of electric circuits, known under the general term of "bridges," are used for the comparison of unknown with known resistances, capacities and inductances. The fundamental principle of an electric bridge is the adjustment of the component circuits or arms of the bridge in such a manner that the drop in potential  $V$  in the arm formed by the circuit to be tested is to the drop of potential  $V_r$  in an arm having known constants as the drop of potential  $V_0$  in one "ratio" arm is to the drop  $V_2$  in the second "ratio" arm.

A bridge may be made up of separate resistance boxes (see *Resistors, Standard*), but where frequent tests are to be made it is more desirable to have all the resistances, keys, etc., mounted together in a single box. Complete bridges of this kind can be obtained from instrument manufacturers.

**SLIDE-WIRE BRIDGE** (Fig. 1). — This is the simplest form of bridge but is seldom used in commercial testing, as its range is limited. In principle it is the same as a Wheatstone bridge (see below), the difference being a structural one only, in that a wire is used for the "ratio" arms.

The slide wire,  $AB$  in Fig. 1, is generally a wire of uniform cross-section stretched along a meter scale which is divided into millimeters. All connections in the  $X$  and  $R$  circuits are made of heavy low-resistance material. A slider is provided for sliding over and making contact on the wire. When the bridge is balanced (i.e., no current through the galvanometer),

$$X = \frac{AR}{1000 - A},$$

where  $A$  is the distance in millimeters between the slider and the left-hand end of the bridge. The slide wire can be made uniform to  $\frac{1}{10}$  per cent and the error in observation may be even smaller than this. When using a ratio greater than 1 to 1 and when a low resistance is being measured, the errors are greater. It is possible when using an even ratio to make very exact comparisons of the standard and unknown resistances by reversing them and taking the mean of the two measurements.

Fig. 1. Slide-wire Bridge

Fig. 2. Wheatstone Bridge

**WHEATSTONE BRIDGES.** — Fig. 2 shows the arrangement of resistances in the ordinary type of Wheatstone bridge used for comparing resistances.  $A$  and  $B$  represent two coils or sets of coils, usually referred to as the "ratio" coils, whose relative resistances must be known but whose actual resistance values are unnecessary;  $R$  is a standard variable resistance, or resistance box (see *Resistors, Standard*);  $X$  is the unknown resistance;  $G$  is a sensitive galvanometer connected across two points of the diamond and  $B$  is a battery connected across the other two points of the diamond.

For no deflection of the galvanometer when the switches  $S_1$  and  $S_2$  are closed, i.e., when the bridge is balanced,

$$X = \frac{A}{B} \cdot R,$$

where the letters represent the resistances of the four arms.

**Construction.** — Wheatstone bridges having the various parts mounted in one box may be divided into three classes: (1) portable bridges, in which not only the resistance coils and keys but also the battery and galvanometer are mounted in one box; (2) laboratory bridges, in which the coils and in some cases the keys are mounted in one box, but for which separate galvanometers and batteries must be provided; and (3) precision bridges, arranged in the same manner as laboratory bridges but made with greater care and capable of greater precision.

Since the construction of the resistance coils, blocks, plugs and other minor details of bridges is practically the same as for resistance boxes (see *Resistors, Standard*); only the arrangement of coils and connections will be described here.

**Rheostat Arrangements.** — The coils forming the rheostat (the variable resistance  $R$  in Fig. 2) may be arranged on the 1, 2, 3, 4, plan as shown in Fig. 3, on the 1, 2, 2, 5 plan, on the decade plan of Fig. 4, or on any other plan. (See *Resistors, Standard*.)

Fig. 3. Wheatstone Bridge (Post Office Type)

Fig. 4. Wheatstone Bridge (Anthony Type)

The advantage of the decade arrangement is that few plugs are required, and, therefore, there is less likelihood of error due to the contact resistance. A very good form of the decade type of rheostat is used in the Anthony type of Wheatstone bridge, shown in Fig. 4. In this bridge the coils may be joined in series or multiple or in any desired combination of series and multiple.

**Plug and Dial Arrangements.** — The resistances of the various arms of the bridge may be varied either by the insertion of plugs between the heavy metal terminals of the coils provided on the top of the box, or a dial arrangement similar to that employed on ordinary rheostats (but more carefully made to reduce the contact resistance) may be used.

**Ratio Coils (Figs. 5 to 7).** — The connections of the ratio arms in a common construction of dial bridge is shown in Fig. 5. The values of the coils are so chosen that the ratio of these coils is always that given by the stamping for various settings of the contact  $S$ . An advantage of this type of ratio coils is

that there is no error due to contact resistance in the ratio coils, as the contact is in series with the battery.

The arrangement of an improved form of ratio coils is shown diagrammatically in Fig. 6. This arrangement of ratio coils has the advantage over the old post-office arrangement shown in Fig. 7, in that there are but two plugs to operate and the coils can be checked by reversal.

**Precision of Measurements by Wheatstone Bridge.**—The degree of accuracy with which a resistance can be measured by means of a Wheatstone bridge is determined by the following conditions:

1. The accuracy to which the resistances of the various coils is adjusted. The range of accuracy is from about 0.1 per cent for portable bridges to 0.02 per cent for precision bridges.

2. The relative value of the coil resistances and the contact resistances at plugs and terminals. A well-fitting, clean plug has a resistance of from 0.001 to 0.00005 ohm; a poorly fitting or greasy plug a resistance of 0.01 ohm or higher.

Fig. 5. Dial Type Ratio Coils

Fig. 6. Improved Arrangement of Ratio Coils

Fig. 7. Post-Office Arrangement of Ratio Coils

The contact resistance at a binding post between the binding post and wire, even when well clamped, ranges from 0.001 to 0.0001 ohm.

3. The relative value of the coil resistances and the insulation resistances between the coils. Dirt and grease on the top of the box may introduce a considerable error. Hard rubber, which is commonly used for the tops of resistance boxes, is also liable to have a thin film of acid formed on it when exposed for a long period to the action of the moisture and impurities in the air, which attack the sulphur in the rubber. Such a film will greatly reduce the insulation resistance between the lugs on top of the box.

4. The effect of changes of temperature in changing the resistances of the coils and in producing thermoelectric effects. The thermal e.m.f. in a copper-brass-copper circuit is about  $2 \times 10^{-6}$  volts per degree C. difference in temperature between the two junctions. Thermoelectric troubles can usually be avoided by reversing the connections of the battery to the bridge and taking the mean of the values of the resistances corresponding to the balance when the battery current flows through the bridge first in one direction and then in the other.

5. The maximum current that the coils will safely carry; this ranges from about 0.5 ampere for 1-ohm coils down to 0.005 ampere for a 5000-ohm coil.

6. The resistances of the galvanometer and battery, particularly the former. The battery resistance is usually small.

7. The relative resistances of the various arms of the bridge.

8. The sensitiveness of the galvanometer, i.e., the deflection per unit current.

**Best Galvanometer Resistance.**—Referring to Fig. 2, the best galvanometer resistance is

$$G = \frac{(A + X)(B + R)}{A + B + R + X},$$

where the letters designate the resistances of the various branches.

**Best Location of Galvanometer.**—Knowing the galvanometer and battery resistances (the galvanometer resistance is usually the larger), connect the one having the higher resistance so that it joins the junction of the two arms of the bridge having the highest resistances to the junction of the two arms having the lowest resistances.

**Precautions in Making Measurements.**—The following rules should be observed in using a Wheatstone bridge:

1. Do not employ a battery having an e.m.f. of over 5 volts; a lower value is desirable if sufficient sensitiveness can be obtained.
2. Always shunt the galvanometer during preliminary adjustments. The shunt circuit should be opened when the final balance is made.
3. See that all binding posts are screwed up tightly and all plugs firmly inserted. After withdrawing a plug those adjacent to it should be retightened.
4. For a preliminary balance use a 1 to 1 ratio.
5. In manipulating the keys be careful not to touch the metal work, as the heat and moisture of the hand is likely to set up appreciable electromotive forces.
5. Always close the battery switch first and then the galvanometer switch, to avoid momentary deflections of the galvanometer due to the transient e.m.f.'s set up while the currents are establishing themselves.
7. If the contact or lead resistances are appreciable relative to the resistances of the coils with which they are in series, these resistances should be separately determined.

**Care of Bridge.**—In order that a bridge or resistance box may remain in first-class condition, it must be carefully protected from dust and moisture by being covered when it is not in use. To insure high insulation the top must be kept clean, especially between the blocks. The plugs must be kept free from grit, grease or from contact with mercury. Grease may be removed by the use of a little benzol. Never use sand or emery paper for cleaning the plugs or holes, for the surfaces of the taper will be spoiled by this treatment. These materials work into the metal and cannot be removed, thus causing the plugs to "cut." If it becomes absolutely necessary to clean the plugs and sockets, a little of the very finest whiting may be employed. Extra holes of the proper taper bored in the brass blocks are convenient for holding the plugs when they are not in use, and also for attaching a movable terminal. Never apply undue force in inserting the plugs.

**KELVIN BRIDGE.**—The ordinary form of Wheatstone bridge is not suitable for measuring with accuracy a resistance of 0.1 ohm or less, due to the contact resistances introduced at the binding posts, this contact resistance being of the order of 0.0001 to 0.001 ohm. An arrangement of circuits to avoid these contact resistances devised by Lord Kelvin (*Wm. Thomson*) is shown in Fig. 8, and is known as the Kelvin or Thomson bridge. There will be no current in the galvanometer when

$$X = \frac{A}{B} \cdot R + \frac{bd}{a+b+d} \left( \frac{A}{B} - \frac{a}{b} \right).$$

If  $\frac{a}{b}$  is made equal to  $\frac{A}{B}$ , then

$$X = \frac{A}{B} \cdot R.$$

It is also well to make the resistance of  $d$  extremely low in comparison with  $X$  or  $R$ , since the lower the resistance of  $d$  the less an error in  $a/b = A/B$  will affect the accuracy of measurement.

In the above formulas  $X$  and  $R$  are the resistances between the arrowheads which represent the "potential terminals." Such terminals are always provided on low-resistance standards. (see *Resistors, Standard.*)

Fig. 8. Kelvin Bridge

Fig. 9. Modification of the Kelvin Bridge

**Simple Modification of the Kelvin Bridge.** — When suitable resistances are not available for  $a$  and  $b$ , these resistances may be omitted and the galvanometer terminal be connected first at 1 and then at 2, and  $A$  adjusted for a balance in each case; let  $A_1$  and  $A_2$  be the corresponding values of  $A$ . Then

$$X = R \frac{A_1 (B + A_2)}{B (B + A_1)}$$

This method is very convenient for measuring the resistance  $X$  of a low-resistance shunt (see *Shunts*). The only standard resistances required are a low-resistance standard  $R$  and a resistance box with three terminals (or two separate resistance boxes). Fig. 9 shows such an arrangement.

**HOOPES' CONDUCTIVITY BRIDGE.** — This bridge is also a modification of the Kelvin bridge, designed for the rapid determination of the relative conductivity (see *Resistance and Conductance*) of samples of wire. It is extensively used in wire factories. A diagram of the connections is shown in Fig. 10.

Fig. 10. Hoopes' Conductivity Bridge

The standard  $A-B$  and the unknown  $C-D$  are of the same metal; consequently if care be taken that they are at the same temperature, all corrections due to temperature are avoided. The arms  $p$ ,  $r$ ,  $p_2$ ,  $r_2$  are in the same case and are made of material of low temperature coefficient so that their relative values will not change. They are adjusted so that  $p=r$  and  $p_2=r_2$ ; consequently at balance the resistance of  $c-d$  equals the resistance of  $a-b$ .

The sample *C-D* is placed alongside a scale *I* divided into 100 parts, so that the graduations represent percentages of the total length of the scale. Accompanying the standard wire *A-B* is a scale *H*, on which are laid off a number of points corresponding to the weights of the standard length (38 inches) of a range of sizes of sample wires.

To make a conductivity reading, the weight of the standard length of the sample *C-D* is found to within an accuracy of  $\frac{1}{100}$  per cent. The contact *b* is set at the point on scale *H* corresponding to this weight, the contacts *a* and *c* being at the zero points of their respective scales. After the case has been closed a sufficient length of time to allow both the standard and sample to assume the same temperature, the contact *d* is moved until the galvanometer shows no deflection; this will occur when the resistance between *a* and *b* is equal to that between *c* and *d*. The scale reading corresponding to the position of *d* for a balance is equal to the per cent conductivity.

The Hoopes' bridge is so designed that the standard wire with its scale is removable from the bridge and so that a single standard covers a range of sizes equal to 3 numbers of B. & S. gauge. Any number of standards can be supplied with a bridge, so that it can cover an extensive range of sizes and can also be used for wires of different materials. In order to keep the standard wire and the test wire at the same temperature the bridge is mounted in a metal-lined case and the scale read through a glass window in the case, the window being closed by a metal screen when readings are not being taken.

**Resistance of Electrolytes.**—The resistance of an electrolyte can be measured by using the Wheatstone bridge principle with an a-c. source substituted for the battery and an a-c. detector in place of the a-c. galvanometer. Alternating current must be used on account of the polarizing action of a direct current. A convenient source of alternating current is an induction coil with the secondary winding in place of the battery, as in an ordinary set-up. A telephone receiver makes a very good detector when an induction coil is used. The current from an induction coil gives a very clear and sharp sound in the telephone, making accurate balancing of the bridge quite simple. If a sinusoidal alternating current is used, a vibration galvanometer may be used to better advantage than a telephone. To measure merely the resistance of an electrolyte it is only necessary to place the electrolyte in a vessel provided with two electrodes, preferably of gold or platinum, and connect this vessel into one arm of a Wheatstone bridge and balance for alternating current. The other arms of the bridge are resistances which must be strictly non-inductive.

To determine the resistivity it is necessary to place the electrolyte in a vessel whose length and cross-section can be accurately measured. Such a vessel may be made from a glass tube, whose internal diameter is known, and in the two ends of which metal plugs are inserted. These plugs may be any convenient distance (say 20 cm.) apart. There should be several small holes in the side of the tube. The tube is then immersed in a vessel containing the electrolyte and the bridge balanced as before. The resistivity is then the product of the cross-sectional area of the tube and the resistance, divided by the length of the tube.

**COSTS (Pre-war prices).**—A good slide-wire bridge costs about \$20, a portable Wheatstone bridge from \$50 to \$125, depending upon the design, a laboratory Wheatstone bridge from \$25 to \$75 and a high-precision standard bridge from \$300 to \$400. A Hoopes' conductivity bridge with a single standard, covering 3 sizes of B. & S. gauge wire, costs about \$500; additional standards cost about \$50.

**BIBLIOGRAPHY.**—*The Building Code of The City of New York, amendments to July 17, 1910; Revised Building Ordinances, Chicago; Amendments to May 26, 1920; Laws and Ordinances Relating to the Bureau of Building Inspection, Philadelphia, July 1, 1920; Building Laws of the City of St. L. 1917; The Building Law of the City of Boston, with amendments to Oct., 191*

**BUS-BARS AND BUS-BAR STRUCTURES.** — (See also *Circuit Breakers; Power Stations; Substations; Switches; Switchgear Equipment for Power Stations; Wires and Cables.*) Bus-bars, or "omnibus bars," as they were finally called, are the common circuits into which the various generators deliver their output and from which the different feeders draw their supply of power. In large-capacity, moderate-voltage a-c. plants the bus-bars are usually arranged in structures and connected to the various generators, feeders, etc., by suitable wiring. The bus-bars and their connections, together with the bus-bar structures, form one of the most important parts of large plants, as the entire output of the station is usually concentrated thereon.

**BUS-BAR SYSTEMS.** — Where there is only a single set of bus-bars whether in d-c. or a-c. stations the connections are said to be arranged on the "single-throw" system; when the connections can be made to either of two sets of bus-bars the system is spoken of as "double-throw"; but if the connections can be made to both sets of bus-bars instead of only to either set, the system is spoken of as the "selector system." Occasionally three or more sets of bus-bars are used.

If there is only one set of bus-bars, but with switches provided for dividing it into two or more sections, it is spoken of as a "sectioned bus." Where there are two sets of these sectioned bus-bars connected together at the ends, the system forms a "ring bus." In many high-voltage plants having tap-off transformers each generator normally connects to the low-tension side of its own transformers, but switches are provided so that any transformer or generator can connect to a bus; such a bus is spoken of as a "relay bus." Where a number of feeders connect to a bus which in turn connects to the main bus through a switch or breaker, such a bus is spoken of as a "group bus."

**BUS-BAR MATERIAL.** — Depending on the current and voltage, bus-bars may be made of wire, rod, tubing, cable or strap, either bare or insulated. Solid wire is seldom used for more than 200 amperes, rod is used for less than 600 amperes, tubing for 300 to 600 amperes, cable up to 1000 amperes, while strap is used up to any capacity.

Strap for bus-bars, particularly for heavy current, possesses several advantages over other shapes, the chief one being the ease with which additional straps may be added and the excellent radiating surface secured. Straps of different sections are in use, a typical one being 3 inches  $\times$   $\frac{1}{4}$  inch. Where more than one strap is required, a space is left between adjacent bars making the so-called uniminated bus. The usual spacing left with 3 inches  $\times$   $\frac{1}{4}$  inch bars is  $\frac{3}{4}$  inch. The connections from switches, circuit breakers, etc., to the bus are made of one or more similar straps suitably interleaved and clamped together.

With this construction and due to the large surface exposed in comparison to the section of copper used a comparatively high current density may be employed for a small number of straps without exceeding a safe temperature rise. The exact amount of current to be carried for a given rise depends somewhat on local conditions, ventilation, etc., and whether the bus is being used for direct current, 15-cycle, or 60-cycle service, and the temperature rise is not the same for different parts of the bar. A typical test under average conditions, 60-cycle service, 35° rise, indicated that one bar would carry 650 amperes, two bars 1150, three 1500, four 1800, five 2000, six 2160, showing that due to skin effect, lack of ventilation, etc., the permissible current density falls off rather rapidly as the number of bars increases.

It is usually necessary to interleave the phases or to adopt special arrangements of the strap connections to balance the mutual induction, to secure proper cur-

rent distribution in the various straps for 60-cycle service to carry 3000 amperes or more without an excessive amount of copper.

**Tubing for Small Currents and High Voltages.**—For extremely high voltages with their correspondingly small currents, copper tubing for bus-bar and connections has many advantages over rods, cable or wire. These advantages are principally increased stiffness for the same amount of material, large and effective radiating surface, and the facility of making connections by flattening out the tubing at the point desired and bolting the tubing together at such points. On extremely high-voltage circuits tubing of approximately 1 inch outside diameter is not apt to be troubled by the brush discharge or corona effect that is sometimes noted with small wires or straps having sharp edges. In some plants iron piping is used for bus-bars and connections.

**BUS-BAR STRUCTURES.**—(See also *Power Stations; Substations; Switch gear.*) In large-capacity a-c. plants of 15,000 volts or less, with generator connected directly to the bus, the current that can be developed on a short circuit is something enormous, and every precaution has to be taken to prevent trouble from spreading if it ever starts. For this reason it has become customary to employ masonry compartments and cellular construction for the oil circuit breakers and bus-bars. In higher-voltage plants open wiring possesses several decided advantages. The vertical walls and septums of the circuit-breaker and bus-bar structures are usually built of brick or concrete, and the horizontal shelves between the bus-bars are ordinarily made of concrete, sandstone, soap stone, slate or marble. These substances are named in the order of their increasing cost. In some instances the bus-bar structures have been made of asbestos lumber, transite or similar material.

Low tension bus-bars when not too heavy can be supported by the wall bushing for the lead. For heavier work, or where bushings are not used, the bus-bars are supported on porcelain pillars, petticoat insulators, and similar devices resting on the bus-bar shelf, or attached to the wall.

In the larger generating stations due to the mechanical stress caused by the magnetic effects of the tremendous short-circuit current resulting from the size and number of turbo generators represented in present day station practice, close attention must be given to the adequacy of the bus-bar supports. Various curves and formulae have been deduced for the purpose of calculating the mechanical strain on bus-bar supports at the instant of short-circuit. A typical formula is the following:

$$P = .27 K.V.A.^2 \text{ divided by } A \times V^2 \times Z^2 \text{ where}$$

$P$  = Maximum force exerted in pounds per foot of bus.

$K.V.A.$  = Normal rating of the station including all synchronous apparatus.

$A$  = Distance between buses in inches.

$Z$  = Impedance in per cent expressed in decimals to the point of short-circuit.

$V$  = Line voltage.

In using this formula a typical example with 150,000 K.V.A. station capacity at 6600 volts, 8 per cent reactance, gives a maximum force on the bus-bars per foot of length, 735 pounds with 30 inch spacing between bars, 1470 pounds with 15 inch spacing between bars. With 4 feet between bus supports, each bus support would have to stand a strain of 2940 pounds if the buses are 30 inches on centers; 5880 pounds if the buses are 15 inches on centers. For heavy duty of this kind, multi-point supports are frequently used.

For supports for high tension bus-bars and connections it is customary to employ high-tension insulators of the pillar type, pin type, or suspension type, depending on the voltage.

the open system of wiring is preferable for any voltage higher than that for which generators can be conveniently wound. This opinion is based on the following reasons:

For the same kilovolt-ampere capacity back of an arc the current established is approximately inversely proportional to the voltage, and consequently violence of the arc and its destructive effects are less on a high-voltage system than on a low-voltage system.

The distance from wire to ground has to be greatly reduced from what would be obtained with open wiring in the same space, as the conductivity of the proof barriers is sufficiently good to permit large currents to flow with high voltages, in case an arc or a dead ground is established.

A more expensive building and more costly construction are usually needed for enclosed bus-bars and wiring than are required for open wiring.

Inspection and repairs are more difficult when bus-bars, wiring, disconnect-switches and similar appliances are boxed in masonry compartments, and conductors are visible and accessible only by the removal of doors. Inspections will be more frequent and thorough and incipient trouble will be noticed sooner with open wiring than with enclosed, as the station attendant can examine everything in a walk of a few minutes, and will not have to remove many doors and visit two or three floors to examine the condition of the apparatus.

**CONNECTIONS TO BUS-BARS.** — Where the currents exceed 600 or 800 amperes, it is usual to employ laminated copper straps for connecting to bus-bars; for smaller currents, cable, wire, rod or tubing is used. Cable and, to a certain extent, bare wire are used for connections involving bends or long runs through conduits, but for straight runs or simple bends rod or tubing can be used. Tubing, though more costly than rod or wire, is stiffer for the same size, and can often be flattened out for making connections to studs, bars, etc., without the necessity of additional terminals.

**CALORIMETERS, FUEL.** — (See also *Fuel*.) A fuel calorimeter is an instrument for determining the heating value of a fuel. Its essential features are a closed chamber in which a weighed sample of the fuel can be quickly and completely burned, a vessel of water surrounding this chamber, into which the heat generated by the combustion is transferred, a delicate thermometer for measuring the rise of temperature of the water, means for igniting the fuel, and provisions for preventing loss of heat from the apparatus by radiation by the escape of the gases and vapors produced by the combustion. The most approved form of the instrument is Mahler's modification of Berthel's calorimeter. The combustion chamber is a strong cylindrical steel vessel enameled on the inside, called a "bomb," into which about 1 gram of powdered coal, contained in a small platinum dish, is placed. Oxygen under a pressure of 20 to 25 atmospheres is introduced, and the coal is ignited by an electric spark and burned explosively. The bomb is set in a water pail of thin brass, which is heavily felted and surrounded by a double-walled vessel filled with water of the temperature of the room. A stirring apparatus is used in the pail to circulate the water around the bomb. The thermometer is finely graduated. Readings of the temperature are made and recorded every minute until the maximum is reached, and a few minutes afterward to obtain a correction for radiation. The weight of the water, together with the water equivalent of the bomb and pail, multiplied by the rise in temperature, corrected for radiation and other minor errors, gives the number of heat units generated by the combustion of the coal.

The Junker calorimeter is commonly used to determine the heating value of fuel gas. A measured volume of gas is burned with air or oxygen in a vessel which is surrounded with water, and the calculations are made in the same manner as those for the Mahler calorimeter.

**BIBLIOGRAPHY.** — The Bureau of Standards (Washington) has published a comprehensive paper on *Combustion Calorimetry* (1915) in *Bulletin* 11, No. 1, p. 189, and a comprehensive monograph on *Industrial Gas Calorimetry*, (1915) Tech. Pap. No. 36. See also Bibliography under *Boilers, Steam*.

**ORIMETERS, STEAM.** — (See also *Steam*.) For the purpose of finding the percentage of moisture in the steam, in a boiler or engine test, a calorimeter is used. Several forms of this instrument have been used but the most common is that of Professor Peabody, known as the throttling meter. The action of this instrument depends upon the fact that the latent heat of saturated steam is greater the greater the pressure, and consequently when the pressure is reduced by throttling, the heat rendered available will convert moisture into steam and in general produce more or less superheating.

A  $\frac{1}{2}$ -inch pipe, closed at the end and perforated with several  $\frac{1}{8}$ -inch holes in all, is inserted into the main steam pipe so that steam may enter these holes. The other end of the calorimeter pipe is throttled by an orifice  $\frac{1}{16}$  inch in diameter through which the steam escapes into a chamber which has an outlet to the atmosphere. The temperature and pressure of the steam on each side of the orifice are observed. The steam in the chamber is superheated more or less according to the amount of moisture contained in the sample drawn from the steam main.

The per cent of moisture in the steam is then

$$W = 100 \frac{H - h - K(T - t)}{L}$$

where  $H$  = total heat and  $L$  = the latent heat of saturated steam at the pressure of the steam in the main pipe;  $h$  = total heat of saturated steam at the pressure of the discharge chamber of the calorimeter (= 1150.4, corresponding to a pressure of 14.7, when this chamber opens directly to the atmosphere);  $K$  = specific heat of superheated steam (= 0.48 approximately);  $T$  = actual temperature in the discharge chamber;  $t$  = temperature of saturated steam at the pressure in the discharge chamber (= 212 when this chamber opens directly to the atmosphere). The above formula becomes

$$W = 100 \frac{H - 1150.4 - 0.48(T - 212)}{L}$$

when the discharge chamber opens directly to the atmosphere, and when the atmospheric pressure is 14.7 pounds per square inch.

When the steam is very moist, so as to reduce the superheating on the discharge side to 0°, the instrument fails, and a separating calorimeter, which is really a small steam separator (q. v.), must be used between the throttling calorimeter and the steam pipe to collect the greater quantity of moisture. The moisture collected in the separator is then added to that determined by the calorimeter. The instrument must be thoroughly felled to reduce the error due to radiation. There is also usually a considerable error in obtaining steam of an average quality from the main pipe by the perforated tube.

**BIBLIOGRAPHY.** — Carpenter and Diederichs, *Experimental Engineering*, report of Committee on Power Tests, A.S.M.E.

**CAMBRIE, VARNISHED.** — (See also *Insulating Materials, Wire and Cables, Insulated.*) Varnished muslin, variously known as varnished cloth, varnished cambrie is an insulating material for cables, which consists of tapes of cotton fabric coated with insulating varnish, wound helically around the conductor with a thin layer of plastic compound between turns. This compound prevents the absorption of moisture, precludes air spaces and permits the layers of fabric to slide upon each other when the cable is bent. It is also used for machine coils without the plastic compound.

The fabric is prepared by coating it with a mixture whose principal constituents are boiled linseed oil, resin, gilsonite, and benzine. This mixture dries and the oil is oxidized by contact with air, leaving a hard smooth surface. These such coats are usually applied. The plastic material between layers is usually a mixture of petrolatum and resin.

The varnished fabric usually has a thickness between seven and thirteen mils, the thinner cambrie being used on smaller cables. There are usually between 65 and 70 threads to an inch.

The tensile strength of the varnished tape should be not less than 2000 pounds per square inch.

After the varnished cambrie has been placed in hot petrolatum having a temperature of 150° C., removed from petrolatum and allowed to cool, the film of varnish should not become soft or tacky.

**Specific Resistance.** — The value of  $K$  in the formula  $M = K \log \frac{D}{d}$  (See article on rubber) ranges from  $K=300$  to  $K=1000$ , the usual value being between 400 and 600.

The resistance of varnished cambrie is more affected by temperature change than that of rubber or impregnated paper. The amount of variation differs in different makes and in different batches of the same make, so that the accompanying table should be considered as an approximation only.

Temperature		Per cent of resistance at 60° C
C.°	F.°	
15.5	60	100
18.3	65	61
21.1	70	37
24.0	75	24
26.7	80	15
29.4	85	11
32.2	90	8
35.0	95	6
37.8	100	5

**Dielectric Strength.** — The dielectric strength of varnished cambrie depends greatly upon the size and shape of electrodes used for testing. Using the equipment described below, the puncture voltage per mil at 25° C. is between 800 and 1000 volts. This decreases rapidly as the temperature rises, being between 500 and 600 volts per mil at 75° C.

Farmer, Kennelly and Wiseman have shown that the apparent dielectric

length of 0.33 mm. varnished cambric decreased more than 50 per cent in aging from very small discs to discs exceeding 15 inches in diameter.

Tests are most readily made between the rounded edge of a strip of brass  $\frac{1}{8}$  inch thick and 6 inches long, which constitutes the upper electrode, and a strip of brass about  $\frac{3}{8}$  inch wide and 8 inches long, which is placed directly below the strip of varnished cambric to be tested, and forms the lower electrode. The electrodes may be attached to a strip of wood about 16 inches long and 4 inches wide. Also the top electrode may be fastened to supports with revolving arms so that it can be thrown out of the way when the test has been completed. In order to prevent flash-overs from one electrode to another, a wide strip of varnished cambric is placed underneath the lower electrode and petrolatum smeared over this strip of varnished cambric before the strip to be tested is placed over the lower electrode. The test strip of varnished cambric is pressed firmly against the lower strip so that the petrolatum makes a seal between the two strips thus preventing flash-overs from the top electrode to the bottom one.

**Power Factor.** — The power factor of varnished cambric insulation in cables is much higher than that of impregnated paper. The following values are typical:

Temperature Deg. Cent.	Power factor, Per Cent
20.....	6.0
30.....	8.0
40.....	10.5
50.....	14.0
60.....	19.0
70.....	49.0
80.....	33.0
90.....	43.0
100.....	56.0

**GENERAL RELATIONS AND DEFINITIONS.** — Consider any number of conductors 0, 1, 2, 3, etc., either (1) at a great distance from all other conductors or (2) completely surrounded by a hollow conducting shell, the inside surface of which shell is to be considered as one of the conductors, say No. 0, of the system. The electrostatic condition of such a system of conductors is uninfluenced by any electrostatic effects produced outside the system; it may therefore be called an "electrostatically independent system."

**Potential Coefficients (A).** — Any conductor of an electrostatically independent system may be chosen as a conductor of reference; let this reference conductor be designated as conductor No. 0. Let  $v_1, v_2, v_3$ , etc., represent the potential drop from No. 1 to No. 0, from No. 2 to No. 0, from No. 3 to No. 0, etc., and let  $q_0, q_1, q_2, q_3$ , etc., represent the charges on No. 0, No. 1, No. 2, No. 3, etc. Then, if the relative positions of the various conductors and insulators in the field remain unaltered and the specific inductive capacities (see *Electricity and Magnetism, Principles of*) of the various insulating materials between the conductors are constant (not necessarily the same for each insulating material, however), the following relations hold for all values of the charges on and potential drops between conductors irrespective of how the conductors may be connected: \*

$$\left. \begin{aligned} v_1 &= A_{11}q_1 + A_{12}q_2 + A_{13}q_3 + \text{etc.}, \\ v_2 &= A_{21}q_1 + A_{22}q_2 + A_{23}q_3 + \text{etc.}, \\ v_3 &= A_{31}q_1 + A_{32}q_2 + A_{33}q_3 + \text{etc.}, \\ v_0 &= -(q_1 + q_2 + q_3 + \text{etc.}), \end{aligned} \right\} \quad (1)$$

where the  $A$ 's are all constants depending upon the distances apart of the con-

\* By wires of small cross-section and length compared with the dimensions of the conductors.

factors and the nature of the insulating medium between them. The coefficients  $A$  in these equations may be called the "potential coefficients" of the system of conductors. It should be noted particularly that *these coefficients are independent of how the conductors may be charged and of how they may be interconnected* (provided the connecting wires are small compared with surfaces of the conductors). In certain simple cases these coefficients  $A$  are readily calculated; see below.

**Electrostatic Induction Coefficients ( $B$ ).** — The above equations may also be written

$$\left. \begin{aligned} q_1 &= B_{11}v_1 + B_{12}v_2 + B_{13}v_3 + \text{etc.}, \\ q_2 &= B_{21}v_1 + B_{22}v_2 + B_{23}v_3 + \text{etc.}, \\ q_3 &= B_{31}v_1 + B_{32}v_2 + B_{33}v_3 + \text{etc.}, \end{aligned} \right\} \quad (2)$$

or

$$q_0 = -(q_1 + q_2 + q_3 + \text{etc.}),$$

where the  $B$ 's are also constants and may be expressed directly in terms of the potential coefficients  $A$  by solving equations (1) for  $q_1, q_2, q_3$ , etc. The constants  $B$  are called the "electrostatic induction coefficients," and like the constants  $A$  are independent of how the conductors may be charged and of how they may be interconnected. The  $B$ 's may be expressed directly in terms of the normal and grounded capacities of the various conductors; see below.

**Normal Capacity of Two Conductors ( $C$ ).** — By the normal capacity between any two conductors is meant the capacity of the condenser formed by these two conductors when all the other conductors are connected to one another and to the conductor of reference, the two conductors of course being insulated therefrom. The normal capacity between any two conductors of a system, say Nos. 1 and 2, is, then, from equation (2),

$$C_{12} = \frac{B_{11}B_{22} - B_{12}^2}{B_{11} + B_{22} + 2B_{12}} \quad (2a)$$

When the arrangement of the conductors is perfectly symmetrical (as in a three-conductor cable),  $B_{11} = B_{22}$  and the normal capacity between 1 and 2 is

$$C_{12} = \frac{1}{2}(B_{11} - B_{12}). \quad (2b)$$

**Grounded Capacity ( $C_g$ ).** — By the grounded capacity of any conductor of a system is meant the capacity of the condenser formed by this conductor as one "plate" and all the other conductors, including the conductor of reference, connected together as the other plate.\* The grounded capacity of conductor No. 1, say, is then, from equation (2),

$$C_{1g} = B_{11}. \quad (2c)$$

That is, the "electrostatic coefficient of self-induction" of any given conductor is the same as the grounded capacity of this conductor.

**Capacity to Neutral ( $C_n$ ).** — In calculating the charging current, voltage drops, etc., in a single-phase or balanced three-phase transmission line it is sometimes convenient to consider the actual capacity between wires as made up of two capacities in series, each of twice the actual capacity between wires. This double capacity, viz.,

$$C_n = 2C_{12} \quad (2d)$$

is called the capacity to neutral, since this capacity multiplied by the voltage to neutral, in either a single-phase or balanced three-phase line, gives the charge on wire, which charge is also in phase with the voltage to neutral. This prod-

\* The term "grounded" arises from the fact that the conductor of reference is usually be ground.

uct, however, does not give the charge per wire when the system is unbalanced; the general equations (2) must then be used.

**Charging Current and Capacity Susceptance.** — The charging currents taken by the various conductors of a system are found by differentiating equations (2) with respect to time; this gives the instantaneous values of the charging currents. In the case of sine-wave voltages all of frequency  $f$ , the effective values and phase relations of the charging currents in each conductor, in terms of the voltage drops to the conductor of reference, all expressed in vector notation (see *Alternating Currents*), are as follows:

$$\left. \begin{aligned} I_1 &= j 2 \pi f (B_{11} V_{10} + B_{12} V_{20} + B_{13} V_{30} + \dots) \\ I_2 &= j 2 \pi f (B_{21} V_{10} + B_{22} V_{20} + B_{23} V_{30} + \dots) \\ I_3 &= j 2 \pi f (B_{31} V_{10} + B_{32} V_{20} + B_{33} V_{30} + \dots) \\ \text{etc.,} \\ I_0 &= - (I_1 + I_2 + I_3 + \dots) \end{aligned} \right\}$$

Note that the quantities in the brackets are to be added *vectorially*.

In the case of a system of but two conductors, i.e., a simple condenser, the relations reduce to

$$I = j 2 \pi f C V,$$

when  $V$  is the voltage drop through the condenser,  $I$  the current in the direction of this drop, and  $C$  the capacity of the condenser. That is, the charging current of a simple condenser leads the voltage drop by  $90^\circ$  and is equal numerically to the product of this voltage by  $2 \pi f C$ . The factor

$$b = 2 \pi f C$$

is called the capacity susceptance\* of the condenser. Capacity susceptance expressed in mhos or micromhos, being of the same dimensions as conductance. Numerically, the charging current of a simple condenser may be then expressed as

$$I = b V.$$

When  $V$  is in volts and  $b$  in mhos, the current  $I$  is in amperes. For either single-phase or balanced three-phase line the charging current per wire may also be expressed as  $I = b_0 V_0$ , where  $b_0 = 2 \pi f C_0 = 2 b$ , and may be called the "capacity susceptance to neutral." When  $b_0$  is in micromhos (see tables below) and  $V_0$  is in volts to neutral, the charging current per wire is

$$I = 10^{-6} b_0 V_0.$$

In a single-phase line  $V_0 = V/2$  and in a balanced three-phase line  $V_0 = V/\sqrt{3}$  when  $V$  in each case is the voltage between wires.

### FORMULAS FOR THE CAPACITY OF SIMPLE CONDENSERS

— Let

$K$  = specific inductive capacity of medium between conductors; medium assumed uniform; for air  $K = 1$ ,

$C$  = capacity of the condenser formed by the two conductors,

$C_0 = 2 C$  = capacity to neutral.

**Two Concentric Spheres.** — Let  $r'$  = internal radius of outer sphere and  $r$  = external radius of inner sphere, both in centimeters, and  $R'$  and  $R$  the corresponding dimensions in inches.

$$\begin{aligned} C &= \frac{K r r'}{r' - r} && \text{statfarads,} \\ &= 2.822 \times 10^{-9} \frac{K R R'}{R' - R} && \text{microfarads.} \end{aligned}$$

\* The inductive susceptance of a condenser is  $-2 \pi f C$ ; see *Alternating Currents*.

**Two Parallel Plates.** — Unless the plates are large compared with their distance apart no simple formula can be deduced, since the electrostatic field at the edge of the plates is not uniform. Let  $S$  = surface, in square inches, of contact between the metal plate and dielectric (the dielectric sheet is usually greater than the metal sheet, hence  $S$  is generally the surface, one side only, of metal plate);  $D$  = thickness of dielectric in inches,  $K$  = specific inductive capacity, and let  $s$  and  $d$  be the dimensions in centimeters corresponding to  $S$  and  $D$  respectively. Then for  $D$  small compared with  $S$ , the capacity of two parallel plates is

$$C = \frac{Ks}{4\pi d} \quad \text{statfarads}$$

$$= 2.246 \times 10^{-9} \frac{KS}{D} \quad \text{microfarads.}$$

**Stack of Plates.** — Let  $N$  = the number of metal plates in the stack; there will then be  $N - 1$  effective dielectric sheets or  $N - 1$  parallel plate condensers in series. Using the same notation as above, the capacity of a stack of  $N$  metal plates, connected in series, is

$$C = \frac{Ks}{4\pi d(N-1)} \quad \text{statfarads}$$

$$= 2.246 \times 10^{-9} \frac{KS}{D(N-1)} \quad \text{microfarads.}$$

**Round Wire in Concentric\* Sheath.** — Dimensions as in Fig. 1; since the ratio only is involved, it is immaterial what units are used for  $D$  and  $d$  provided both are expressed in the same unit. For a length of cable long compared with its diameter,

$$C = \frac{K}{2 \log_e \frac{D}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{7.354 \times 10^{-9} K}{\log_{10} \frac{D}{d}} \quad \text{microfarads per 1000 ft.}$$

Fig. 1.

**Two Parallel Round † Wires.** — Dimensions as in Fig. 2; since the ratio only is involved, it is immaterial what units are used for  $D$  and  $d$  provided both are expressed in the same unit. For a length of line large compared with the distance apart of the wires, the exact formula † for the capacity between wires is

Fig. 2.

\* When the wire is off center by a distance  $m$  (center of wire to center of sheath),

$$C = \frac{K}{2 \cosh^{-1} \alpha} \quad \text{statfarads per centimeter}$$

$$= \frac{16.93 \times 10^{-9} K}{\cosh^{-1} \alpha} \quad \text{microfarads per 1000 ft.,}$$

$$\alpha = \frac{D^2 + d^2 - 4m^2}{2Dd}$$

† When the wires are far apart compared with the linear dimensions of their cross-section, the second group of formulas also applies approximately to wires of any shape cross-section provided  $d$  is taken equal to the perimeter of the cross-section divided  $\pi$ , i.e., equal to the "equivalent" diameter of the cross-section.

‡ Taking into account the non-uniform distribution of the charge on each wire; see *Mcder and Osborne, Elec. World, 1910, Vol. 56, p. 667.*

$$C = \frac{K}{4 \cosh^{-1} \frac{D}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{8.467 \times 10^{-9} K}{\cosh^{-1} \frac{D}{d}} \quad \text{microfarads per 1000 feet.}$$

When  $D$  is greater than  $10d$  the following formulas for the capacity between wires may be used instead of the above with an error of less than 0.1 per cent:

$$C = \frac{K}{4 \log_{10} \frac{2D}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{3.677 \times 10^{-9} K}{\log_{10} \frac{2D}{d}} \quad \text{microfarads per 1000 feet}$$

$$= \frac{19.41 \times 10^{-6} K}{\log_{10} \frac{2D}{d}} \quad \text{microfarads per mile.}$$

The *capacity to neutral* in all cases is  $C_0 = 2C$ . Tables of capacity to neutral for various sizes of wires and various spacings, when separated by air ( $K = 1$ ) are given in the tables below. Note that these tables and the above formulas are strictly applicable to ordinary overhead lines only when the distance from the wires to other conductors, particularly the earth, is large compared with their distance apart. However, the effect of the earth is usually small in most practical cases (see below), and the formulas and tables give a very fair approximation to the actual capacities.

The capacities of standard strands given in the following tables are calculated by the same formula as for smooth round wires using for the diameter  $d$  the diameter of the strand; see *Wires and Cables, Bare*. The values as thus calculated are therefore not exact, but the error is probably less than 3 per cent for all practical cases.

## CAPACITY TO NEUTRAL\* OF SMOOTH ROUND WIRES

\* The susceptance between conductors equals one-half the values given in this table.

**Single Round\* Wire Parallel to the Ground.** — Dimensions as in Fig. 3. The dotted circle represents the "image" of the wire in the plane. The capacity of the actual condenser formed by the wire and the earth (assumed equivalent to an infinite conducting plane parallel to the wire) is the same as the capacity to neutral of the fictitious condenser formed by the wire and its image, the distance between the two wires of this fictitious condenser being  $D = 2H$ . Hence using the approximate expressions, since the wire is practically always more than 10 times its diameter above the other, the capacity between the wire and the earth is

$$C = \frac{K}{2 \log_e \frac{4H}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{7.354 \times 10^{-9} K}{\log_{10} \frac{4H}{d}} \quad \text{microfarads per 1000 feet}$$

$$= \frac{38.83 \times 10^{-3} K}{\log_{10} \frac{4H}{d}} \quad \text{microfarads per mile.}$$

Fig. 3.

**SYSTEMS OF THREE CONDUCTORS.** — Three practical examples of an electrostatically independent system consisting of three conductors only are: (1) three parallel overhead wires at a distance above the earth large compared to their distances apart, (2) two wires in a lead sheath and (3) two overhead wires and the earth. In the first case any one of the three wires may be considered as the conductor of reference; in the second case it is convenient to choose the sheath of the cable as the conductor of reference, whether grounded or not, and in the third case to choose the earth as the conductor of reference. The general equations (1) and (2) are applicable to either case. Designating the reference conductor as No. 3 instead of No. 1, and the other two conductors as No. 1 and No. 2 respectively, the general equations may be written

$$\left. \begin{aligned} v_1 &= A_{11}q_1 + A_{12}q_2, & q_1 &= B_{11}v_1 + B_{12}v_2, \\ v_2 &= A_{21}q_1 + A_{22}q_2, & q_2 &= B_{21}v_1 + B_{22}v_2, \\ q_3 &= -(q_1 + q_2). \end{aligned} \right\} \quad (5)$$

$v_1$  and  $v_2$  indicate the potential drop from 1 to 3 and from 2 to 3 respectively. Solving the first set of equations for  $q_1$  and  $q_2$  gives

$$B_{11} = \frac{A_{22}}{A_{11}A_{22} - A_{12}^2}, \quad B_{21} = \frac{A_{12}}{A_{11}A_{22} - A_{12}^2}, \quad B_{12} = \frac{-A_{11}}{A_{11}A_{22} - A_{12}^2} \quad (5a)$$

**Possible Combinations of Three Conductors which may be used as a Condenser — "Part Capacities."** — The following combinations are possible:

- No. 1 against † No. 3 with No. 3 insulated,
- No. 2 against No. 3 with No. 1 insulated,
- No. 3 against No. 1 with No. 2 insulated,
- No. 1 against No. 2 and No. 3 connected together,
- No. 2 against No. 3 and No. 1 connected together,
- No. 3 against No. 1 and No. 2 connected together.

\* When the wire is at a height large compared with the linear dimensions of its cross-section these formulas also apply approximately to wires of any shape of cross-section provided  $d$  is taken equal to the perimeter of the cross-section divided by  $\pi$ .

† By "against" is here meant that the source of e.m.f. is connected between the two conductors designated, e.g., in the fourth case No. 1 is charged positively say, and an equal and opposite charge divides between 2 and 3.

The capacities corresponding to these various combinations may be called "part capacities," and may be designated by subscripts thus:  $C_{12}$  = capacity of No. 1 against No. 2 with No. 3 insulated (= normal capacity between 1 and 2),  $C_{1(23)}$  = capacity of No. 1 against No. 2 and No. 3 connected together (= grounded capacity of No. 1), and so on for the others. The values of these part capacities can be deduced directly from equations (5), viz.,

$$\left. \begin{aligned} C_{12} &= \frac{1}{A_{11} + A_{22} - 2A_{12}}, & C_{1(23)} &= B_{11} \\ C_{23} &= \frac{1}{A_{22}}, & C_{2(13)} &= B_{22} \\ C_{31} &= \frac{1}{A_{11}}, & C_{3(12)} &= -(B_{11} + B_{22} + 2B_{12}) \end{aligned} \right\} \quad (6)$$

**Three Overhead Parallel Wires, Effect of Earth Neglected.**—Arrangement of wires and dimensions as in Fig. 4; distance apart of wires and diameters both in the same unit of length, but this unit may be either centimeters or inches. From equation (20c) in the article on *Electricity and Magnetism, Principles of*, the following closely approximate values of the  $A$ 's (accurate to within less than 0.1 per cent when the distance apart of the wires is greater than 10 diameters) may be deduced, taking  $K$  as unity, since the dielectric in the case under consideration is air:

Fig. 4.

$$A_{11} = 2 \log_e \frac{4D_{12}^2}{d_1 d_2}, \quad A_{22} = 2 \log_e \frac{4D_{23}^2}{d_2 d_3}, \quad A_{33} = 2 \log_e \frac{4D_{13}^2}{d_3 d_1}, \quad (7)$$

all in c.g.s. electrostatic units for a length of one centimeter.\*

From these relations the values of the coefficients  $B$  may be calculated for any arrangement of three parallel wires.

**Equilateral Triangle Arrangement.**—A common arrangement of the three wires of a three-phase transmission line is to place them so that their centers form the three vertices of an equilateral triangle. In this case  $D_{12} = D_{23} = D_{13} = D$ , say; and if all three wires are of the same diameter  $d_1 = d_2 = d_3 = d$ , say, then  $A_{11} = A_{22} = 4 \log_e \frac{2D}{d}$  and  $A_{12} = 2 \log_e \frac{2D}{d}$  in c.g.s. electrostatic units, and therefore, from equation (6) the normal capacity between any two of the wires with the third wire insulated is

$$\begin{aligned} C_{12} &= \frac{1}{4 \log_e \frac{2D}{d}} && \text{statfarads per centimeter,} \\ &= \frac{3.677 \times 10^{-9}}{\log_e \frac{2D}{d}} && \text{microfarads per 1000 ft.,} \end{aligned}$$

which is the same as the capacity between two parallel wires by themselves see above.

**Equilateral Triangle Arrangement with Balanced Three-phase Voltages.**—For sine-wave voltages between the wires equal in effective value to  $V$  and differing in phase by 120 degrees, the above equations for the charges and

\* To find the values of the  $B$ 's in microfarads per 1000 feet change  $2 \log_e$  in these formulas to  $136 \log_{10}$  and apply equations (5a).

charging currents give the following relations between the *effective* values of the voltages, charges and charging currents, for each of the three wires.

$$Q = C_0 V_0, \quad I = 2\pi f C_0 V_0,$$

where

$$V_0 = \frac{V}{\sqrt{3}} = \text{voltage to neutral,}$$

$$C_0 = 3 C_{12} = \text{capacity to neutral.}$$

When the  $C$ 's are in microfarads the charge  $Q$  is in microcoulombs and the charging current in micro-amperes.

The charge on any particular wire is in phase with the voltage between that wire and the neutral (*see Alternating Currents*) and the charging current for that wire is 90 degrees ahead of the voltage drop from that wire to the neutral. For the same voltage  $V$  between wires in a single-phase system as in a three-phase balanced system, the charging current per wire in the three-phase system

with the equilateral triangle arrangement of wires is  $\frac{3}{\sqrt{3}} = 1.155$  times the

charging current per wire in the single-phase system.

For any other arrangement of wires and for an unbalanced three-phase system, the general equations (5) and the general formulas for  $A_{11}$ ,  $A_{22}$  and  $A_{12}$  given above must be used.

**Two-conductor Cable.**—Arrangement of wires and dimensions as shown in Fig. 5. The sheath forms the conductor of reference and is designated as conductor No. 3, general equations (5), (5a) and (6) apply directly to this case also. For the symmetrical arrangement of the wires shown in the figure,  $A_{11} = A_{22}$  whence, dropping the first subscript,

$$B_1 = \frac{A_1}{A_1^2 - A_2^2}, \quad B_2 = \frac{-A_2}{A_1^2 - A_2^2}.$$

Fig. 5.

Russell (*Alternating Currents, Vol. 1*) gives the following values of  $A_1$  and  $A_2$ , assuming a dielectric filling the space between the wires and the sheath to have the *same*\* specific inductive capacity throughout:

$$A_1 = \frac{2}{K} \log_e \frac{D^2 - a^2}{Dd}, \quad A_2 = \frac{2}{K} \log_e \frac{D^2 + a^2}{2Dd}, \quad (8)$$

both in c.g.s. electrostatic units for a length of one centimeter. To reduce to practical units for a length of 1000 ft. change  $2 \log_e$  to  $1.36 \log_{10}$ .

**Normal Capacity of a Two-conductor Cable.**—Substituting Russell's values for  $A_1$  and  $A_2$  in equation (6) gives

$$C_{12} = \frac{K}{4 \log_e \left( \frac{2a}{d} \cdot \frac{D^2 - a^2}{D^2 + a^2} \right)} \quad \text{statfarads per centimeter}$$

$$= \frac{3.677 \times 10^{-9} K}{\log_{10} \left( \frac{2a}{d} \cdot \frac{D^2 - a^2}{D^2 + a^2} \right)} \quad \text{microfarads per 1000 ft.}$$

**Grounded Capacity of a Two-conductor Cable.**—The capacity in this case, from equations (6), is

$$C_{1(3)} = B_{11} = \frac{A_1}{A_1^2 - A_2^2}.$$

\*This is seldom realized in practice, since the dielectric is made up of insulative fillers and braids having different specific inductive capacities; see *Wires and Cables, Insulated*.

By substituting Russell's values of the  $A$ 's an approximate value for this capacity may be obtained; it will be greater than the normal capacity  $C_{12}$ .

**Effect of the Earth on the Capacity of Two Overhead Wires.** — As a fair approximation the earth may be considered as a conducting plane of infinite extent and the wires as parallel to this plane. Such a combination is electrostatically equivalent to two wires and their two "images" at a distance below the earth equal to the distance of the actual wires above the earth, see Fig. 6. Let  $q_1$  and  $q_2$  represent the charges on the actual wires and  $q_3$  the actual charge on the earth, and  $V_{12}$  and  $V_{23}$  the potential differences between the two wires and the earth respectively (the p.d. between the two wires  $v_{12} = v_{11} - v_{22}$ ); equations (5), (5a) and (6) then apply to this case also. The values of the  $A$ 's in this case are (putting  $K = 1$ , since the dielectric is air)

$$A_{11} = 2 \log_e \frac{2D_{1a}}{d_1}, \quad A_{22} = 2 \log_e \frac{2D_{2b}}{d_2}, \quad A_{12} = 2 \log_e \frac{D_{1b}}{D_{21}}, \quad (9)$$

all in c.g.s. electrostatic units per centimeter length.

To find the values of the  $B$ 's directly in microfarads for a length of 1000 feet change  $2 \log_e$  to  $1.36 \log_{10}$ .

Consider the special case where both wires are at the same height  $H$ , say, and both of the same diameter  $d$ ; then from equation (9), putting  $D$  for the distance between their centers,

$$A_{11} = A_{22} = 2 \log_e \frac{4H}{d}, \quad A_{12} = 2 \log_e \frac{2H}{D'}, \quad (9a)$$

where

$$D' = \frac{D}{\sqrt{1 + \left(\frac{D}{2H}\right)^2}} = \text{"equivalent" distance apart.}$$

Then from equations (6)

$$C_{12} = \frac{1}{4 \log_e \frac{2D'}{d}} \quad \text{statfarads per centimeter.} \quad (10)$$

Comparing the formula for  $C_{12}$  with that for two wires by themselves, equation (4), it is evident that the effect of the earth in this case is to increase the capacity by an amount equal to the increase in capacity which would result from decreasing the distance between the wires from the actual distance  $D$  to the "equivalent" distance  $D'$ . For  $D$  small compared with the height  $H$ , which is usually the case, the equivalent distance  $D'$  is practically equal to  $D$  and the effect of the earth is therefore negligible.

**Effect of the Earth When One Wire is Grounded.** — Let No. 2 be grounded. Consider the same case as in the preceding paragraph, i.e., both wires at the same height  $H$  and of the same diameter  $d$ . From equation (5a)

$$B_{11} = B_{22} - 2C_{12} \left( \frac{A_{11}}{A_{11} + A_{12}} \right), \quad B_{12} = -2C_{12} \left( \frac{A_{12}}{A_{11} + A_{12}} \right),$$

where  $C_{12}$  has the value given by equation (10) and the  $A$ 's the values given by (9a). The charge taken by conductor No. 1 is then  $B_{11}$ , the charge taken

Fig. 6.

conductor No. 2 is  $B_{22}$ , and the charge taken by the earth  $(B_{11} + B_{12})v$ , here  $v$  is the drop of potential from No. 1 to No. 2.

**Effect of the Earth When Middle or Neutral Point of the System is Grounded.** — In this case  $v_{12} = -v_{21} = v_0$ , where  $v_0 =$  voltage to neutral. From equation (5) it is then evident that grounding the middle point of the system has no effect upon the charging current.

**SYSTEMS OF FOUR OR MORE CONDUCTORS.** — The method of calculating the capacities for a three-conductor system, described in detail above, may be readily extended to a system of any number of circuits, independent or otherwise, made up of any number of conductors.

**Relations Between the  $A$ 's and  $B$ 's for a Four-conductor System.** — For a four-conductor system the relations are as follows: put

$$M = A_{11}A_{22}A_{33} + 2A_{12}A_{23}A_{31} - (A_{11}A_{22}^2 + A_{22}A_{11}^2 + A_{33}A_{11}^2),$$

$$\left. \begin{aligned} B_{11} &= \frac{A_{22}A_{33} - A_{11}^2}{M}, & B_{12} &= -\frac{A_{12}A_{23} - A_{11}A_{33}}{M}, \\ B_{22} &= \frac{A_{11}A_{33} - A_{11}^2}{M}, & B_{23} &= -\frac{A_{23}A_{11} - A_{11}A_{33}}{M}, \\ B_{33} &= \frac{A_{11}A_{22} - A_{11}^2}{M}, & B_{31} &= -\frac{A_{12}A_{23} - A_{11}A_{33}}{M}, \end{aligned} \right\} \quad (11)$$

There are 33 part capacities in the general case of a four-conductor system and in cases of symmetry they reduce to a lesser number.

**Three-conductor Cable.** — Arrangement and dimensions as shown in Fig. 7. The sheath forms the conductor of reference; let it be designated as conductor No. 0. From symmetry  $A_{11} = A_{22} = A_{33} = A_1$ , say, and  $A_{12} = A_{21} = A_{13} = A_{31} = A_2$ , say. Equations (11) then reduce to

$$B_{11} = B_{22} = B_{33} = \frac{A_1 + A_2}{(A_1 - A_2)(A_1 + 2A_2)} = B_1, \text{ say,}$$

$$B_{12} = B_{21} = B_{13} = B_{31} = \frac{-A_2}{(A_1 - A_2)(A_1 + 2A_2)} = B_2, \text{ say,}$$

and the capacity between any pair of wires is

$$C_{12} = \frac{1}{2}(B_1 - B_2).$$

Fig. 7.

For sine-wave voltages equal in effective value and differing in phase by 120 degrees, the effective value of the charging current per wire is then, from equation (3),

$$I = 2\pi f(B_1 - B_2)V_0 = 2(2\pi fC_{12})V_0,$$

where  $V_0 = \frac{V}{\sqrt{3}}$ , the voltage  $V$  being the p.d. between wires. This current

leads the voltage drop to neutral,  $V_0$ , by 90 degrees.

**Calculated Value  $C_{12}$  for a Three-conductor Cable.** — Russel (*Alternating Currents, Vol. 1*) gives the following approximate values for  $A_1$  and  $A_2$ , assuming the insulation fillers and braids to have the same specific inductive capacity (which is not usually the case),

$$A_1 = \frac{0.1360 \times 10^9}{K} \log_{10} \left( \frac{D^2 - 1.33 d^2}{Dd} \right) \text{ and } A_2 = \frac{0.0680 \times 10^9}{K} \log_{10} \left( \frac{0.75 D^2 - 1.78 d^2}{d^2 D^2 (3D^2 - 4d^2)} \right)$$

in practical units for a length of 1000 feet. Using these values the normal capacity between wires is

$$C_{12} = \frac{3.677 \times 10^{-8} K}{\log_{10} \frac{2 ap}{d}} \quad \text{microfarads per 1000 feet,}$$

where

$$p = \sqrt{\frac{(3D^2 - 4a^2)^2}{(3D^2)^2 - (4a^2)^2}}$$

That is, the capacity is the same as that of two parallel wires by themselves but at a distance  $ps$  between centers instead of the actual distance  $s$ .

**Effect of the Earth on the Capacity of Three Overhead Wires.** — For any kind of arrangement, as shown in Fig. 8 (the dotted circles are the "images" of the actual wires), the general expressions for the  $A$ 's in c.g.s. electrostatic units\* for a length of one centimeter are as follows:

$$A_{11} = 2 \log_e \frac{2D_{1a}}{d_1}, \quad A_{22} = 2 \log_e \frac{2D_{2b}}{d_2}, \quad A_{33} = 2 \log_e \frac{2D_{3c}}{d_3},$$

$$A_{12} = 2 \log_e \frac{D_{1b}}{D_{12}}, \quad A_{13} = 2 \log_e \frac{D_{1c}}{D_{13}}, \quad A_{23} = 2 \log_e \frac{D_{2c}}{D_{23}}.$$

The values of the  $B$ 's may then be calculated from equation (11) and the charging currents from equation (3). For any numerical case the calculations are tedious, but not difficult. Ordinarily the formulae given above neglecting the effect of the earth are sufficiently accurate for all practical purposes; compare with the effect of the earth on a two-wire line.

**Electrostatic Induction From One Circuit to Another.** — The general equations (1), (2) and (3) together with the method of calculation of the  $A$ 's given in the last paragraph make it possible to calculate the induced voltages from one line to another, e.g., the voltages induced from a high-tension line to a telephone line. The method is straightforward, but tedious. The discussion given above indicates how such a problem may be attacked; space is not available for a detailed discussion here.

**MEASUREMENT OF CAPACITY.** — See the article on *Condensers, Electric*.

**BIBLIOGRAPHY.** — Russell, Alex., *Alternating Currents*; Ferguson, *Elements of Electrical Transmission*; Deutsch, W., *Graphical Method of Calculating the Capacity of Cylindrical Combinations*, Archiv f. Elektrotechnik, 2, p. 435, 1914, gives a method for calculating the capacity of parallel conductors of any form of cross-section whatever.

\* To find from these  $A$ 's the values of the  $B$ 's in microfarads per 1000 feet change  $2 \log_e$  in these formulae to  $136 \log_{10}$  and apply equations (11).

Fig. 8.

**CAR BARNS AND INSPECTION SHEDS.** — (See also *Cars, Electric; Locomotives, Electric; Railways.*) In every electric railway system it is necessary to provide car barns and inspection sheds where the cars may be taken regularly for a systematic inspection. In some cases these barns are used for the storage of cars and in special cases are equipped as regular repair shops. Provision for inspection is necessary, provision for storage is optional, although it is customary to provide storage at least for those cars which are idle during the daytime. The expense of providing for the storage under cover of all the cars that are idle between midnight and 6 a.m. is of doubtful value, for the deterioration of the cars left in the open is likely to be less than the fixed charges on the increased capacity of the sheds.

**Location.** — The location of the car barn may be determined by several considerations. It may be located in the city on account of the convenience of the employees, the possibility of placing the general offices in the same building, and on account of the fact that the city service is an important part of the whole system. It may be located in the suburbs where real estate is cheap and ample space available. It may be located at a convenient point such as the center of gravity of the system, so that the dead mileage of the cars will be a minimum. Finally, it may be located adjacent to the power station, so that the repair shops of the two departments may be combined and thus become more efficient.

**Construction.** — Preparatory to designing a car house it is necessary to become acquainted with municipal and underwriters' regulations and conforming with these, to provide space for car storage, inspection, administration offices, line department, road department, car employees' lobby, car sign storage, sand drying and storage, salt storage, oil storage, wash-room and toilets.

The standard construction consists of a concrete foundation and brick walls, but many of the smaller railroads have mill frame buildings with 2-inch cement curtain walls. The floors are made of concrete with cement finish and sloped for drainage.

**Illumination.** — The illumination of a car barn should be both general and local. The general illumination should consist of incandescent lights, suspended from overhead between the tracks and spaced about a car length apart. These may be run five in series on the trolley circuit, although an ungrounded system is better. The intensity of illumination on the floor should be from 1 to 1.5 foot-candles or lumens per square foot. Frequent sockets for drop lights must also be provided for many portions of the car equipment are in dark corners.

**Inspection Pits.** — Inspection pits between the rails are usually 4 ft. 6 in. deep below the top of rails. It is important to have these pits thoroughly drained and well illuminated.

**Tracks.** — Tracks should be spaced not less than 11 feet between centers where there are no posts between tracks and not less than 13 feet where there are posts. The tracks at the entrance to the car house should be designed to permit the rapid movement of cars with the least interruption to traffic.

**Fire Risks.** — Attention should be given to the prevention of fire by the adoption of the following precautions:

1. Use of automatic sprinklers.
2. Provision of two sources of water supply such as mains and tank.
3. Division of building by fire-proof walls. The underwriters stipulate that no section shall contain cars to the value of over \$200,000.
4. Avoiding proximity to inflammable buildings.

5. Having ample provision of water pails, sand pails, chemical extinguishers and short hoses, the last being usually 2  $\frac{1}{2}$  inches in diameter and provided with 1  $\frac{1}{4}$  inch nozzles.
6. Locating car house near a fire station.
7. Building tracks on a grade so that cars may be easily pushed out by hand.
8. Having numerous auxiliary fire alarms.
9. Consulting underwriters when planning.

**Repair Shops.** — It is usual to provide about 200 sq. ft. of repair shop floor per car owned. This area is usually divided about equally between departments, with, and those without car tracks. Where tracks are installed the usual spacing is from 15 to 16 feet between centers. Cars and car parts are usually lifted by travelling cranes, but in the smallest shops it is common practice to use jacks, hydraulic lifts, screw hoists and chain hoists. Transfer tables are preferred to ladder tracks for moving cars between departments.

Shop buildings should be surrounded with sufficient ground for storage of trucks, lumber, scrap material, etc.

**BIBLIOGRAPHY.** — Electric Railway Engineering Association, *Engineering Manual and Proceedings*.

**CARS, ELECTRIC.**— (See also *Control Systems for Railway Motors; Collectors, Current; Locomotives, Electric.*) The cars used on electric railways may be divided into two classes, viz., single-truck and double-truck. Each of these classes may be subdivided into types according as the cars are open or closed.

**SINGLE-TRUCK CARS** have a seating capacity as high as 32 passengers. Their characteristics are given in the accompanying table.

Item	Dimension
Over-all length.....	28 to 31 ft.
Rigid wheel base.....	5 to 7 ft.
Weight loaded and equipped.....	12 to 20 tons
Maximum speed.....	25 m.p.h.
Maximum motor capacity, total.....	80 h.p.
Number of motors.....	2

They are only used in city service with frequent stops and usually have a cylinder-type controller at each end with hand brakes, although there are cases where these cars have been fitted with remote control and air brakes.

Considerable attention is being given at present to the subject of equipping these cars so that during the hours of heavy traffic they may be run in trains of two, controlled by one motorman. This causes less congestion in the streets for a given service and obviates the waste of operating throughout the day cars of large capacity designed to meet rush-hour conditions.

**DOUBLE-TRUCK CARS.**— The double-truck type of car has an over-all length of from 30 to 70 feet, a seating capacity of from 32 to 70 passengers and a maximum speed of from 40 to 70 m.p.h. One of these cars consists of a body mounted on two, four-wheel trucks. The car body under-frame is supported on a cross piece in the truck known as the bolster and is kept in position by a king-pin fitted into a king-pin center plate on the car body. The truck may swivel around this king-pin through quite an angle, guided by curved plates on each member.

**Construction of Trucks.**— The truck consists of axles, carried in journal boxes in side frames, transoms which connect the side frames, and the bolster which is carried by the transoms by means of springs (either spiral or elliptical) and a spring plate swung from the transoms. Coil springs are inserted between the journals and the side frames. The bolster may be of the "rigid," "floating," or "swinging" type depending upon the amount of play in the bolster. The rigid bolster is employed in locomotives only. The swinging bolster is most generally used for passenger cars, particularly in high-speed service, as it makes a much more easy riding construction. The three-axle truck is common in high-speed steam railroad practice, but the two-axle truck is generally used in electric railway practice as it allows more room for the motors. Four-wheel trucks are sometimes called "bogie" trucks or "swiveling" trucks to distinguish them from the "pony" or "radial" trucks having two wheels, which are used on steam locomotives.

Motor-car trucks have wheels of from 33 to 36 inches in diameter, and usually weigh from 10,000 to 15,000 pounds depending upon the size of the motors and body they are intended to carry. The rigid wheel base is from 6 to 8 feet. The problem of making a motor-driven truck guide properly is considerably more difficult than guiding the trucks of a car that is hauled, as there is a tendency for the motor-driven truck to get out of line and become cramped between the

rails. On this account and on account of the weight of the motors, trucks for a motor car must be stronger and heavier than for a trailer car.

**Suspension of Motors.** — The motors are usually hung between the axle on a single-truck car and between each axle and the transom on a double-truck car. In the "nose" suspension a lug is cast on the side of the motor frame away from the axle and this is attached to the transom with or without springs. The other side of the motor is carried by arms containing bearings which encircle the car axles. Thus about one-half of the weight of the motor is carried as a dead weight on the car axle, and the rest by the truck framing. In the "cradle" suspension both motors of a truck are carried by a cradle which is suspended from the car axles by springs. By this arrangement the entire weight of the motors is spring supported and carried by the axles, thus relieving the transom and side frames of the weight of the motors.

**Maximum Traction Truck.** — This is a special form of bogie truck with two axles having wheels of different diameters. The equalizing arrangements in this truck are such that about three-quarters of the total weight comes on the main axle which has the larger wheels and carries the motor, and the balance comes on the other axle which has small wheels. This arrangement gives a double-truck car with only two motors and yet provides that about three-quarters of the total weight shall be on driving axles, thus yielding "maximum traction." This type of truck is used on cars which are too long and heavy to use the two axle rigid truck but which have such slow speed that only two motors are required. It is not adapted to high-speed work.

**CAR BODIES** may be classified as closed, convertible, semi-convertible and open.

**Closed Cars.**— The small closed type for city service is always of wood and has longitudinal seats. The general dimensions are given in the table below. Large closed cars with double trucks for interurban or rapid-transit service have both transverse and longitudinal seats, the proportion depending upon the proportion of long-haul traffic. The longitudinal seats give an arrangement permitting convenience of movement into and out of the car and allow more room for standing, but are not comfortable for long trips. Transverse seats are most comfortable for a long trip and for a service employing a high rate of acceleration.

**Convertible Cars** are constructed so that all the side panels of the body may be folded either up into the roof, or down to the floor leaving only the upright posts carrying the weight of the roof, thus converting a closed car into an open car at will.

**Semi-convertible Cars.** — A semi-convertible car, as its name implies, is arranged so that it may be partly opened in the summer time. It makes a very good car for high-speed interurban service because it is not advisable to operate open cars in high-speed service.

**Open Cars** usually have the transverse seats extending clear across the car. Access is obtained by steps running the length of the car on each side. They may be of the single- or double-truck type. They provide the maximum seating capacity for a given weight.

**Cars for Rapid Handling of Traffic.** — In large cities where the service is congested special means must be provided to aid and direct the rapid loading and unloading of cars. In a rapid transit service having stations this is accomplished by placing doors in the sides of the cars at the center and at or near the ends, and requiring all passengers to enter by the end doors and leave by the center doors. Both center and end doors are operated by compressed air and controlled by a guard at one end of the car. For street service the pre-payment or "pay as you enter" car is employed. This is built with extra long platform

at each end. The passengers are required to deposit their fare in a box as they enter the car from the rear platform, where the conductor stands, and to leave by the front door and platform. The rear platform is made roomy to take care of congestion while the conductor is making change. Cars of this type recently installed in Chicago and Philadelphia are arranged for both entrance and exit of passengers at the front end, the conductor's station also being at this end.

The "One Man Safety Car" was introduced in 1914 to give more frequent service with decreased expense and in 1919, more cars of this type were built than of all other types combined. The principal data on a typical car are: Seats 32, single truck, length overall 28 feet, two 25 h.p. motors, wheel base 8 feet, wheels 24 inches, total weight equipped 7 tons, maximum speed 18 to 20 m.p.h., energy consumption 0.75 kw.-hr. per car mile. The car is equipped with air brakes, control system automatically interlocked with brakes and car doors and other special safety devices making it possible for one man to operate it with minimum possible chance of mistakes.

**Construction of Car Bodies.** -- Most of the car bodies used on electric railways are constructed of wood, but for underground roads or for roads operating a high-class suburban service of multiple-unit trains the cars are preferably constructed of steel to reduce the dangers from collision and fire. This construction is demanded by consideration of safety, but it is directly contrary to the general tendency of the present day to reduce the weight of cars as much as possible. The proportion of weight of car to weight of load is very high and it entails a considerable waste of energy to propel this dead weight. The weight of car per passenger or seat capacity is a figure that should receive careful consideration and it should be kept at the minimum value compatible with strength and safety.

#### DIMENSIONS AND WEIGHTS OF TYPICAL EQUIPMENTS. —

There are indicated in the following table the principle data for electric cars which are being operated in various typical services.

Service	City	City	City	City P. A. Y. E.	Suburban	Interurban	Subway	N. Y. C. R.R.	W. S. R.R.
Seating capacity	14	24	32	32	38	40	52	64	52
Number of trucks	1	1	1	2	2	2	2	2	2
Length over-all, ft.	22	30	32	41	38	40	50	60	49
Length of body, ft.	16	20	21	28	28	29	41	50	38
Number of motors	2	2	2	2	2	4	2	2	4
H.p. of each motor	40	40	40	70	70	50	200	200	75
Weight of body, lb.	6,000	9,530	7,500	15,800	15,670	19,200	34,300	55,000	35,110
Weight of trucks, lb.	4,600	4,800	4,500	10,400	10,600	16,000	22,500	14,940	23,000
Weight of electric equipment, lb.	5,990	6,962	7,062	9,500	8,350	16,542	21,510	25,460	21,680
Weight, total, lb.	16,590	21,292	19,062	35,700	34,620	51,742	78,310	95,400	79,790
Weight per passenger, lb.	1,185	887	594	1,118	911	1,293	1,506	1,490	1,534
Weight of load, lb.	2,240	3,640	4,760	4,760	5,600	5,889	7,560	9,240	7,560

**CASTINGS, IRON AND STEEL.** — These are made by pouring the molten material into sand or iron molds of the desired shape and allowing to cool. Sand molds are generally used, and are made by packing molding sand about a wooden pattern having the shape of the desired casting and somewhat larger dimensions to allow for the contraction of the metal in cooling. The removal of the pattern leaves a hollow in the sand of the shape of the object to be cast. In order to have sufficient consistency the sand should either contain some clay and be somewhat moist, giving a "green sand" mold, or it should be mixed with a binding material giving a "dry sand mold."

Simple patterns may be made in one piece, but if the pattern be at all complicated it must be made in two or more pieces to permit withdrawal from the sand without disturbing the latter.

Steel castings are more difficult to make than iron castings, as they are more porous; thin steel sections should be avoided for such castings, as the steel cools too rapidly when thin.

In all castings sudden changes in the thickness of the metal should be avoided, as the unequal cooling of sections of different thicknesses causes temperature stresses and may crack the metal. This is particularly true in steel castings.

Care should be exercised in designing castings to make them such that the patterns can be readily removed from the sand molds.

**Process of Making a Mold.** — A wooden or iron box called a flask, consisting of sides only, is used in making the molds. This is divided into a bottom portion called the drag, and an upper portion called the cope; see Fig. 1. Intermediate portions, called checks, are used for complicated patterns.

A hole is made through the cope to convey the metal to the mold. Molds made of "dry sand" should be baked in an oven before pouring. The surface of the mold is frequently coated with "blacking."

If holes are to be made in the casting they are formed by cores of hard-baked sand inserted after the pattern is removed and are held in place by studs of metal, called "chaplets," and by impressions in the mold made by projections on the pattern called "prints."

**Cost of Iron and Steel Castings (Pre-war prices).** — The cost of an iron casting, exclusive of the pattern, depends somewhat upon the intricacy of the pattern; representative costs in 1914 were for simple patterns of moderate size 3 to 5 cents per pound; for large engine and dynamo castings 3 to 4.25 cents per pound; for small intricate castings 6 to 10 cents per pound. Malleable iron and steel castings about 50 to 100 per cent more.

**BIBLIOGRAPHY.** — See bibliographies in the articles on *Iron, Pig and Cast; Steel.*

Fig. 1.

**CELLS, STANDARD.** — (See also *Batteries, Primary; Electrochemistry, Principles of; Potentiometers.*) The need of a standard of electromotive force was recognized in the early days of the electrical industry, and the Daniell cell (see *Batteries, Primary*) was largely used for this purpose. This cell is readily prepared from ordinary chemicals, and is still used to some extent as a rough and ready standard. Such a cell, however, deteriorates quite rapidly, and has therefore been supplanted, for all accurate measurements, by other cells which possess to a greater degree the necessary characteristics of permanence and reproducibility. There are at present two types of standard cells in general use, the Clark and the Weston cells. The latter is the more generally used at the present time.

**Pure Chemicals Required.** — In order that the e.m.f. of any form of primary standard cell may accord with the stated value, great care must be exercised in the preparation of the materials, the processes for which have been carefully worked out by Kahle and later by Wolff and Waters (*Bull. Bureau of Standards, 1907, Vol. 4, p. 1*).

**CLARK CELL.** — In Fig. 1 is shown the Kahle's H-form of the Clark cell, which is one of the most satisfactory of the several forms in which the Clark cell is made. The container is of glass, which is mounted in a metal case with insulated binding posts connected to the two platinum terminals. The saturated solution of zinc sulphate forms the electrolyte, the paste of mercurous sulphate and zinc sulphate acts as a depolarizer, the mercury forms the positive pole and the zinc the negative pole. Detail directions for the preparation of the cell are given in the Bulletin of the Bureau of Standards, 1907, Vol. 4, p. 1.

Fig. 1. Kahle's H-form of Clark Cell

**Electromotive Force of Clark Cell.** — The e.m.f. of the Clark cell, as determined at the time of the adoption of the international units (see *Units, Practical Electrical*), was given as 1.434 volts at 15° C. Subsequent investigations have shown that its true value is 1.4328 international volts at 15° C. At any other temperature  $t^{\circ}$  C. its e.m.f. is

$$E_t = 1.4328 [1 - 0.00077 (t - 15)].$$

The chief objections to the Clark cell are its relatively high temperature coefficient and the length of time required for the e.m.f. to attain a constant value after a change in the temperature of the cell.

**Carhart-Clark Cell.** — To reduce the temperature coefficient and time lag of the saturated or "normal" Clark cell, Carhart devised a form of Clark cell in which the zinc sulphate solution was just saturated at 0° C. with no excess of crystals. The e.m.f. of this type of cell is approximately

$$E = 1.440 [1 - 0.00039 (t - 15)].$$

For accurate work, however, such cells must be calibrated, as the e.m.f. of individual cells may differ appreciably.

**WESTON OR CADMIUM CELL.** — In Fig. 2 is shown the construction of the "normal" Weston or cadmium cell. The container is of glass suitably mounted in a case provided with binding posts to which the platinum wires are attached. This cell differs from the Clark cell chiefly in the use of cadmium amalgam and cadmium sulphate in place of the zinc amalgam and zinc sulphate

for the negative pole and electrolyte respectively. The particular advantage in the use of cadmium instead of zinc arises from the low temperature coefficient and small temperature lag thus obtainable. It also has a longer life and polarizes less rapidly than the Clark cell.

**Electromotive Force of Weston Normal Cell.** — The e.m.f. at 20° C. of the Weston normal cell (the word normal designating that the cadmium sulphate solution is saturated) is 1.01830 international volts. At any other temperature  $t^{\circ}$  C. its e.m.f. is

$$E_t = 1.01830 - 10^{-6}[40.6(t - 20) + 0.95(t - 20)^2 + 0.001(t - 20)^3].$$

(See *Bulletin Bureau of Standards*, 1909, Vol. 5, p. 309.)

The e.m.f.'s of normal cadmium cells as set up by various observers following the same specifications differ among each other by less than 1 part in 10,000.

**Portable Cadmium Cell.** — A portable form of cadmium cell is made, which differs from the normal cadmium cell chiefly in that the cadmium sulphate solution is just saturated at 4° C., and therefore does not contain an excess of cadmium sulphate crystals at ordinary temperatures. This type of cell is to be used between the temperatures of 4° and 40° C. The temperature coefficient is much smaller than that of the normal cell and is negligible for any ordinary measurements; each cell is accompanied by a certificate stating its e.m.f. The extreme variation among 145 cells of this type was found to be 0.0009 volt. This is at present the best form of secondary standard cell, being remarkably permanent. The e.m.f. is approximately 1.0186 international volts; the resistance, roughly, 200 ohms.

**PRECAUTION IN USING STANDARD CELLS.** — No appreciable current can be taken from a standard cell without alteration of its e.m.f., due to polarization. It is found that the change is not permanent, for the cell gradually recovers its original e.m.f.; of course the cell is unreliable until the recovery is complete. Consequently standard cells should be used only where their e.m.f. is opposed to an equal p.d., as in connection with potentiometers. They should always be protected by a key, which is closed only momentarily, and for preliminary adjustments a high resistance, several thousand ohms at least, should be in series with the cell. When an approximate balance has been obtained this resistance should be cut out and the final balance then made.

**COSTS (Pre-war prices).** — A normal Clark cell costs about \$12, a normal cadmium cell \$15, a portable Weston cell \$15.

Fig. 2. Weston Cell

**CEMENT.** — (See also *Concrete*.) The cements used in engineering construction are Portland, natural and Puzzolan (or slag) cements. Of these Portland cement is the most reliable and should always be used in reinforced concrete construction. The processes of manufacture and general characteristics of these cements are given in the following paragraphs, the descriptions being copied from the report of the Joint Committee as published in *Trans. Am. Soc. C. E.*, 1917.

**PORTLAND CEMENT.** — This is the finely pulverized product resulting from the calcination to incipient fusion of an intimate mixture of properly proportioned argillaceous and calcareous materials. Portland cement should be used in reinforced concrete construction and in any other construction that will be subject to shocks or vibrations or stresses other than direct compression.

**Specifications.** — The following specifications are taken by permission from the *Am. Soc. Test. Mat. Standards*, 1918.

The following limits shall not be exceeded:

**Chemical Limits.** — Loss on ignition, 4 per cent; insoluble residue, 2.5 per cent; sulfuric anhydride ( $\text{SO}_3$ ), 2 per cent; magnesia ( $\text{MgO}$ ), 5 per cent.

**Specific Gravity.** — The specific gravity of cement shall be not less than 1.57 (1.57 for white Portland cement). Should the test of cement as received be below this requirement a second test may be made upon an ignited sample. A specific gravity test will not be made unless specifically ordered.

**Fineness.** — The residue on a standard No. 200 sieve shall not exceed 2.2 per cent by weight.

**Soundness.** — A pat of neat cement shall remain firm and hard, and show no signs of distortion, cracking, checking or disintegration in the steam test for soundness.

**Time of Setting.** — The cement shall not develop initial set in less than 45 minutes when the Vicat needle is used or 60 minutes when the Gillmore needle is used. Final set shall be attained within ten hours.

**Tensile Strength.** — The average tensile strength in pounds per square inch of not less than three standard mortar briquettes composed of one part cement and three parts standard sand, by weight, shall be equal to or higher than the following:

Age at test, days	Storage of briquettes	Tensile strength pound per sq. in.
7	1 day in moist air, 6 days in water...	200
28	1 day in moist air, 27 days in water...	300

The average tensile strength at standard mortar at 28 days shall be higher than the strength at seven days.

**NATURAL CEMENT.** — This is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas. Natural cement does not develop its strength as quickly, nor is it as uniform in composition, as Portland cement. Natural cement may be used in massive masonry where weight rather than strength is the essential feature. Where economy is the governing factor, a comparison

may be made between the use of natural cement and a leaner mixture of Portland cement that will develop the same strength.

**Specifications.** — The following specifications are taken from the *Am. Soc. Test. Mat. Standards*, 1918 by permission.

**Fineness.** — The residue on a standard No. 100 sieve shall not exceed per cent and on a standard No. 200 sieve shall not exceed 30 per cent by weight.

**Soundness.** — Pats of neat cement about 3 inches in diameter,  $\frac{1}{2}$  inch thick at center, tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(a) A pat shall then be kept in air at normal temperature.

(b) Another pat shall be kept in water maintained as near 70° F. as practicable.

These pats shall be observed at intervals for at least 28 days, and, to satisfactorily pass the tests, shall remain firm and hard and show no signs of distortion, checking, cracking, or disintegrating.

**Time of Setting.** — The cement shall not develop initial set in less than ten minutes, using the Vicat needle. Final set shall be attained in not less than 30 minutes nor more than 3 hours, using the Vicat needle.

**Tensile Strength.** — The minimum requirements for tensile strength for briquettes 1 sq. in. in cross-section shall be as follows; and the cement shall show no retrogression in strength within the periods specified:

Neat cement	Strength
24 hours in moist air.....	75 lb.
7 days (1 day in moist air, 6 days in water).....	150 lb.
28 days (1 day in moist air, 27 days in water).....	250 lb.
<b>One part cement, three parts standard Ottawa sand</b>	
7 days (1 day in moist air, 6 days in water).....	50 lb.
28 days (1 day in moist air, 27 days in water).....	125 lb.

**PUZZOLAN OR SLAG CEMENT.** — This is the finely pulverized product resulting from grinding a mechanical mixture of granulated basic blast-furnace slag and hydrated lime. Puzzolan cement is not nearly as strong, uniform or reliable as Portland or natural cement, is not used extensively and never in important work; it should be used only for foundation work underground where it is not exposed to air or running water.

**COST OF CEMENT.** — As the cost of transportation is an important item in the cost of cement, the market price depends largely upon the place of sale. Quotations are given in the first number each month of *Engineering News-Record*.

**BIBLIOGRAPHY.** — *U. S. Government Specifications for Portland Cement*, Bur. Stand., Circ. No. 33, 1913. See also *Bibliography* in article on *Concrete*.

**CHAINS AND CHAIN DRIVE.** — Chains for hoisting and similar purposes may be made with straight open links, twisted links or with links with transverse studs to prevent the links from collapsing under heavy loads. These types of chains are known as straight-link chains, twisted chains and stud chains, respectively. The twisted chain is usually employed when the chain has to be wrapped around a smooth drum. Crane chains are straight-link chains carefully made to fit the corrugations of the winding drum.

Chains for transmitting power are of various forms. The more common types are block chains, roller chains and various makes of "silent" chains. In all these chains the links are made of several pieces of metal, the longitudinal pieces being riveted, bolted or screwed to the end pieces or studs. In the block chain, an example of which is the ordinary bicycle chain, the end pieces are solid blocks of metal; in the roller chain the end pieces form studs which carry small rollers. With block or roller chains the power is transmitted from or to the sprocket directly by the studs or rollers, whereas in the various types of "silent" chains, e.g., the Morse and Renold chains, the longitudinal pieces of the links are provided with lugs or fingers which mesh with the teeth of the sprocket wheel and thus pull it around.

Link belts are essentially power transmitting chains made by mounting a number of single chains side by side, so that they all move as a unit. Link belts are used both for power transmission and for belt conveyors.

DATA ON ORDINARY CHAINS (Penn. R.R. Specifications, 1920)

Description	Diam. of wire, inches	Width of links, inches	Length of 100 links, inches	Weight per foot, pounds	Breaking load, pounds	Safe working load, pounds
Twisted iron . . .	$\frac{3}{32}$	....	....	....	1,250	315
Twisted iron . . .	$\frac{3}{16}$	....	....	....	1,800	450

Elongation of all sizes 12 per cent. Proof test one-half of breaking load.

**SIZE, PITCH, STRENGTH AND WEIGHT OF CHAINS.** — The size of an ordinary chain in which the links are made of wire or rods is specified by the diameter of the wire or rod. The pitch of a chain is the distance between the centers of successive links, usually expressed in inches. The proof test of a chain is the specified load it must carry without deformation, and is usually taken as one-half the breaking load. The ordinary safe load is usually taken about two-thirds of the proof test, or one-third the breaking load.

The safe working load is dependent on the amount of rivet-bearing surface, speed, size of sprockets, etc., and ranges from  $\frac{1}{8}$  to  $\frac{1}{10}$  of the tensile strength.

**CHAIN DRIVE.** — The advantages of chain drive are positive speed ratio, capability of transmitting large amounts of power at low speeds, not seriously affected by moisture, oil or grease, no stretch, and for short transmissions greater efficiency than leather, rubber or fiber belting. Roller chains should not as a rule be run at speeds of over 1000 feet per minute, and block chains not over 700 feet per minute.

Wherever possible, the distance between centers of shafts should permit of adjustment in order to regulate the sag of the chain. A chain should be adjusted, in proportion to its length, to show slack when running, care being taken to have it neither too tight nor too loose, as either condition is destructive.

The principal cause of trouble within the chain itself is elongation. It is the result of stretch of material or natural wear. Sudden jars or jolts beyond the limit of elasticity of the material will quickly render the chain useless. For any reason a link elongates unduly it should be replaced at once, as an elongated link will eventually ruin the entire chain.

To minimize wear, chains should be kept well greased and protected from mud and grit, cleaned often, and when replaced put back so that they run in the same direction and same side up. A new chain should never be applied to a much-worn sprocket.

**Sprockets.** — Properly proportioned and machined sprockets are essential to successful chain gearing. For block chain these are obtained as follows:

Sprockets should be gauged to discover thick teeth and inaccurate diameters. A poor chain may operate on a good sprocket, but a bad sprocket will ruin a good chain. Sprockets of 12 to 60 teeth give best results. Fewer may be used, but cause undue elongation in the chain, wear the sprockets and consume too much power. Eight-tooth sprockets ruin almost every roller chain applied to them, and ten and eleven teeth are fitted only for medium and slow speeds with other conditions unusually favorable.

**CHIMNEYS.** — (See also *Draft, Mechanical.*) A chimney serves as a means of establishing a sufficient draft through a furnace to produce the combustion of the fuel. The amount of air required per hour depends upon the quantity of fuel burned per hour and the quality of fuel. The amount actually used depends also on the manner of firing, or the judgment and skill of the fireman. The force required to produce this draft in turn depends upon the quality of the fuel, the method of firing, the thickness of the fuel bed, the design of the furnace, the length and cross section of the gas passages, the height and cross section of the chimney, the location of the chimney with respect to neighboring buildings and hills, and the direction and velocity of the wind which may be blowing. The force available for producing the draft depends upon the height and cross section of the chimney and the difference in temperature of the hot gases in the chimney and the cold air outside. On account of the number of these variables and their great range of variation from time to time, it is practically impossible to deduce a rational formula for the size of the chimney required for the combustion of fuel at a given rate. The following approximate method for determining the height and cross section of a chimney, however, has been found satisfactory in practice. The formula connecting the height, cross section and rate of fuel consumption is an empirical one, deduced by the author from numerous actual cases, and first published in 1884. It has been extensively employed with satisfactory results by numerous engineers since that time.

**INTENSITY OF DRAFT AND HEIGHT.** — The difference in weight between the hot gases inside the chimney and the weight of an equal column of the external air is the cause of the draft produced by the chimney. The pressure due to this difference is called the "intensity" of the draft and is usually measured in inches of water column required to balance it. The measurement is made by a draft gauge, usually a U-tube partly filled with water, one leg connected by a pipe to the interior of the flue between the boiler and chimney and the other open to the external air. For finer and more accurate readings the form of multiplying gauge is used.

Let  $t_1$  be the average temperature of the chimney gases,  $t_2$  the temperature of the external air, both in degrees Fahrenheit, and let  $H$  be the height of the chimney in feet. Then the total intensity of draft produced by the chimney, expressed in inches of water column for normal atmospheric pressure, is

$$F = H \left( \frac{7.64}{460 + t_2} - \frac{3.00}{460 + t_1} \right).$$

For an atmospheric pressure of  $P$  inches of mercury, multiply the left-hand side by  $\frac{P}{30}$ .

The intensity of the draft and consequently the velocity and the volume of the hot gases will of course be greater the greater the temperature of the hot gases, but as the temperature increases the volume of a given weight increases, but its density decreases. When the temperature of the gases exceeds a certain value the increase in the velocity due to a further increase of temperature will be more than offset by the decrease in density. According to Rankine the temperature corresponding to the maximum value of the product of volume and density, that is the maximum weight of gases discharged, is, under ordinary conditions,  $600^\circ \text{F.}$  when the external temperature is  $60^\circ$ . Hence the total intensity of draft  $F_0$  corresponding to maximum weight of discharged gases may be found approximately by substituting 600 in the above formula for  $t_1$ , and 60 for  $t_2$ . The formula then reduces to  $F_0 = 0.007 H$ .

The actual intensity of the draft is usually less than that calculated from the

temperature taken at the bottom of the chimney, on account of the cooling of the gases as they ascend the chimney and from other causes. Taking the reduction at 20 per cent the formula expressing the relation of intensity of draft to height of chimney becomes  $F_n = 0.0057 H$  on the assumption of a temperature of  $600^\circ$  at the bottom of the chimney.

**MINIMUM HEIGHT.** — Hence when the intensity of the draft necessary to produce the necessary current of air through the breeching, boiler and furnace is known, the minimum height of chimney which will produce this draft is

$$H = 175 F_n \text{ feet,}$$

where  $F_n$  is the net intensity of draft in inches of water required. The following table gives the intensity of draft required under ordinary conditions.

**DRAFT PRESSURE REQUIRED FOR COMBUSTION OF DIFFERENT FUELS**

Kind of fuel	Total draft in inches of water	Kind of fuel	Total draft in inches of water
Straw.....	0.20	Slack, very small.....	0.7-1.1
Wood.....	0.30	Coal dust.....	0.8-1.1
Sawdust.....	0.35	Semi-anthracite coal.....	0.9-1.2

Thurston gives the following formulas for the intensity of draft and height of chimney in terms of the fuel consumption per square foot of grate per hour.

Let  $C$  = pounds of coal burnt per hour per square foot of grate. Then for anthracite coal

$$F_n = 0.001875 (C - 1)^2 \quad \text{and} \quad H = \frac{(C - 1)^2}{4};$$

for best Penn. or Welsh

$$F_n = 0.00148C^2 \quad \text{and} \quad H = \frac{C^2}{5};$$

for Pittsburgh or Illinois

$$F_n = 0.000833C^2 \quad \text{and} \quad H = \frac{C^2}{9}.$$

In any particular case the required draft may differ considerably from the figure given above. The design of a chimney should be left to an engineer of experience in this kind of work.

According to C. L. Hubbard (*Am. Elec., Mar., 1904*), the following heights have been found to give good results in plants of moderate size (500 horse-power or less), with sufficient draft to force the boilers 20 to 30 per cent above the rating:

With free-burning bituminous.....	75 feet
With anthracite of medium and large size.....	100 feet
With slow-burning bituminous.....	120 feet
With anthracite pea.....	130 feet
With anthracite buckwheat.....	150 feet
With anthracite slack.....	175 feet

For plants of 700 or 800 horse-power or over, the chimney should not be less than 150 feet high regardless of the kind of coal used. It is evident that the figures in the above table are subject to wide variations with different qualities of fuel as regards caking and non-caking, clinkering and non-clinkering, etc., with different proportions of grate to heating surface and with different kinds of grates and furnaces.

On account of the elimination of the grate in oil-burning boilers and the injection of oil under pressure the height of a chimney for an oil-burning boiler is less than for a coal-burning boiler of the same capacity. According to Gebhardt a height of from 80 to 90 feet is sufficient to force oil-burning boilers to 20 per cent above their rating. In large oil-burning plants, however, the chimney is usually designed on the coal-burning basis, in order to permit the use of coal should this subsequently prove desirable.

**CROSS-SECTION OF CHIMNEY.** — All chimney formulas are based on the hypothesis that the capacity or theoretical coal consumption of a chimney varies directly as the area (or effective area) and the square root of the height.

Let  $C$  = coal consumption in pounds per hour.

$A$  = area of actual cross-section of chimney in square feet.

$H$  = height above the grates in feet.

Then the typical formula may be written:

$$C = KA\sqrt{H}$$

where  $K$  = a constant. Kent uses the formula

$$C = K'A\sqrt{H}$$

where  $A'$  is the "effective" area, taken equal to  $(A - 0.6\sqrt{A})$ , and  $K'$  is a constant.

The value of the constant  $K$ , as given by different authorities, varies greatly, Toldt gives  $K=5$ ; Prechtl,  $K=6.4$ ; Molesworth,  $K=9$ ; Ser,  $K=9.3$ ; Hutton,  $K=10$  to 16; Seaton and Rounthwaite,  $K=12$ ; Henthorn,  $K=16.6$ ; Brinckerhoff (average),  $K=18.1$ . Kent gives for  $K'$  the value 16.65. Toldt and Prechtl refer mainly to German metallurgical practice, Ser to general French practice, Molesworth and Hutton to English practice, Seaton and Rounthwaite to marine practice, Henthorn to American mill practice.

An average of 30 stacks of various sizes now doing good work gives  $K=9.4$ . An average of three notoriously overworked stacks gives  $K=17.9$ .

Ser's figure  $K=9.3$ , was obtained theoretically by allowing for twice the amount of air necessary for perfect combustion. By allowing an excess of one-half the amount necessary for perfect combustion, which result can readily be obtained by the use of automatic stokers, the constant  $K=12$  will be obtained.

For preliminary calculations the above formula with  $K=12$ , gives practical results, but the chimney should be checked by comparison with known stacks of similar diameter and height for the final calculations.

The value of  $K=12$  applies only to brick-lined stacks. In case an unlined iron or steel stack is being considered, the value of  $K$  may be increased to 14 or 15 and for small stacks 16 may be used.

**STABILITY — THICKNESS OF WALLS.** — All chimneys of any considerable size should consist of an outer stack of sufficient strength to give stability to the structure, and an inner stack or core, independent of the outer one, to protect the latter from the high temperature of the hot gases. The core sometimes extends up to a height of but 50 or 60 feet above the base of the chimney, but better practice is to extend it the full height or to 100 to 150 feet in chimneys over 120 feet high. The core is usually constructed of fire brick; the outer stack may be built of common brick, or radial brick (the Custodia chimney is an example of the latter) or of steel or of reinforced concrete. To determine whether a chimney is stable, treat it as a cantilever loaded throughout its length with a load equal to the total pressure (see *Elasticity and Strength; Wind Pressure*); at no section of the chimney should the stress in the walls exceed the safe working stress for the material of which it is constructed.

**Brick Chimneys.** — The base of a brick stack should rarely be less than one-tenth of the height. The allowable batter according to different authorities varies from 1 in 192 to 1 in 20 on each side, but the best practice lies between 1 in 30 and 1 in 40 for ordinary brick, with 1 in 60 to 1 in 80 for the Custodia hollow-tile method of construction.

In brick chimneys practice varies as to the thickness of the walls. The lining are not exposed to wind pressure, and consequently can be much thinner than the outside wall. The usual practice is to make the steps about 50 feet high and 8 inches thick at the top up to a height of 150 feet.

For higher chimneys the lining should be 8 inches thick at the top. The outside walls for chimneys up to 150 feet high may be 8 inches thick at the top, with the steps about 50 feet high or the upper steps may be as high as 60 feet with 50 feet for the lower steps. For stacks built on the Custodia principle the top courses are from 8 to 13 inches thick, depending on the height. The thickness of the moulded brick is increased 2 inches every 5 meters, or about every 16 2/3 feet.

All brick stacks should be topped with a waterproof cap, usually of cast iron although in many cases it is made of stone or monolithic concrete.

**Reinforced Concrete Chimneys** began to come into extensive use in this country in 1901 and several hundred of them are now in use. Reinforced concrete chimneys built by the Weber Co., of Chicago consist of two parts: the lower double shell and the single shell above. The inside shell is usually 4 inches thick, while the thickness of the outside shell depends upon the height and varies from 6 to 12 inches. The single shell is from 4 to 10 inches thick. The height of the double shell depends upon the height of the chimney, nature and temperature of the gases, etc. The bending forces caused by wind pressure are taken up by vertical steel reinforcement; the resistance of the concrete itself against tension is not considered in calculation.

**Steel Chimneys** are largely used, especially for tall chimneys of iron-work from 150 to 300 feet in height. The advantages claimed are: greater strength and safety; smaller space required; smaller cost, by 30 to 50 per cent, as compared with brick chimneys; avoidance of infiltration of air and consequent checking of the draft, common in brick chimneys. The best constructions for steel stacks include a number of vertical stiffeners riveted to the shell which support horizontal cast-iron or steel rings on which the linings are built. The vertical stiffeners are usually spaced about 5 feet apart, and the horizontal rings about 20 feet apart. By this method any section of the lining may be replaced without disturbing the other sections. The thickness of the metal at the top of the stack in such cases is usually 3/8 inch, increasing 1/8 inch

ry 30 feet. Stacks in which the linings are not supported may be  $\frac{3}{4}$  inch at the top increasing  $\frac{1}{16}$  inch every 30 feet. They are usually made conical in shape, with a wide-curved flare for 10 to 25 feet at the bottom. A heavy cast-iron base-plate is provided, to which the chimney is riveted, and the plate is secured to a massive foundation by holding-down bolts. No-guys are used.

**Sheet Iron Smokestacks.** — Guyed stacks of light sheet iron are frequently used for single boilers and even for quite large plants especially where the expected life of the plant is short. The smaller stacks are made up in lengths of about 20 feet of  $\frac{1}{4}$  inch steel connected by angle rings on the outside or the whole stack may be riveted in one piece on the ground and erected with a gin.

For these stacks the value of  $K$  in the general formula may be as high as 20 as they are usually connected directly to the boiler uptake and are exposed to high temperatures.

Such stacks deteriorate very rapidly and cannot be considered a desirable structure, but occasionally circumstances will require their use. Galvanized steel wire cables form the best guys and the anchors may be concrete blocks for the larger sizes. For the smaller sizes the guys usually lead to the steel build-structure.

**Evasé Stacks.** — During the last few years a type of stack has been developed in Europe which offers marked advantages both as to cost and ease with which draft may be controlled. The stack action is based on the injector principle, the theory has not been well worked out as yet. The stack resembles a Venturi meter set up on end, the upper cone or diffuser enclosing an angle of  $7^\circ$ . These stacks are rarely over 60 or 70 feet in height and are usually applied to small boilers or batteries, in order that the control may be perfect. It is usually possible to attain an evaporation of about 2 lb. of water per square foot of boiler area with the stack alone. For the higher ratings air is injected just below the Venturi throat, thereby inducing a higher rate of suction than the height of the stack would make. It is possible so to proportion the stack and blower capacities that a suction draft of 3 or 4 inches of water may be obtained, but this is usually unnecessary, as drafts of from 1 inch to  $1\frac{1}{2}$  inch will fulfill most of the requirements.

For empirical rules for design of Evasé stacks, see *Engineering of Power Plants*, by D. P. Ud and Orrok.

**FOUNDATIONS.** — Chimney foundations are as a rule constructed of concrete except where the nature of the soil necessitates the use of piles or a grill of timber or steel. (For the bearing power of various soils see section on *Foundations* in article on *Power Stations*.) For masonry chimneys the foundation is designed to give the necessary support for the shaft without particular regard to its weight and shape. In steel and reinforced concrete chimneys the weight and shape of the foundation are important factors in securing the proper stability of the chimney, since the shaft is usually securely fastened to the foundation and the two form practically one mass.

**SIZES OF FOUNDATIONS FOR HALF-LINED STEEL CHIMNEYS**  
(Selected from circular of Phila. Engineering Works.)

Diameter, clear, feet.....	3	4	5	6	7	9	11
Height, feet.....	100	100	150	150	150	150	150

Least depth foundation, feet....	.....	7	10	10	12	12	13

**BRECHING.** — The area of the flue or breeching leading from the boiler to the stack is usually made 20 per cent greater than that of the stack. When several boilers discharge into the same flue its section may be tapered and proportioned to the number of boilers. When two flues enter the stack on opposite sides at the same level a diaphragm is inserted between the openings.

**COSTS (Pre-war figures).** — The following table gives the cost of brick chimneys:

**COST OF BRICK CHIMNEYS**

Approximate horse-power	Height, feet	Diameter flue, inches	Cost, erected
85	80	25	\$598
135	90	30	786
200	100	35	1226
300	110	43	1492
400	120	51	1785
750	130	61	2528
1000	140	74	3060
1650	150	88	3750
2500	160	110	5095

The following approximate cost of radial brick chimneys (adapted from Gebhardt, *Steam Power Plant Engineering*) will serve to indicate the variation with height and diameter:

## COST OF RADIAL BRICK CHIMNEYS.

Diameter in feet	Height in feet					
	75	125	150	175	200	250
4	\$1,400	\$3,500	.....	.....	.....	.....
6	2,000	4,300	.....	.....	.....	.....
8	2,700	4,700	\$6,200	\$7,100	\$9,300	.....
10	3,700	5,100	7,100	7,900	10,500	\$16,500
12	.....	.....	7,800	9,000	11,100	18,300
14	.....	.....	8,300	9,700	12,500	21,500
16	.....	.....	.....	.....	.....	24,300

The following are approximate costs of sheet-iron stacks:

## COST OF GUYED IRON STACKS

Approximate horse-power	Height, feet	Diameter, inches	Cost, erected
25	40	16	\$60
...	40	18	70
...	50	18	85
75	50	20	90
...	50	26	105
...	60	22	110
100	60	24	125
...	60	26	135
...	60	28	150
125	60	28	165
...	60	32	190
...	60	34	205
150	60	36	215
200	60	38	230
225	60	42	260
250	60	46	290
300	60	52	340
400	100	60	500

brick and concrete stacks involve little expense for maintenance, 2 per cent liberal allowance for both maintenance and depreciation. Steel and iron stacks require occasional painting to prevent excessive corrosion.

**CIRCUIT BREAKERS.** — (See also *Bus-Bars; Switchboards; Switchgear Equipment for Power Stations.*) A circuit breaker is a device to open an electric circuit which is normally held closed by the action of a latch, toggle or similar mechanism. This tendency to open is the feature that usually distinguishes a circuit breaker from a switch, as the latter, although used to open electric circuits, is without any latch or similar device and hence will remain in the closed position. This distinction between switches and circuit breakers is not always followed, as circuit breakers which open in oil are frequently spoken of as "oil switches."

**TYPES OF CIRCUIT BREAKERS.** — When a circuit breaker automatically opens the circuit as the result of certain abnormal conditions, such as overload, the circuit breaker is said to be "automatic," but if the breaker does not open unless tripped by the attendant it is spoken of as "non-automatic." An automatic breaker usually can be released by hand also. A breaker designed to be closed directly by the operator is spoken of as "direct controlled," while a breaker mounted at a distance is "remote controlled." The latter can be "manually operated" if worked through a system of bell cranks, levers or similar devices; "electrically operated" if worked by motor or solenoid; or "pneumatically operated" if controlled by compressed air.

Small circuit breakers, particularly of low voltage, are usually direct controlled and large-capacity high-voltage breakers are usually remote controlled, an auxiliary source of power being employed. For such distant-controlled breakers automatic operation is secured through relays (see *Relays*). Relays are frequently used with direct-controlled breakers.

**Underload, Over-voltage, Under-voltage and Reverse Current Breakers.** — The principal demand for circuit breakers is to have them open the circuit when the current reaches a certain predetermined value. Some breakers are designed with this end in view. They are also built for underload conditions to open on minimum current, for over-voltage to open when the voltage exceeds a certain amount, for under-voltage to open when the voltage falls below a certain minimum value, for reversal when the current flows in the opposite direction through the breaker from that which was intended. It is, of course, possible to combine these various features of overload, underload, reversal, etc., in one and the same breaker. (See *Relays*.)

**PRINCIPLE OF OPERATION.** — The opening of a circuit breaker is usually secured by the releasing of a latch or the upsetting of a toggle joint which keeps the breaker closed. Various schemes have been adopted to secure adjustment or "calibration" of the overload tripping device, so that it may be made to operate within reasonably wide limits, usually 80 to 160 per cent of normal rating.

**Breakers Opening in Air.** — Fig. 1 shows the general arrangement of the magnetic circuit of a typical carbon-break circuit breaker, arranged for hand or solenoid operation, as used on heavy-capacity d-c. and low-voltage a-c. circuits. The current passes in at one stud across the contact brush and back through the other stud, thus forming a loop or turn in the electric circuit. A U-shaped frame is placed around the lower stud and the movable armature completes the magnetic circuit.

The current passing through the breaker magnetizes the iron circuit and causes the movable armature to lift. At a certain predetermined current the attractive force overcomes the force of gravity, and the raising of the moving arm opens the latch or upsets the toggle which holds the breaker closed.

Two methods of securing the necessary range or calibration can be employed, one by varying the air gap between the stationary and moving iron, and

other by giving the electromagnet more work to do by increasing the weight to be lifted. This latter method can employ either additional weights at a fixed

Fig. 1. Carbon-break Circuit Breaker

distance from the fulcrum, or a fixed weight at a variable distance from the fulcrum.

For small currents the electrical circuit is carried more than once around the air gap, which results in a solenoid design with a movable plunger. With this scheme the tripping range is secured by adding weights to the solenoid or by varying the air gap.

**Oil Circuit Breakers (Figs. 2 to 6).** — With high-voltage oil circuit breakers a tripping coil is usually a solenoid of a fairly large number of turns, which is connected in series with the main circuit or serves as the secondary of a current transformer whose primary is connected in the high-tension circuit. For poly-phase circuits two or more tripping coils are used.

**DESIGN.** — For different classes of service various types of circuit breakers are used, and the functions of these types overlap more or less. The following table gives the approximate values of the maximum normal current and voltage for which these various types are used at present.

In connection with the carbon-break circuit breaker 24,000 amperes is the present size in actual service, but larger breakers could be built if desired. The maximum d-c. voltage at present used for railway service in America, is 5000 volts but carbon breakers can be built for higher d-c. voltages if desired; they have been used up to 22,000 volts for a-c. service.

The fuse type has not been built for more than 100 amperes or 66,000 volts, but could be made for higher voltages if desired.

Type	Max. Current Amperes	Max. Volts
Carbon Break.....	24,000	5,000
Fuse Type.....	100	66,000
Magnetic Blowout, old design.....	10,000	750
Magnetic Blowout, new design.....	3,000	3,000
Oil Break.....	6,000	220,000

The magnetic blowout type in the old design for street railway service has been built up to 10,000 amperes but it has been practically superseded by carbon breakers for this service. For d-c. railway service above 750 volts and up to 3,000 volts the magnetic blowout breaker has been used owing to the very high speed that can be obtained and the efficient blowing out of the arc.

The oil break type is in service for current capacities up to 6,000 amperes and for voltages up to 150,000. It has recently been built for 220,000 volts.

**Air-break Carbon-type Breakers** are made in a variety of designs; Fig. 1 shows a typical single-pole carbon-break circuit breaker. As shown in the figure, the circuit-breaker mechanism consists of a swinging arm carrying the main and the arcing contacts actuated by a handle and toggle-joint mechanism. The main contacts are of copper and are laminated to insure a perfect contact with the copper blocks which are fastened to the base and connected to the line. Above the copper contacts are the arcing contacts of carbon. These contacts consist of one or more carbons carried by a swinging arm and pressed firmly against stationary contacts when the breaker is closed. These carbons are mounted on a pivot to insure proper adjustment.

When the breaker opens the current is gradually shifted through the copper shunts to the carbon contacts, and thus no arc is formed until the final break takes place between the carbon contacts at the top. This arrangement, combined with the natural tendency of an arc to rise, prevents any injury to the breaker by the arc.

For large capacities strap connections are almost invariably used and to facilitate the employment of these strap connections the studs of large breakers are made of laminated construction.

Heavy capacity carbon-break circuit breakers are also made solenoid or motor-operated. With the solenoid design there is a definite end to the movement of the core that prevents damage to the mechanism from overtravel. The motor mechanism has a device that disconnects the worm gear and shuts down the motor when the breaker has closed and the toggle or latch has locked. This device is also so arranged that if an overload or short-circuit exists when the breaker is closed, the breaker will immediately trip out even though the control switch is held in the "close" position. This feature of being "nonclosable on overload" is one that is embodied in a large number of breakers of all kinds, and is a very valuable and useful one.

**Switch and Breaker for Rotary Converters.** — A combination motor-operated switch and circuit breaker has been supplied for various rotary converters and 600-volt feeder circuits supplying current for third-rail electrifications. One motor is provided for each combined circuit breaker and switch and it has suitable clutches, shafts, operating rods and mechanism, so that in the act of closing the circuit breaker is first thrown in and the closing device is then disconnected before the switch is thrown in, so that in case of trouble the breaker can immediately trip out and open the circuit.

**Air-break Fuse-type Breaker.** — This type is a modification of the carbon-break type and is intended for moderate capacity circuits for voltages of 6,000 to 60,000. This breaker consists essentially of a stationary and a movable

mounted on suitable insulators supporting the line connections. These arms are hinged together at one end. The free ends are held together against gravity and a strong spring by a piece of aluminum fuse wire that passes through a blow-out tube. When the current exceeds a certain amount, the fuse wire melts and the free end of the movable arm swings away from the stationary arm, the arc being ruptured in a blow-out tube.

**Magnetic Blow-out Type Breaker.** — This type of breaker is provided with auxiliary contacts that open in a strong magnetic field which blows out the arc formed at these auxiliary contacts. The main contacts are solid copper blocks ridged by a laminated copper brush. These open first when the breaker operates, leaving the final arc to be broken on the auxiliary contacts, which are rotated by the magnetic blow-out device and which can be readily renewed at a comparatively small expense. Although breakers of this type have been installed on the switchboards of power plants, they have been practically superseded by carbon breakers for this work. For such service as the protection of the circuits on a railway car, requiring a few hundred amperes at 600 volts, the magnetic blow-out principle is used to advantage, as the discharge vent from the blow-out compartment can be so set that the vapors from the arc will do no damage.

Since the advent of the high voltage d-c. railways operating at voltages of 1500-1500 or 2400-3000 the magnetic blowout effect has been utilized to great advantage in connection with the high speed breakers developed for that class of service.

**Oil Circuit Breaker (Figs. 2 to 6).** — The essential feature of this type of breaker is the opening of the circuit under oil and the smothering of the arc in a restricted space. These breakers are used almost to the exclusion of all other designs on circuits of large capacity and high voltage. Oscillograph tests show that the circuit is ruptured at the time of zero point of the alternating-current wave, and, therefore, there is little tendency to set up surges in the circuit. The rapid interruption of a direct current, however, is apt to set up surges, and therefore the oil-break design is not commonly used with d-c. service.

Oil-break circuit breakers are designed to meet various conditions of current, voltage and amount of power that they might be called upon to handle in case of a short-circuit. For moderate amounts of power where the size and cost of the breaker is to be kept to a minimum it is often possible to locate all the poles in one oil tank. For slightly larger amounts of power each pole is in a separate oil tank but all the poles are mounted on the same frame. For still greater amounts of power at moderate voltages each pole is in a separate tank and each is in a separate compartment. For very high-voltage work each pole is in a

Fig. 2. 300-ampere, 15,000-volt, 4-pole Circuit Breaker

separate steel tank of such substantial construction as to be proof against any explosion due to the effects of a short-circuit.

Fig. 2 shows a 300-ampere, 15,000 volt, 4-pole breaker of a type that is built on various frames for various sizes up to 2000 amperes at 7500 volts, and 600 amperes at 25,000 volts. In this type of breaker each pole with its pair of contacts is in a separate tank with an insulating lining and all poles on the same frame. This breaker is readily arranged for manual operation or electrical operation by a solenoid and it can be mounted on a wall, framework, switchboard panel or on suitable supports of pipe or structural iron for open construction or for masonry compartments.

Fig. 3 shows a solenoid operated breaker of a type built on various frames for wall mounting, pipe mounting, or structure mounting, in capacities up to 2000 amperes at 15,000 volts and 1200 amperes at 25,000 volts. Each pole of this breaker is in a separate tank mounted on an independent frame and arranged

Fig. 3. 2000-ampere, 15,000-volt Solenoid Operated, Oil Circuit Breaker

Fig. 4. Solenoid Operated, 15,000-volt, Oil Circuit Breaker

so that it can readily be located in a masonry compartment or on a framework. Two, three, or four pole units are made by connecting the mechanisms of two, three, or four poles to the same solenoid operating device. The mechanism at terminal insulators are mounted on the steel top of the breaker and a simple system of toggles operated by a powerful solenoid is used for closing the breaker. A second solenoid is used to disengage a trigger on the operating mechanism to trip the breaker. A two pole, double throw switch is mounted on the breaker and operated by the motion of the levers in opening or closing the breaker; this switch being used to control the signals on the switchboard.

Fig. 4 shows a solenoid operated back connected heavy capacity breaker built in capacities of 600 to 3000 amperes at 15,000 volts, guaranteed capable of rupturing 23,000 amperes per phase at 15,000 volts. Both terminals of each pole are in a single circular tank pressed out of  $\frac{3}{8}$  inch sheet steel, forming a sealess tank of great strength. An insulated lining is provided and each tank has a gauge glass for observing the height and condition of the oil. These breakers in service are placed in masonry structures and their design is based on securing the maximum rupturing capacity in a given space. A heavy steel casting carries the powerful operating mechanism as well as the contact rods, tanks &

making the breaker a self-contained unit. A modification of this breaker has three poles independent, each pole being located in a separate masonry compartment.

Fig. 5 shows a 400 ampere 30,000 volt indoor frame mounted 3 pole solenoid operated oil circuit breaker. Each pole of the breaker is located in a welded steel tank with mica lining. All of the operating mechanism is mounted in the tank top and provision is made for readily replacing any tanks to obtain access to the mechanism.

This type of breaker is built for indoor and for outdoor service, frame mounted, and floor mounted, for voltages from 15,000 to 73,000 frame mounted, and from 37,500 up to 155,000 volts for floor mounting. Designs are available up to 220,000 volts.

A three pole breaker is made up of three elements entirely independent of each other, except that they are connected by a single operating rod. The spacing of the poles, particularly on the floor mounting breaker, can readily be made to suit the station wiring. For manual operation the operating solenoid is replaced by a bell crank device. The condenser bushing leads that run to the stationary terminals can readily be unclamped and moved through the cover.

Series transformers for the location of ammeters and relays are usually arranged to be clamped directly around the condenser bushing leads which form the single turn primary. This permits the use of a simple, compact and cheap form of series transformer.

Fig. 6 shows a 400 ampere, 30,000 volt outdoor floor mounting electrically operated breaker that is built in sizes from 50,000 up to 155,000 volts. This type of breaker is provided with cylindrical tanks having domed tops and bottoms, following out steam. For practice and utilizing tanks that withstand pressures as high as 150 pounds per square inch. Designs are available up to 220,000 volts, the breaker shown on Fig. 6 has main features corresponding closely with that of Fig. 5 previously described.

For outdoor service the condenser bushing leads of the breaker are covered with series of porcelain insulators, and the space between the bushing and the insulator is filled with a moisture proof compound.

Fig. 5

Fig. 6. Three-Pole Outdoor Breaker, 400-ampere  
30,000 volts

The operating mechanism is covered by a metallic hood and the pull rods connecting the poles of the breaker pass through pipes. The various joints are made thoroughly water proof. Access to the interior of the tank is secured by the removal of the mechanism cap or manhole cover which exposes the lever system and presents a sufficiently large opening to withdraw any necessary parts. The mechanism is so disposed that a terminal bushing complete with its contact details can be withdrawn without disturbing any other details, and the moving contact elements can be withdrawn through the mechanism cover.

Where circuit breakers are exposed to temperatures of  $0^{\circ}$  C. or below, ordinary oil becomes sufficiently viscous to seriously impair the efficiency of the circuit breaker. This is caused by the slowing up of the opening action due to the heavy oil and also to the sluggish action of the oil itself in flowing in and suppressing the arc. Special grade oil having low freezing characteristics is available to overcome this difficulty, but for very large units heating elements may be installed in the tanks and put in service during the continuance of dangerously low temperatures. These heating elements can easily be placed so as not to interfere with the action of the mechanism in any way. The cost of these heating elements and the amount of power consumed by them is less on very large units than the difference in cost between the low freezing oil and the ordinary oil.

High voltage breakers of the outdoor type have been in service for a number of years in various parts of the United States, and have also been supplied to Japan, France, Spain and Italy.

**RATING** — (See below for Table of Sizes.) The rating of a circuit breaker is usually given as the normal current which it will carry continuously with temperature rise not exceeding  $30^{\circ}$  C. for carbon breakers and  $50^{\circ}$  C. for oil breakers, above the surrounding air. This rating has no direct relation to the maximum short-circuit current which the breaker will safely interrupt. (See below under *Ultimate Capacity*.) The tripping range of the breaker is usually from 80 to 160 per cent of this normal rating. The cross-section of the conductors and the area of contact surfaces depend so much upon the character of design, the cooling effect of bodies of oil and masses of metal, that no definite current density can be given as an average value for the various types of breaker.

**Ultimate Breaking Capacity.** — (See table below.) When a short circuit or ground occurs on a line, the rush of current thereby produced depends upon (1) the total resistance and reactance of all parts of the circuit through which flows this current or other currents induced thereby, (2) the demagnetizing action of these currents on the fields of the generators producing them, and (3) the lag of this demagnetizing action behind the current producing it. The ability of a breaker to interrupt, without damage to itself, a current of a given magnitude depends upon various features of design, and it is evidently impossible to state how much synchronous or transforming apparatus may be safely connected directly to a breaker of a given rating, unless the conditions of operation are also fully specified.

In the table below the ultimate capacity of various breakers is given in terms of the amperes that they will actually rupture at the arc at their maximum rated voltage. They will rupture this current twice with a two minute interval between short circuits, and will be in condition to carry their full rated current, but may not be in condition to open up under short circuit without further attention.

For voltages less than the rated voltages the rupturing capacity in amperes can be increased usually more rapidly than the decrease in voltage, but a limit is reached when the short-circuit current amounts to approximately fifty times the normal current rating of the breaker.

Curves were published in the February 1918 Proceedings of the A.I.E.E. giving the short-circuit currents of typical American generators with various percentages

of reactance after the expiration of various lengths of time and these can be used to advantage in determining the short circuit to be expected in any system.

In determining the short-circuit characteristics of any particular system, the reactance of the generators and other devices has to be considered. On the basis of an average reactance of 8 per cent the momentary short-circuit current is roughly  $12\frac{1}{2}$  times normal and this usually dies down to about one-half this amount or  $6\frac{1}{2}$  times normal by the time that any automatic breaker can open. At the expiration of a certain time that may be taken roughly as two seconds, the output of the system will be down to the continuous short-circuit basis of possibly two or three times normal rating.

The larger rupturing capacity breakers for 15,000 volts or less are almost invariably mounted in masonry compartments, usually with each pole in a separate cell and the leads carefully isolated from each other. The very high voltage breakers do not utilize the cellular construction and are very frequently arranged for outdoor installation.

**DIMENSIONS, WEIGHTS AND COSTS.** — Although the dimensions, weights costs etc. of breakers of various manufacturers naturally differ and are subject to change with the progress of designs, and while the same manufacturer frequently builds various grades for the same capacity the data that follows will give an idea of the range covered by the breakers of a single manufacturer.

CIRCUIT BREAKER DATA

Item	Amperes	Volts	Rupture, Amperes	Height, inches	Width, inches	Depth, ins.	Weight	Prices
1	400	750	.....	24	4 $\frac{3}{4}$	14 $\frac{3}{4}$	130	\$140
2	800	750	.....	24	4 $\frac{3}{4}$	14 $\frac{3}{4}$	140	149
3	2000	750	.....	24	4 $\frac{3}{4}$	14 $\frac{3}{4}$	150	227
4	8000	750	.....	32	11 $\frac{3}{8}$	21 $\frac{1}{2}$	500	785
5	300	4,500	2,800	22 $\frac{3}{4}$	9 $\frac{3}{8}$	16	185	100
6	300	15,000	1,100	31 $\frac{1}{2}$	15 $\frac{3}{8}$	18	220	235

14	400	37,500	2,400	92	94	30	1,575	2,775
15	400	50,000	2,400	108	101	33	1,875	4,375
16	400	73,000	2,400	119	94	42	4,025	6,075
17	400	95,000	2,400	124	149	48	8,200	9,100
18	400	115,000	2,400	139 $\frac{3}{8}$	172	58 $\frac{1}{2}$	10,700	11,500
19	400	73,000	2,400	124	118	42	5,500	4,975
20	400	115,000	2,400	139 $\frac{3}{8}$	174	58 $\frac{1}{2}$	12,050	9,660
21	400	135,000	1,600	171	216	69 $\frac{1}{2}$	26,600	14,875
22	400	115,000	3,750	157	201 $\frac{1}{2}$	69 $\frac{1}{2}$	14,700	14,030
23	400	135,000	5,350	170	272	84 $\frac{3}{4}$	26,400	17,660

The information in the above table is based on apparatus manufactured by one of the largest American builders of switchgear and is practically correct at the date of its preparation (October, 1920). Changes are made, from time to time in the design of equipment that may slightly modify this information.

The dimensions, height, breadth, and depth for carbon circuit breakers, items 1, 2, 3, and 4, refer to single pole switchboard mounting breakers; and the depth is given from the front of the panel, that is, the length of the studs projecting through the panel is neglected. For the switchboard mounting oil circuit breakers the dimensions are given from the back of the panel, that is, the length of the handle sticking through the board is neglected. All of the oil breakers are three pole, items 5, 6, and 7, being hand operated, the remainder being electrically operated. For the electrically operated breakers the dimensions include the operating solenoids. For cell mounting breakers the dimensions include the cells but the weight and prices are exclusive of cells, oil, current and potential transformers. For the high voltage breakers the dimensions are over the terminals and the width is based on the minimum spacing recommended for any particular voltage. The dimensions are in every case the maximum overall dimensions except as mentioned. The costs given are the approximate selling prices under date of October 1920, and are sufficiently accurate for the preparation of preliminary estimates, but for accurate work should be checked by actual quotations from a reliable builder.

Items 1 to 4 are single pole hand operated carbon circuit breakers, similar to Fig. 1.

Items 5 and 7 are hand operated oil circuit breakers with all contacts in the same tank and barriers between contacts.

Item 6 is an oil breaker with each pole in separate tanks but all tanks on the same frame.

Item 8 is an electrically operated breaker with each pole in a separate tank on a separate frame, and arranged for cell mounting, wall mounting or pipe mounting.

Item 9 is a three pole breaker with all poles in separate tanks, all tanks on a common frame arranged for wall mounting, pipe mounting, or cell mounting.

Items 10 and 11 are essentially cell mounting breakers with each pole in a separate cell, and items 12 and 13 are cell mounting breakers with circular tanks with each pole in a separate tank, all three tanks on the same frame.

Items 14, 15, and 16, are frame mounted solenoid operated indoor breakers.

Items 17 and 18 are solenoid operated floor mounting indoor breakers.

Item 19 is a solenoid operated frame mounting outdoor breaker.

Items 20 and 21 are solenoid operated floor mounting outdoor breakers with oval tanks.

Items 22 and 23 are solenoid operated outdoor breakers with cylindrical tanks.

**COLLECTORS, CURRENT.** — (See also *Cars, Electric; Locomotives, Electric; Third-Rail Systems; Trolley Systems, Overhead; Trolley Systems, Underground.*) Current collectors for electric cars or locomotives are divided into three classes in accordance with the form of the working conductor from which they collect current, as follows:

- a) Overhead Trolley, which may be of the wheel, scraping bow or roller type.
- b) Third-Rail Shoes, which may be of the over-running or under-running type.
- c) Underground Conduit Plow.

**WHEEL TROLLEY.** — The wheel trolley consists of a grooved brass or copper wheel held in bearings in a prong called a "harp" at the end of a steel pole which is pressed upward by a system of springs and levers. The trolley wire is from 18 to 22 feet above the rails. The pole presses the wheel upward against the wire with a pressure of from 20 to 40 pounds, the higher pressure being used for the higher speeds. The current which a wheel trolley can collect is limited at the higher speeds as indicated in the accompanying table. If greater currents are required, resort must be had to the third rail. The trolley wheel is not satisfactory on cars in trains as each trolley wheel requires the attention of a conductor to replace it at curves and switches, and moreover, it is difficult to manipulate the trolley wire from a platform between two cars.

Miles per hour	Amperes
5	1200
15	600
40	350
60	200

**BOW TROLLEY.** — This type of trolley is used to collect current from a high-voltage conductor because it is self-adjusting and needs no attention while the cars are running. At high voltages its current capacity is sufficient to supply power for a train of considerable size but it would not have sufficient capacity to supply power for heavy trains at 600 volts. In America, bows are usually made of mild steel. In Europe aluminum is preferred but it has been found that aluminum containing 6 per cent of copper, gives the best results. The bow may be held up either by simple springs in the same manner as the trolley pole or it may be mounted upon a pantograph mechanism which is held up by springs and folded down by a compressed-air cylinder. The St. Paul 2400 volt locomotives have pantographs with two pans pressing upward with a pressure of about 50 pounds per pan and have successfully collected currents of 3000 amperes at low speeds. The pans are hinged to the pantograph proper in order to make better contact with the trolley wire. A special form of overhead construction must be used for the bow trolley as the bow would strike the downwardly projecting cars and the guy wires of the ordinary trolley construction. The roller trolley may be used in place of the bow on the same form of mechanism. The roller has a greater current capacity and causes less wear on the trolley wire than the bow. The rollers used by the Butte, Anaconda and Great Ry., are steel tubes 5 inches in diameter and 2 feet long. They are each wired to collect 750 amperes at 2400 volts.

**THIRD-RAIL SHOES.** — A third-rail shoe will collect currents as high as 3000 amperes at low speeds and 600 amperes at 60 miles per hour. As they are self-adjusting two or three may be placed on a locomotive or car just as well as one, so that there is practically no limit to the current that can be collected in this way. In fact it is always customary to put two on each side of each locomotive or car in order to prevent a cessation of current when passing

over breaks in the third rail due to switches or crossings. (See article on *This Rails*.)

**Over-running vs. Under-running Types.** — The third rail for top contact or for over-running shoe is cheaper to install, to protect and to maintain and most generally used. The under-contact rail is less liable to trouble from snow and ice and is therefore warranted where climatic conditions are bad.

**UNDERGROUND CONDUIT PLOW.** — The underground plow consists of an insulated steel plate hung from a movable structure on the car. On the two sides of this plate and thoroughly insulated from it are two shoes pressed outward from the plate by springs. These shoes press against the two working conductors which are usually steel Tees separated from each other by about inches and supported on some form of ceramic insulator. The current is taken from the shoes to the car body by flexible insulated conductors.

**BIBLIOGRAPHY.** — Case, F. E., *Current Collection*, G. E. Rev. 1914, Vol. 17, p. 1128; Stewart, S. B., *Current Collecting Devices*, G. E. Rev., 1915, Vol. 16, p. 911.

**IMPLEX QUANTITIES.**—(See also *Vectors*.) The square root of a negative quantity is called an "imaginary" quantity, or a pure imaginary quantity consisting of the sum or difference of a real quantity and an imaginary quantity is called a "complex" quantity. For example,  $\sqrt{-3}$  is a pure imaginary, and  $2 + \sqrt{-3}$  is a complex quantity. All the rules of ordinary algebra apply to pure imaginaries and complex quantities. For example,  $\sqrt{-3}$  may be written  $\sqrt{-1} \sqrt{3}$ , and in general  $\sqrt{-a}$ , where  $a$  is a positive quantity, may be written  $\sqrt{-1} \sqrt{a}$ . The square root of minus one is called the imaginary unit and is usually represented by the symbol  $j$  (writers on pure mathematics use the symbol  $i$ ), that is,

$$j = \sqrt{-1}.$$

A complex quantity may then be written

$$a + jb,$$

where  $a$  and  $b$  are both real quantities.

**Geometrical Representation of a Complex Quantity.**—A positive real quantity may be represented by a line drawn in a given direction; a negative real quantity may be represented by a line drawn in the opposite direction. Multiplying a quantity by  $-1$  then reverses its direction. Also, since multiplying a quantity by  $\sqrt{-1}$  twice is equivalent to multiplying it by  $-1$ , the operation of multiplying once by  $\sqrt{-1}$  may be represented by turning the line representing the quantity through  $90^\circ$  in the positive direction of rotation. The positive direction of rotation is taken as the opposite direction to that in which the hands of a clock move. Hence, a complex quantity  $a + jb$  may be represented by the line  $OP$  in the figure, where  $OA = a$  and  $AP = b$ . The complex quantity  $a + jb$  is then completely specified by a line of length  $\sqrt{a^2 + b^2}$  making an angle  $\theta$ , with the axis of reference  $OX$  where  $\tan \theta = \frac{b}{a}$ .

Fig. 1

The length  $M = \sqrt{a^2 + b^2}$  is called the magnitude of the complex quantity and the angle  $\theta = \tan^{-1} \frac{b}{a}$  is called its angle. From the figure it is evident that the complex quantity  $a + jb$  may also be written

$$a + jb = M(\cos \theta + j \sin \theta).$$

Expanding  $\cos \theta$  and  $\sin \theta$  into series (see *Series*) and adding, the resultant series obtained is the series for  $e^{j\theta}$ ; hence

$$a + jb = M e^{j\theta}. \quad (1)$$

From the above definitions and equation (1) it is evident that complex numbers possess the following properties:

**Addition of Two Complex Quantities.**—

$$(a + jb) + (a_1 + jb_1) = (a + a_1) + j(b + b_1).$$

**Subtraction of Two Complex Quantities.**—

$$(a + jb) - (a_1 + jb_1) = (a - a_1) + j(b - b_1).$$

**Multiplication of a Complex Quantity by a Complex Number. —**

$$(a + jb)(a_1 + jb_1) = aa_1 - bb_1 + j(ab_1 + a_1b)$$

or, putting  $a + jb = Me^{j\theta}$  and  $a_1 + jb_1 = M_1e^{j\theta_1}$ ,

where  $M = \sqrt{a^2 + b^2}$ ,  $M_1 = \sqrt{a_1^2 + b_1^2}$ ,

$$\tan \theta = \frac{b}{a},$$

and  $\tan \theta_1 = \frac{b_1}{a_1}$

we have  $(a + jb)(a_1 + jb_1) = Me^{j\theta}M_1e^{j\theta_1} = MM_1e^{j(\theta+\theta_1)}$ .

Hence the product of two complex quantities is in general a complex quantity which has a magnitude equal to the product of the magnitudes of the two quantities and an angle equal to the sum of the angles of the two quantities.

**Division of a Complex Quantity by a Complex Number. —**

$$\frac{a + jb}{a_1 + jb_1} = \frac{(a + jb)(a_1 - jb_1)}{(a_1 + jb_1)(a_1 - jb_1)} = \frac{aa_1 + bb_1 - j(ab_1 - a_1b)}{a_1^2 + b_1^2}$$

or

$$\frac{a + jb}{a_1 + jb_1} = \frac{Me^{j\theta}}{M_1e^{j\theta_1}} = \frac{M}{M_1}e^{j(\theta-\theta_1)}.$$

Hence the quotient of two complex quantities is in general a complex quantity which has a magnitude equal to the quotient of the magnitudes of the two quantities and an angle equal to the difference of the angles of the two quantities.

**Example. —** Suppose

$$I = \frac{10 + j15}{3 + j2};$$

then by the rule for division

$$I = 4.5 + j3.5,$$

that is,  $I$  contains a real part 4.5 and an imaginary part  $j3.5$ .

**Equations Containing Complex Quantities. —** Since a real quantity cannot be equal to an imaginary quantity it follows that any equation of the form

$$A + jB = A_1 + jB_1,$$

where  $A$ ,  $B$ ,  $A_1$  and  $B_1$  are all real quantities (which may, however, consist of any number of terms), is equivalent to the two equations

$$A = A_1$$

and

$$B = B_1.$$

Also, if one member of an equation reduces to the form  $A + jB$ , then the other member of this equation must likewise contain an equal real and an equal imaginary part.

**CONCRETE.**— (See also *Cement, Concrete, Reinforced.*) Concrete as used by engineers in construction is generally formed of an artificial mixture of Portland cement (see *Cement*) and an aggregate consisting of sand and gravel or broken stone. These ingredients are mixed with water either by hand or by machine mixers.

**Light-weight Concrete.**— During the Great War a light-weight concrete was developed for building concrete ships in the U. S. In this concrete the aggregate instead of being ordinary stone is made from calcined clay specially treated. This light-weight concrete weighs about 110 pounds per cubic foot and has a crushing strength of about 4000 pounds per square inch after 28 days ageing. It has to be made richer in cement than ordinary concrete and is consequently more costly. (*W. L. Scott, Engineering, 108, p. 33, July, 1919.*)

**SPECIFICATIONS.**— The quality of the materials can be determined only by careful tests, but for construction of minor importance and magnitude the following simple specifications should give good results.

**Cement.**— The cement shall be first-class American Portland cement of standard brand, guaranteed to conform to the Standard Specifications of the American Society for Testing Materials. (See *Cement*.) Such cement may be delivered either in bags or barrels but must be kept dry during storage.

**Sand.**— The sand shall be clean and coarse and free from dust, vegetable, bit or other organic matter, and other impurities, and should pass, when dry, through a screen with holes  $\frac{1}{4}$  of an inch in diameter.

**Gravel.**— The gravel shall consist of clean pebbles, and contain no foreign matter. It shall be screened over a  $\frac{1}{4}$ -inch mesh; the sand passing through the screen may be remixed in definite proportions with the gravel. If dirty or lumpy, the gravel should be washed by a hose before mixing.

**Broken Stone.**— The broken stone shall consist of hard and durable stone such as trap, granite and limestone. Unless otherwise specified, all stone shall pass through a  $\frac{1}{2}$ -inch screen.

**Water.**— The water used for mixing shall be free from oil, acid and other injurious substances.

**PROPORTION OF INGREDIENTS.**— The amount of each ingredient is usually measured by volume. The concrete is designated by the proportion of volume of each of the ingredients in the following order: Cement, Sand, Stone or Gravel. For example, a 1 : 2 : 4 mixture is one consisting of one barrel of cement, two barrels of coarse sand, and four barrels of loose gravel or broken stone (standard cement barrels contain 3.8 cu. ft; four bags of packed cement may be considered as equal to one barrel).

The following proportions are somewhat generally adopted for different classes of work.

1 : 2 : 3 or 1 :  $1\frac{1}{2}$  : 3 for water tanks and standpipes carrying considerable pressure and required to be water-tight.

1 : 2 : 4 for arches, reinforced floors, beams, columns, engine foundations subject to vibration, sewers, and in general for structures subjected to bending stresses of some magnitude. A mixture as rich as this is also desirable where concrete is to be deposited under water since in such a case some of the cement may be washed away from the mixture.

1 :  $2\frac{1}{2}$  : 5 for bridge abutments and piers when laid in air, retaining walls and ordinary machine foundations.

1 : 3 : 6 for heavy walls, ordinary foundations, backing for stone masonry, etc.

**Quantity of Ingredients.**—The following rule devised by Wm. B. Fuller may be used for approximate determination of the quantity of the various ingredients.

Let  $c$  = number of parts of cement,  
 $s$  = number of parts of sand,  
 $g$  = number of parts of gravel or broken stone. Then

$\frac{10.5}{c+s+g} = N$  = number of barrels of Portland cement required per cu. yd. of concrete,

$\frac{1.55}{c+s+g} s$  = number of cu. yd. of sand required for one cu. yd. of concrete,

$\frac{1.35}{c+s+g} g$  = number of cu. yd. of stone or gravel required for one cu. yd. of concrete.

For tables giving more accurate values see Taylor and Thompson, *Concrete, Plain and Reinforced*.

**MIXING.**—The ingredients consisting of sand and aggregate should be thoroughly mixed while dry until the mass is uniform in color and homogeneous. Mixing should preferably be done by machine. When necessary to mix by hand, the mixing should be done on a water-tight platform and the ingredients should be turned not less than six times. Enough water should be used to produce a mixture which will flow readily into its place in forms or elsewhere.

**Concrete Mixing in Freezing Weather.**—Reinforced concrete should not be mixed or deposited in freezing weather unless special precautions are taken to keep the materials free from ice, and to protect the concrete from freezing until it has been thoroughly hardened. To accomplish these results the aggregate may be heated, salt water used in mixing, and the concrete carefully covered after it has been deposited. Portland cement concrete which is to be deposited in large masses may be laid in freezing weather provided the surface appearance is not important, and provided that hardened surfaces be thoroughly cleaned from frost as well as dirt before a new surface is laid. Natural cement concrete should never be laid in freezing weather.

**Concrete Shrinkage and Temperature Changes.**—Cracks in cement concrete may be caused by contraction in setting, or by temperature changes, as well as by excessive stress. To preserve a good appearance it is common to establish artificial cracks in long walls, sidewalks, etc. For spacing of such cracks see reference in *Bibliography*. The insertion of steel reinforcing bars even when not needed to carry stresses due to applied loads is an expedient often adopted to prevent the occurrence of such cracks. The amount of reinforcement to be used for this purpose should generally be not less than one-third of one per cent.

**Effect of Sea Water and of Acids on Concrete.**—The data available relating to the effect of sea water upon concrete indicate that there may be some chemical action resulting in a softening and disintegration of the surface. To offset this action as far as possible, concrete laid in sea water should be carefully proportioned and well mixed. There is also great danger from disintegration due to frost in cold climates in concrete lying between high water and low water. To protect against this the concrete may be protected by a surface stone in the zone exposed to such action.

Thoroughly hardened concrete of good quality may be considered as resistant to the action of acids and mineral oils as well as other building materials. Oil containing fatty acids may produce injurious effects by combining with the lime in the concrete, resulting in a disintegration of the latter.

**Waterproofing Concrete.**—Concrete may be made reasonably impervious to water under moderate pressures by using a rich mixture and by careful practice.

portioning and mixing. In the case of building foundations and other structures where leakage is not permissible it is usually advisable to protect the concrete by a separate coating applied either on the outside or inside of the wall or floor. The usual method of waterproofing the exterior is to construct a so-called membranous coating consisting of alternate layers of pitch and tarred felt. The inner surface of concrete basement walls and floors of many of the important buildings in New York City and other large American cities have been waterproofed by the use of a patented compound called "Hydroolithic Cement." Many so-called waterproofing powders, pastes, etc., are manufactured which are claimed to make concrete entirely water-tight if incorporated with it during mixing, but their value is problematical.

**COMPRESSIVE STRENGTH AND WORKING STRESSES.**— In the Joint Committee Report (*Trans. Am. Soc. C.E.*, 1917) the following table of compressive strength of thoroughly set concrete is given:

**COMPRESSIVE STRENGTHS OF DIFFERENT MIXTURES OF CONCRETE**

Tested in cylinders 8 inches in diameter and 16 inches long

Set 28 days under favorable conditions

In Pounds per Square Inch

Aggregate	1 : 3	1 : 4½	1 : 6	1 : 9	1 : 7½
Granite, trap rock.....	3300	2800	2200	1800	1400
Gravel, hard limestone and hard sandstone.....	3000	2500	2000	1600	1300
Soft limestone and sandstone.....	2200	1800	1500	1200	1000
Cinders.....	800	700	600	500	400

The following recommendations are also made:

When compression is applied to a surface of concrete of at least twice the loaded area, a stress of 35 per cent of the compressive strength may be allowed in the area actually under load.

For concentric compression on a plain concrete pier, the length of which does not exceed four diameters, or on a column reinforced with longitudinal bars only, the length of which does not exceed twelve diameters, 22.5 per cent of the compressive strength may be allowed.

The extreme fiber stress of a beam, calculated on the assumption of a constant modulus of elasticity for concrete under working stresses may be allowed to reach 33 1/3 per cent of the compressive strength.

For reinforced structures see the full report of the Committee in the *Trans. U.S.C.E.*, 1917.

**Modulus of Elasticity.**— The value of the modulus of elasticity of concrete has a wide range, depending on the materials used, the age, the range of stresses between which it is considered, as well as other conditions. It is recommended that in computations for the position of the neutral axis and for the existing moment of reinforced concrete beams and for the compression of concrete in columns it be assumed as:

(a) One-fifteenth of that of steel, when the strength of the concrete is taken as 2200 lb. per sq. in. or less.

(b) One-twelfth of that of steel, when the strength of the concrete is taken as greater than 2200 lb. per sq. in., or less than 2900 lb. per sq. in., and

(c) One-tenth of that of steel, when the strength of the concrete is taken as greater than 2900 lb. per sq. in.

**COST OF CONCRETE** (Pre-war prices). — The following table\* gives approximate costs of concrete in place not including excavation forms, steel or miscellaneous items. The values include superintendence, overhead charges and general expense but not office expense nor profit.

Item	Cost per cubic yard	
	Range	Average
Mass concrete as in dams, piers, foundations, etc.:		
Labor only.....	\$0.75 to \$2.50	\$1.25
Material and labor.....	3.00 to 9.00	5.50
Concrete in tunnels and conduits:		
Labor only.....	1.00 to 3.00	2.00
Material and labor.....	4.50 to 8.00	6.25
Concrete reservoirs and standpipes:		
Labor only.....	0.75 to 3.00	1.50
Material and labor.....	3.50 to 13.00	7.00
Concrete buildings:		
Labor only.....	0.75 to 4.00	1.50
Material and labor.....	4.50 to 9.00	6.50
Concrete bridges:		
Labor only.....	0.50 to 2.50	1.50
Material and labor.....	4.00 to 8.00	6.00
Concrete sewers:		
Labor only.....	0.75 to 1.75	1.50
Material and labor.....	3.50 to 8.00	6.00
Granolithic sidewalks:		
Labor only.....	1.00 to 3.00	1.75
Material and labor.....	6.25 to 9.00	7.00
Granolithic sidewalks:		
Labor only.....	2¢ to 4¢ per sq. ft.	2½¢ per sq. ft.
Material and labor.....	5¢ to 14¢ per sq. ft.	10½¢ per sq. ft.

**CONCRETE, REINFORCED.** — (See also *Cement; Concrete; Structures, etc.*) Reinforced concrete beams, girders and slabs are made of Portland cement concrete with the addition of steel bars or steel mesh to resist tensile stresses. They are usually fixed at the ends by being built into columns, walls, other girders and are continuous over intermediate supports; they are, therefore, subject to negative bending moments at the ends and at intermediate supports and positive bending moments between supports. It is common to have bottom reinforcement throughout the length and top reinforcement across

Fig. 1.

supports. Vertical or inclined reinforcement is also usually necessary to resist the diagonal tensile stresses occurring in the web. Fig. 1 shows the general character of a reinforced concrete beam and shows methods of making connections to column and floor beams.

**Character of Reinforcement.** — The steel reinforcement may consist of round or square bars of which the diameter or side seldom exceeds  $1\frac{1}{2}$  inches. The round rods are sometimes twisted when cold, this type of bar being known as the Ransome bar. There are also various forms of corrugated or otherwise formed bars on the market, some of which are shown in Fig. 2. Steel mesh is seldom used for ordinary beams, but is frequently employed in floor slabs. The steel reinforcement should preferably be of the same quality as that used for ordinary steel structures, although the use of a slightly less ductile material may be warranted in some cases where the steel is unlikely to be subjected to injurious shocks.

**Proportions of Concrete; Forms.** — The proportions of concrete for beams and other reinforced concrete structures subjected to flexure is commonly 1:2:4 (Concrete). The forms or molds in which reinforced concrete beams are constructed are usually of wood bolted together, although steel forms are sometimes employed. In general, the size of the beam should be such that the forms can be manufactured from standard size boards. Forms should be watertight, and should be left in place until concrete has set sufficiently to carry the load to which it may be subjected at time of removal of forms.

**Fireproofing.** — In order to make reinforced concrete beams and columns fireproof the steel reinforcement must be protected by a reasonable amount of concrete. A common provision is that the metal in girder and columns be protected by a minimum of 2 inches of concrete; that the metal in beams be protected by a minimum of  $1\frac{1}{2}$  inches of concrete; and that the metal in floor slabs be protected by a minimum of 1 inch of concrete. It is also advisable that all steel shall be beveled or rounded.

Fig. 2.

**Spacing of Reinforcement.** — Lateral spacing should not be less than the diameters center to center, with a clear spacing of not less than one inch. The distance from the side of the beam to the center of the nearest bar should be not less than two diameters. More than two layers should not be used and should be securely tied together by metal connections particularly at or near points where bars are bent.

**Electrolysis and Corrosion in Reinforced Concrete.** — The best experimental data available indicate that no danger from electrolysis need be anticipated to the steel reinforcement in carefully mixed and proportioned Portland cement concrete free from salt or calcium chloride. Portland cement concrete may be considered to thoroughly protect embedded steel from corrosion provided the concrete is properly proportioned and mixed. If the concrete is porous corrosion may be expected. See also article on *Electrolysis of Concrete Structures*.

**Reinforced Concrete Beams.** — The table on the following page gives safe uniformly distributed loads per lineal foot for a series of reinforced concrete beams one (1) inch in width. The constants upon which the table is based are as follows: 1:2:4 concrete with ultimate compressive strength 2000 pounds at 28 days. Allowable stress in concrete = 650 and in steel 16,000 lb. per sq. in. Modulus of elasticity of steel 15 times that of concrete. Area of steel = 0.77 per cent area of beam above center of reinforcement.

#### FORMULAS FOR REINFORCED CONCRETE STRUCTURES.

Detail formulas for design cannot be given here; see references in Bibliography.

**Reinforced Concrete Slabs.** — These resemble beams, are much used for floors of buildings, and usually form an integral part of the floor beams and girders as indicated in Fig. 1. They may be computed in the same manner as reinforced concrete beams (see above) provided the shears and moments due to the outer forces are known. For slabs supported on four sides the distribution of load may be determined by the application of the following formula recommended by the Joint Committee (see *Concrete*).

$$r = \frac{l}{b} - 0.5,$$

in which  $r$  = proportion of load carried by the transverse reinforcement per unit length, and  $b$  = breadth of slab.

Using values above specified, each set of reinforcements is to be calculated in the same manner as slabs having supports on two sides only, but the total amount of reinforcement thus determined may be reduced 25 per cent, by gradually increasing the rod spacing from the third point to the edge of the slab.

If length of the slab exceeds one and five-tenths its width the entire load should be assumed as carried by transverse reinforcement.

Girderless floors or flat slabs are much used for factories and warehouses. In this type of construction the flat slab is supported directly on the columns which are constructed with capital of considerable size. For information regarding the methods of design, reference should be made to the Joint Committee Report, the Building Codes of Chicago and Boston, and the standard text-books.

**Columns of Reinforced Concrete.** — For such columns it is customary to limit to 15 the ratio of unsupported length to least width, and to consider the effective area as that within the protective coating (see section on *Fireproofing* above), or for hooped columns or columns reinforced with structural shapes the area within the hooping or structural shapes. The reinforcement may be

either of longitudinal bars or of longitudinal bars connected by bands, hoops, spirals, or of rigid structural forms. The following formulas may be used design. Let  $A_c$  = cross-section of concrete,  $A_s$  = cross-section of steel,  $A = A_c + A_s$  = total cross-section,  $n$  = ratio between modulus of elasticity of steel and concrete, usually 15.  $P$  = total safe load,  $f_c$  = allowable unit stress in concrete,  $f_s$  = allowable unit stress in steel,  $p = A_s/A$ . Then

$$P = f_c(A_c + n A_s) = f_c A [1 + (n - 1)p],$$

$$f_s = \frac{P}{A[1 + (n - 1)p]},$$

$$f_s = n f_c.$$

#### ALLOWABLE LOAD (POUNDS) ON REINFORCED CONCRETE BEAMS

allowable uniformly distributed load in pounds per lineal foot, in excess of weight of beam, for end-supported rectangular reinforced concrete beams. Tabular values to be multiplied by width of beam in inches to get safe applied load (dead + live + impact).

Depth of beam, in.	Distance from top to center of reinforcement, in. = $d$	Area of steel, sq. in.	Moment of resistance, foot pounds	Span in feet

**COST.** — See section on *Costs* in article on *Concrete*.

**BIBLIOGRAPHY.** — See *Bibliography* in article on *Concrete*.

**CONDENSERS, ELECTRIC.** — (See also *Capacity and Charging Current*.) Any two conductors separated from each other by a dielectric form an electric condenser. The capacity  $C$  of such a condenser is the quotient of the numerical value of charge  $Q$  on either conductor by the difference of potential  $V$  between the two conductors when equal and opposite charges are given to the two conductors, i.e.,  $C = Q/V$ . The usual way of giving the conductors equal and opposite charges is to connect them respectively to the two terminals of a battery or other source of electromotive force. Unless the conductors are close to each other relative to the linear dimensions of their surfaces the capacity is small. Large capacities are usually obtained by using flat plates separated from each other by a thin sheet of dielectric. Unless the two conductors are close to each other relative to their distances from other conductors their capacity is influenced by the presence of the other conductors.

**Formulas for Capacity.** — See the article on *Capacity and Charging Current*.

**Condensers in Series and in Multiple.** — See *Electricity and Magnetism Principles of*.

**Energy Stored in a Condenser.** — See *Electricity and Magnetism, Principles of*.

**Electric Absorption and Dielectric Hysteresis in Condensers.** — When an ordinary condenser is charged by connecting it to the terminals of a source of constant e.m.f. the amount of charge which it takes depends upon the time during which the e.m.f. is applied, i.e., there is an apparent absorption of charge by the dielectric. Time is also required for the dielectric to give up this charge when the plates are short-circuited. Absorption is particularly pronounced in such heterogeneous substances as glass, paper, ordinary mica, etc. On account of this absorption both the capacity and apparent resistance of a condenser in general depend upon the time of application of the e.m.f., i.e., upon the time of electrification.

Dielectrics, when submitted to an alternating electric field, absorb a certain amount of energy over and above that corresponding to the direct current "ohmic" loss. This loss is made up of two elements, one due to the conversion of displacement current into the leakage current at the boundaries of electrically dissimilar elements of the insulation, and the other due to a property similar to magnetic hysteresis. The former depends upon the frequency but is not proportional thereto; the latter is directly proportional to the frequency.

**TYPES OF CONDENSERS AND THEIR APPLICATION.** — Condensers may be classified according to the nature of the dielectric used as (1) air condensers; (2) mica condensers; (3) glass condensers; (4) paper condensers; and (5) electrolytic condensers.

**Air Condensers.** — Due to the low specific inductive capacity and relatively low dielectric strength of air, air condensers have very low capacity and are therefore seldom used except for standards of small capacity. For the latter purpose they are well suited, since their capacity is not appreciably affected by temperature, time of electrification, or frequency.

**Mica Condensers.** — These are built of alternate sheets of mica and metal foil, impregnated with paraffine. They are much used for standards of capacity and for telephone, radio and other work requiring condensers which have a small power factor, high insulation resistance and which remain constant. A good working thickness of mica is from .001 to .002 inch.

$\mu$  (product of megohms by microfarads not less than 1000) and the absorption  $\epsilon$ , only sheets of the finest clear "ruby" mica should be used.

Fig. 1 shows the plan view and connection a subdivided mica condenser. Since this arrangement permits of series, parallel, or series-parallel connection of the condensers a very large number of values of capacity may be obtained.

The power factor of well-made standard mica condensers ranges from about 0.1 per cent to about 1.75 per cent; see Grover, F. W., *Bulletin of the Bureau of Standards*, 4, 3, No. 3.

**Glass Condensers.** — On account of its high dielectric strength and specific inductive capacity glass is particularly well suited for high-tension condensers, such as required for wireless telegraphy and the like. The Leyden jar is a common form of glass condenser. Moscicki's modification of the Leyden jar, shown in Fig. 2, consists of specially formed glass tubes closed at one end and lined inside with silver deposited chemically, the outer coating being sometimes plated in the same way and sometimes dispensed with altogether, the outer electrode in the latter case consisting of a mixture of glycerine and water in which the tubes are immersed.

Morley (*Jour. Inst. Elec. Eng.*, 1909, Vol. 43, p. 621) reports a test on a Moscicki condenser consisting of 8 tubes having a total capacity of 0.03 microfarad, designed for 10,000-volt a-c. working. Each tube is 2 inches in diameter and 2 feet 6 inches long, or with connections 3 feet 2 inches long. The power factor of this condenser was approximately constant and equal to 1.0 per cent for frequencies from 40 to 60 cycles per second and for voltages from 5000 to 10,000 volts.

Fig. 2. Moscicki Condenser

Condensers of this type are used to a considerable extent in Europe as a protective device on high-tension overhead transmission lines, as well as for wireless telegraphy. It has also been suggested by Morley that they could be used economically for improving the power factor of highly-inductive loads, such as induction motors.

**Paper Condensers.** — Paper condensers for telephone and telegraph work are made either (1) by building up a stack of alternate sheets of tinfoil (0.0003 inch thick) and tissue paper, two sheets to the layer, each sheet about 0.001 inch thick, or (2) by rolling up alternate strips of foil or "foiled" paper and tissue paper, the roll after being dried and impregnated with paraffin or other wax being pressed into a cubical shape, and suitably mounted in airtight metal boxes. The "foiled" paper is made by depositing very fine flakes of tin on suitable tissue paper which is then run through a press which forces the flakes into contact with another, resulting in a paper resembling the so-called silver paper used for wrapping tea but having a fairly high conductivity. According to G. F. Mansbridge (see reference below) this paper possesses two decided advantages over the binary metal foil, (1) it is much lighter, and (2) when punctured it is self-healing, the spark vaporizing the tin in the immediate vicinity of the puncture without destroying the paper itself. For a complete description of the method of making the paper and the condensers see Mansbridge, G. F., *Jour. Inst. Elec. Eng.*, 1908, Vol. 41, p. 535.

Paper condensers for telephone and telegraph work are usually built to withstand about 400 volts. The following weights and dimensions are taken from British Post Office specifications for metal-cased telephone condensers

One-microfarad paper condensers designed for a working pressure of 1000 and having the dimensions  $8\frac{3}{4}$  by  $6\frac{1}{4}$  by  $\frac{1}{2}$  inches and weighing 8 ounces are made by the Western Electric Co.

#### DIMENSIONS AND WEIGHT OF PAPER CONDENSERS

*British Post Office Specifications*

Capacity, microfarads	Length, inches	Width, inches	Thickness, inches	Weight, ounces
0.5	$4\frac{1}{4}$	$2\frac{3}{8}$	$\frac{5}{16}$	4
1.0	$4\frac{1}{4}$	$4\frac{1}{4}$	$\frac{5}{16}$	8
2.0	$4\frac{1}{4}$	$4\frac{1}{4}$	$\frac{9}{16}$	12
4.0	$4\frac{1}{4}$	$4\frac{1}{4}$	$1\frac{1}{8}$	20
10.0	$4\frac{1}{4}$	$4\frac{1}{4}$	$2\frac{1}{16}$	46

The power factor of well-made paper condensers ranges from about 0.2 to 2 per cent, but unless care is taken in their manufacture the power factor may be considerably larger; values as high as 30 per cent have been obtained.

Paper condensers similar in construction to those used for telephone work are also used for power factor correction on distribution circuits up to 2300 volt. These condensers are usually made up of a number of units in parallel, each unit having a capacity of 5 kv-a. at 60 cycles. See *G. E. Bulletin, No. 40714, Feb., 1920*. Up to about 300 kv-a. the cost of a static condenser is less than that of a synchronous condenser (see *Motors, Synchronous*).

**Electrolytic Condensers.** — Electrolytic cells of the three following types have been used to a limited extent in Germany as condensers for telephone work: (1) acid cells, consisting of two small electrodes of platinum dipping in an acid solution, (2) sodium cells, in which the electrolyte is a solution of sodium salt, and (3) aluminum cells, in which the electrodes consist of aluminum and the electrolyte is some kind of basic solution. The capacity action of these cells arises from the formation of an extremely thin insulating layer at one side of the cell which apparently has an enormously high specific inductive capacity. The anode and electrolyte therefore form two plates of a condenser having this thin layer of dielectric between them, forming a condenser of exceptionally large capacity per unit volume. The power factor of this condenser however, is very high, due to the leakage current from anode to electrolyte, and consequently these cells are little used strictly as condensers, either in telephone or in power work. However, the aluminum cell is very extensively used as a lightning arrester, on power circuits, its capacity action combined with the self-healing property of the film making it an excellent device for this purpose (see *Lightning Protectors*).

**TESTING OF CONDENSERS.** — The three important properties of a condenser are its capacity, its insulation resistance and its power factor. The insulation resistance is determined by the use of direct current (see *Resistors and Conductance*). The power factor is measured by employing a source of alternating e.m.f. and a Wheatstone bridge and may be looked upon as a measure of the effective a-c. resistance. The power factor of a good mica condenser is practically constant over a wide range of frequency.

A great many arrangements of circuits have been devised for measuring the capacity of condensers, cables, etc. Only one or two of the simple methods

In engineering practice can be described here. For a description and comparison of the various methods which have been used see Grover, F. W. *Bulletin of Bureau of Standards*, Vol. 3, No. 3.

**D-C. Versus A-C. Capacity Tests.** — Due to the effect of electric absorption, as above described, the charge taken by a condenser depends upon the time of electrification; the discharge also depends on the time. Consequently, when capacity is measured by any direct-current scheme a standard time of electrification and a standard method of determining the discharge must be chosen. The British Post Office call for the capacity to be measured by taking the instantaneous discharge (by ballistic galvanometer) after the condenser has been charged for a period of 10 seconds. As a rule the capacity measured by a-c. methods is less than that measured by d-c. methods, since the charge does not have time to soak in; for the same reason the a-c. capacity also decreases rapidly with increase of frequency. Hence a-c. tests should be made at a standard frequency, preferably that of the circuit on which the condenser or cable is to be used. It is also desirable, when possible, to make the capacity test at the same voltage, both in value and wave form, as is to be used on the condenser.

**Voltmeter-ammeter Test of Capacity.** — Connect the condenser in series with an a-c. ammeter and impress on this circuit the selected a-c. voltage. Measure the voltage drop across the condenser by means of a high-resistance voltmeter. Let the current read by the ammeter (voltmeter circuit open) be  $I$ , the voltmeter reading  $V$ , the frequency  $f$ , then the capacity is

$$C = \frac{I}{2\pi fV}$$

provided the voltage is a pure sine wave and the power factor of the condenser is negligible. As neither of these conditions are usually fulfilled, such a test only gives only a rough approximation to the true capacity.

**Ballistic Galvanometer Method.** — Fig. 3 shows the arrangement of circuit for testing the capacity of a cable.  $B$  is a battery of the desired constant e.m.f.,  $K$  a highly insulated key,  $G$  a ballistic galvanometer properly shunted (see *Galvanometers and Shunts*). The sheath of the cable is fully earthed. It is best to charge the core of the cable positively as shown. If a condenser is to be tested instead of a cable, the plate corresponding to the sheath may or may not be earthed, as desired. Care should be taken that there is no leakage of current directly from the battery into the galvanometer or into the cable.

Fig. 3.

The procedure is as follows: Throw the key to the left for the desired length of time, note the position of the galvanometer needle (or spot of light), then throw the key to the right and note the first swing or maximum deflection of the spot of light. Call this  $D_x$ . Next, keeping the same battery, substitute for the cable a standard condenser of known capacity  $C$  and make a similar observation. Let the deflection in this case be  $D$ . Then the unknown capacity is

$$C_x = \frac{D_x}{D} C,$$

provided the damping of the galvanometer is the same in both cases. While this method is satisfactory when applied to perfect condensers, it fails to a greater or less extent when applied to cables, especially if they are very long, or to any condenser having high absorption. With such condensers the discharge consists of two portions: a sudden rush when the key is first closed,

followed by a current gradually diminishing toward zero, due to the loss of the "absorbed" charge. Both portions of the discharge are active in producing the deflection, hence the apparent capacity depends to a certain extent on the period of the galvanometer employed, as well as upon the time of electrification.

**Wheatstone Bridge Method.**—The following method gives a means of measuring both the capacity and power factor of a condenser, provided there is available a standard condenser whose capacity and power factor is known. The bridge is arranged as shown in Fig. 4.  $C$  is the standard condenser and  $C_x$  the condenser to be tested. All resistances must be non-inductive and adjustable.  $A$  is a source of alternating e.m.f. of pure sine-wave form and of frequency  $f$ .  $T$  is the detector; it may be either a telephone or, if the frequency be kept perfectly constant, a vibration galvanometer. For ordinary tests the telephone work with it the frequency should be high.

Fig. 4.

The balancing is effected as follows: with  $R_x$  and  $R$  both zero, adjust  $R_1$ ,  $R_2$  until a minimum of sound is obtained; then adjust either  $R_x$  or  $R$  as the case may require, until the minimum is the best possible; then readjust  $R_1$ ,  $R_2$ , and so on, thus obtaining the perfect balance by successive adjustments.

$$C_x = \frac{R_2}{R_1} C,$$

$$\tan \phi_x = \tan \phi + 2\pi f(RC - R_x C_x),$$

where  $f$  is the frequency,  $\phi_x$  is the angle whose sine is equal to the power factor of the condenser under test and  $\phi$  is the angle whose sine is equal to the power factor of the standard condenser. The effective alternating-current conductance of the condenser under test is then

$$G_x = 2\pi f C_x \tan \phi_x,$$

which as a rule is many times the reciprocal of its insulation resistance as measured by direct-current methods (see *Resistance and Conductance*).

The value of the power factor for the standard is best determined at the Bureau of Standards in Washington; it is done by indirect reference to a standard condenser.

**Sources of Error.**—The sources of error when the most refined measurements are to be made are the inductance or capacity of the various resistance error in the ratio of  $R_1$  and  $R_2$ , and electrostatic induction between the bridge and its surroundings. These sources of error are fully discussed by Grover above referred to.

**COSTS OF CONDENSERS (Pre-war prices).**—A good standard mica condenser of  $\frac{1}{2}$  microfarad, guaranteed to stand 300 volts maximum across terminals costs about \$25. An adjustable mica condenser, such as shown in Fig. 1, having a maximum capacity of 1 microfarad and suitable for voltages up to 300 volts costs about \$60. Paper condensers, such as used on telephone circuits, cost about 70 cents per microfarad. A standard 1000 volt, 1 microfarad paper condenser can be had for about \$3.75.

**CONDENSERS, STEAM.**— (See also *Cooling Systems for Power Stations; Power Stations; Pumps; Steam Engines; Turbines, Steam.*) The primary object of a condenser is to reduce the back pressure in the exhaust of a steam engine or steam turbine, although in cases where the supply of suitable feedwater is limited the recovery of the condensed steam is of equal importance. Theoretically the gain in the output of a given engine for the same steam input is proportional to the reduction in back pressure, but practically the gain is much less than this, depending upon the type of engine and conditions of operation.

**CLASSIFICATION OF CONDENSERS.**— Condensers are of two general types, jet condensers and surface condensers.

**Jet Condensers.**— In a jet condenser cooling water and the exhaust steam mingle together in a closed chamber, the water condensing the steam by direct contact. The cooling or injection water on entering the condenser is broken up into a fine spray or is spread out into a thin sheet. Jet condensers may be classified as follows:

**Standard or Ordinary Jet Condensers,** in which the cooling water condensed steam and air are exhausted by a pump.

**Barometric Condensers (Siphon Condensers),** in which the cooling water and condensed steam are exhausted by a barometric column, the air being exhausted with the water and condensed steam or by means of pump. In certain types of barometric condensers the condensing water is forced into the condenser by atmospheric pressure (if the height of the condensing water is over 15 feet), and the condenser is therefore a "siphon" condenser.

**Ejector Condensers,** in which the condensed steam and air are exhausted directly to the atmosphere by the momentum acquired by the cooling water and condensed steam as they pass through the condenser.

**Rotary Condenser.**— The best known form of this type of condenser is the Leblanc Condenser (made by the Westinghouse Machine Co.), which accomplishes the separate removal of water and air by means of a pair of relatively small turbine-type rotors on a common shaft in a single casing, which is integral with or attached directly to the lower portion of the condensing chamber. The condensing chamber itself is but little more than an enlargement of the exhaust pipe. The injection water is projected downwards through a spray nozzle, and the combined injection water and condensed steam flow downward to a centrifugal discharge pump under a head of 2 or 3 feet, which insures the filling of the pump. The space above the water level in the condensing chamber is occupied by water vapor plus the air which entered with the injection water and with the exhaust steam. This space communicates with the air-pump through a relatively small pipe.

The air-pump differs from pumps of the ejector type in that the vanes in traversing the discharge nozzle at high speed constitute a series of pistons, each one of which forces ahead of it a small pocket of air, the high velocity of which effectually prevents its return to the condenser. A small quantity of water is supplied to the suction side of the air-pump to assist in the performance of its functions. The power required for the pumps is said to approximate 2 to 3 per cent of the power generated by the main engine.

**Surface Condensers.**— Ordinary surface condensers consist of nests of small brass or copper tubes usually  $\frac{3}{4}$  inch or 1 inch in diameter through which cooling water is forced and which are surrounded by an air-tight shell to which the exhaust steam is admitted. There may be one, two or more sets of tubes through which the steam passes in succession, the condenser being referred to

"single-flow," "double-flow" or "multi-flow" respectively. Steam is fed at the top of the shell and the condensed steam drawn off at the bottom. Steam enters the lower tubes and is discharged at the top, securing thus the stages of the counter-flow principle. The rate of heat transmission depends upon the state of the tubes. Transmission is much retarded by a water coating the exterior of the tubes and by interior coatings of scale, dirt or rust. In the so-called "dry-tube" type baffles are arranged to catch the steam from each set of pipes, drain it off at the side and so prevent it from falling into the pipes below.

**Evaporative and Air-cooled Surface Condensers** are sometimes used when condensing water is scarce. Brief descriptions and references are found in Gebhardt's *Steam Power Plant Engineering*.

**CLASSIFICATION OF CONDENSER PUMPS.**—(See also *Pumps Pumping Engines*.) The following names are usually applied to the pumps in connection with a condenser.

**Injection or Circulating Pump**, the pump used for injecting the cooling water into a condenser.

**Wet-air Pump**, the pump used for exhausting the air, condensed steam and hot water from a condenser when these are all exhausted together.

**Dry-air Pump**, the pump used for exhausting the air and water vapor only. A dry-air pump must be used when high vacua are required.

**Hot-well Pump.**—This name is applied to the wet-air pump when this pump exhausts to a hot-well. The hot-well is a well provided to hold the condensed steam, which is approximately at the same temperature as that of the exhaust steam in the condenser. If this hot water is to be used over again for boiler feed it is pumped from the hot-well to the boiler by the boiler feed pump (see *Boilers, Steam*).

**CHOICE OF TYPE OF CONDENSER.**—The chief advantage of the surface condenser over the jet condenser is that the condensed steam does not mingle with the cooling water and therefore the condensed steam may be used over again for boiler feed water, provided any oil which may be carried over with the exhaust steam from the cylinders is eliminated before the steam reaches the condenser (see *Separators, Steam*). When there is plenty of cooling water readily handled a higher vacuum is usually obtained by means of a surface condenser than by means of a jet condenser. To offset these advantages, however, the surface condenser is much more expensive than a jet condenser, and requires as a rule a greater amount of cooling water.

Consequently the use of a surface condenser is in general justified only when the cost of obtaining suitable feed water is relatively high (see also *Feed-water Heaters and Purifiers*), and cooling water, unsuitable for feed water however, is readily cheap (see also *Cooling Towers, Ponds, etc*). Before finally selecting the type of condenser an estimate of the total annual cost, including interest, depreciation, maintenance and all operating charges should be made for each type.

According to Prof. Wickenden the following vacua, based on a 30-inch barometer, have been found most economical in general practice.

Piston engines.....	26 to 26.5 inches
Turbines at 20 per cent load-factor or less.....	27 to 27.5 inches
Reaction turbines at high load-factors.....	28 to 29.5 inches
Impulse turbines at high load-factors.....	28.5 to 29 inches

In summer months warm cooling water often renders these vacua impracticable. When cooling towers are required to conserve the water supply the economic

limits of vacuum are lower, due to the extra investment and the relatively warm state of the water. Jet condensers are cheaper to install and are good for vacua up to 27 inches. They require less water and give somewhat higher hot-well temperatures if closely regulated. For higher vacua the load on a dry-air pump becomes excessive, due to the air entrained with the condensing water. Surface condensers are then preferable and for extreme vacua they are indispensable.

#### DEGREE OF VACUUM AND BACK PRESSURE. — Let

$V$  = degree of vacuum, i.e., the reading of vacuum gauge, in inches of mercury column,

$B$  = reading of barometer.

Then the back pressure in pounds is

$$p = 0.491 (B - V).$$

The degree of vacuum is usually referred to a barometric pressure of 30 inches. Calling  $V_0$  the vacuum in inches of mercury corresponding to a barometric pressure of 30 inches, and  $B$  and  $V$  the observed barometric pressure and gauge reading respectively, then

$$V_0 = V + (30 - B).$$

(If  $V_0$  is the vacuum in inches referred to 760 millimeters or 29.92 inches of mercury, substitute for 30 the number 29.92.)

Vacua from 20 to 29 inches are used in practice, corresponding to back pressures of from 4.5 to 0.5 pounds. The higher the vacuum the more cooling water required and the greater the cost of the air and circulating pumps.

#### CONDENSING WATER REQUIRED. — Let

$T$  = temperature, in ° F., of dry saturated steam at the pressure corresponding to the desired degree of vacuum,

$T_i$  = temperature, in ° F., of the injection water,

$T_c$  = temperature, in ° F., of the condensed steam at bottom of condenser,

$T_w$  = temperature, in ° F., of the discharge water (for a jet condenser  $T_w = T_c$ ),

$H$  = total heat (above 32° F.) of the exhaust steam, in B.t.u. per pound.

Then the weight of condensing water required per pound of steam is

$$W = \frac{H - T_c + 32}{T_w - T_i}.$$

In applying this formula the values of  $T_c$  and  $T_w$  must be determined and an allowance must be made for the regulation of the supply of condensing water.

	Jet condensers		Surface condensers	
	Parallel-current	Counter-current	Single and double flow	Multi-flow*
$T_c$ less than $T$ by.....	10 to 15	5 to 10	5 to 10	0 to 5
$T_w$ less than $T$ by.....	10 to 15	5 to 10	10 to 20	0 to 10

\* Cases have been reported where  $T_c$  and  $T_w$  are both higher than  $T$  by a few degrees. (*Proc. Inst. New Arch., March, 1906.*) [Probably due to errors of gauges.]

ness of  $T_s$  and  $T_w$ . — Air is always present in exhaust steam and in the case of jet condensers a certain amount of air also enters the condenser with cooling water. The effect of the air is to reduce the temperature of the steam ( $T_s$ ) below that corresponding to saturated dry steam ( $T$ ) at the same pressure. The amount of air present depends upon the type of condenser and upon the amount of air in the cooling water in the case of a jet condenser.

The relations between  $T_s$ ,  $T_w$  and  $T$ , as shown in the table on page 256, are found to hold in practice.

**Allowance for Regulation of Injection Water.** — It is usual to take for the above formula the value corresponding to dry saturated steam at the same pressure in the condenser (see tables in article on Steam), and then to increase the value of  $W$  so obtained by from 5 to 15 per cent to allow for imperfect regulation of the injection water and for the more or less unknown state of the steam as it enters the condenser.

**Example.** — A vacuum of 25.85 inches, referred to 29.92-inch barometer, is to be maintained in a surface condenser, with injection water at 60° F. The value of  $T$  from the steam tables is 126° F. and  $H = 1115$  B.t.u. Take  $T_s = 120^\circ$ ,  $T_w = 115^\circ$ ,  $T_i = 70^\circ$ ; then

$$W = \frac{H - T_s + 32}{T_w - T_i} = \frac{1115 - 120 + 32}{115 - 70} = 22.8$$

**DIMENSIONS OF CONDENSERS.** — There is so great a difference in the design of the various forms of jet condensers that it is impossible to give average dimensions. See the catalogues of the makers; representative types of the various types are listed above.

In the case of surface condensers the tube surface exposed to the steam varies inversely as the coefficient of heat transfer (i.e., the number of B.t.u. per hour per °F. difference in temperature between the steam and water per square foot of cooling surface) and directly as the mean temperature difference between the water and the steam. Let

- $T_i$  = temperature, in °F., of the injection water,
- $T_s$  = temperature, in °F., of the exhaust steam at condenser pressure,
- $T_w$  = temperature, in °F., of the discharge water,
- $Q$  = pounds of cooling water required per hour,
- $U$  = coefficient of heat transfer.

then, according to Josse (*Power*, Feb. 2, 1909), the required cooling surface in square feet is

$$S = \frac{2.3 Q}{U} \log_{10} \frac{T_s - T_i}{T_s - T_w}$$

The value of  $U$  depends upon the metal used for the tubes, the condition of the external surface of the tubes and especially upon the condition of the internal surface of the tubes (scale and corrosion decreasing the value of  $U$  very markedly), and upon the velocity of the water, being greater the higher this velocity. It may be taken as 150 for water velocities of from 25 to 50 feet per minute and 175 for velocities of from 50 to 75 feet per minute. There is, however, a considerable difference of opinion regarding the proper formula for  $S$  and the proper value to assign to  $U$ . (See Hoefler, K., *A.S.M.E.*, J. 41, p. 662, 1919).

In reciprocating engine plants an allowance of 2 square feet of tube surface per indicated horse-power is customary. In early steam-turbine installations an area of from 2 to 4 square feet per kilowatt was commonly employed, but subsequent improvements in condensers and the water rates of turbines have tended to reduce these areas. In the most modern plants

of large capacity condenser surfaces range from 1.2 to 2.5 square feet kilowatt.

From the relations implied in the above formulas it is seen that the area may be reduced by forcing large quantities of water at high velocities to pass tubes; or, with a given surface, the vacuum may be heightened by increasing the flow of cooling water. However, the gain may be more than offset by the cost of pumping this water.

**SIZE OF CONDENSER PUMPS.** — (See also articles on *Blowers and Compressors; Pumps and Pumping Engines.*) The size of the injection or circulating pump required can be calculated directly from the quantity of injected water to be handled and the head against which it is to be pumped, including of course the friction head. Separate injection pumps for jet condensers are not usually required, as the head does not as a rule exceed that corresponding to the difference between atmospheric and condenser pressure. In the case of surface condensers the intake and discharge tunnels are usually at about the same level, and consequently the head is largely friction head. The friction head of a condenser is not readily calculated, but may be obtained from the manufacturer.

**Wet-air Pumps.** — The predetermination of the size of wet-air pumps is difficult, owing to the uncertainty in estimating the quantity of water vapor and air which they must handle. In the case of jet condensers the total weight of water (including the vapor) and air is equal to the combined weight of exhaust steam and cooling water, whereas for a surface condenser only the condensed steam and air in it is handled by the wet-air pump. Hence the wet-air pump for a surface condenser is usually much smaller than for a jet condenser.

Formulas, partly analytical and partly empirical, for calculating the piston displacement of wet-air pumps will be found in Gebhardt's *Steam Power Plant Engineering*. For average practice the volume capacity or piston displacement is equal to the volume of cooling water multiplied by the following factors.

For jet condensers, single-acting pump.....	3
For jet condensers, double-acting pump.....	3.5

Piston speeds are usually about 50 feet per minute at full load.

For surface condensers the volume capacity is equal to the volume of condensed steam multiplied by the following factors.

For reciprocating engines.....	10
For steam turbines.....	20

These figures are based on a study of some 200 installations (Gebhardt, 1910).

**Dry-air Pump.** — The required volume capacity is found in practice to be equal to the volume of the condensed steam multiplied by the following factors:

For vacua under 27 inches.....	20 to 30
For vacua 28 inches or over.....	50

In both cases the barometer is assumed as 30 inches. These figures are given by Gebhardt and are based on an investigation of some 50 installations.

**POWER REQUIRED FOR CONDENSER PUMPS.** — The power required for the circulating pump is calculated in the ordinary way from the weight of the water delivered and the head, including the friction head (see *article on Pumps and Pumping Engines*).

The power required for the wet-air and dry-air pumps can be accurately determined only when the proportion of air in the exhaust steam and the cooling water, in the case of a surface condenser, is known. Surface steam under atmospheric pressure contains from 2 to 12 per cent, by volume, of air. To allow for leakage, a liberal factor of 20 per cent may be taken.

Power Required to Exhaust the Air. — Let

$p_a$  = atmospheric pressure, pounds per square inch,

$p_c$  = pressure in condenser, pounds per square inch,

$T_i$  = initial temperature of injection water, in ° F.,

$T_f$  = initial temperature of feed water, in ° F.,

$T_c$  = temperature in condenser in ° F. (approximately the temperature of the exhaust steam),

$W_w$  = weight of cooling water in pounds per minute,

$W_s$  = weight of condensed steam in pounds per minute.

$V_1$  for a jet condenser the volume of air in cubic feet per minute at condenser pressure to be handled by the pump is

$$V_1 = \frac{(W_w + W_s) p_a (T_c + 460)}{310 p_c (T_i + 460)},$$

for a surface condenser

$$V_1 = \frac{W_s p_a (T_c + 460)}{310 p_c (T_f + 460)},$$

using in both cases that there is 20 per cent air by volume in the water at atmospheric pressure. This percentage is probably high when the feed water taken from a hot-well, since the heating of the water drives out the air. Also, the temperature  $T_c$  for a counter-current jet condenser and separate air pump is nearly the temperature of the injection water than that of the steam. The horse-power required to exhaust the air is then

$$P_a = \frac{p_c V_1}{66.2 \epsilon} \left\{ \left( \frac{p_a}{p_c} \right)^{0.28} - 1 \right\},$$

where  $\epsilon$  is the mechanical efficiency of the pump, which may range from 30 to 50 per cent. (See article on Blowers and Compressors.)

Power Required to Exhaust the Condensed Steam and Water. — The power required to exhaust the water and condensed steam from a jet condenser can be calculated in the same manner as for an ordinary pump (see article on Pumps and Pumping Engines), using the proper value of the head under which the pump operates. This will depend upon the arrangement of the condenser, location of the pumps and hot-well, etc.

If a wet-air pump only is used, then the total horse-power of this pump will be  $P_a + P_w$ , where  $P_w$  is the horse-power required to remove the condensed steam and water. If a dry-air pump is used in connection with the wet-air pump (which then exhausts the water only) the horse-power of the dry-air pump is  $P_a$  and the horse-power of the wet-air pump  $P_w$ .

Per Cent of Total Available Energy Used by Condenser Pumps. — When steam-driven pumps are employed and the exhaust from these pumps is utilized the steam consumption of the pumps is properly taken as a measure of the energy required for their operation; this may range from 5 to 20 per cent of the total steam generated by the plant. When the exhaust from the steam engines of the pumps is utilized for heating the feed water (see Feed-water heaters), the heat consumption of the pumps is properly taken as a measure of the energy required for their operation; this may range from about 1 to 5 per cent of the total B.t.u. utilized by the main engines, for a large part of the steam in the pumps is returned to the boiler via the feed water. When electrically-driven pumps are employed, the kilowatt-hour input to the motors driving the pumps is properly taken as a measure of the energy required for operating the pumps; this may range from about 2 to 8 per cent of the output of the main generators.

**LOCATION AND ARRANGEMENT OF CONDENSERS.** — When there is only one engine installed the condenser is usually placed close to and just below the engine, so that all condensation may gravitate into it. In the case of large vertical steam turbine outfits the condenser (surface type) is at the base of the turbine and forms an integral part of the structure. When several engines or turbines are installed in a power house a separate condensing outfit may be used for each engine, or the so-called "central system" may be employed in which one condensing outfit serves several engines. This arrangement is particularly well adapted to plants in which the individual units are subjected to extreme variations in load, as in rolling mills.

Additional data on the location and arrangement of condensers will be found in the article on *Power Stations*.

**COST OF CONDENSING EQUIPMENT** (Pre-war figures). — An approximate formula that is sometimes used for determining the cost of surface condensers is,

$$\text{Cost in dollars} = 500 + 1.0 \times \text{h.p.}$$

Potter (*Power*, Dec. 30, 1913) gives:

Type	Capacity	Cost, dollars
Barometric (28-in. vac.)....	Up to 30,000 lb. steam per hour	$1055 + 0.112 \times \text{lb. steam cond. per hr.}$
Jet (28-in. vac.).....	Up to 30,000 lb. steam per hour	$1176 + 0.1138 \times \text{lb. steam cond. per hr.}$
Surface (28-in. vac.).....	Up to 35,000 lb. steam per hour	$1630 + 0.2038 \times \text{lb. steam cond. per hr.}$
Surface (26-in. vac.).....	Up to 30,000 lb. steam per hour	$413 + 0.1015 \times \text{lb. steam cond. per hr.}$

Twenty-eight inch vacuum surface condensers with pumps cost from \$1.80 per square foot of surface, depending on price of copper, or from \$150 to \$250 per 1,000 pounds of steam condensed per hour.

J. R. Bibbins (*Power*, Jan, 1905) gives a curve showing the relative cost of high-vacuum surface condensers compared with 26-inch-vacuum surface condensers. The following figures are taken from this curve.

Degree of vacuum, inches.....	26	26.5	27	27.5	28	28.5
Relative cost, per cent.....	100	111	123	137	158	180

**Maintenance of Condensers.** — The cost of maintenance of a surface condenser is subject to wide variations, depending upon the corrosion and deterioration of the condenser tubes, the exact cause of which is not often understood. With clean, fresh water, free from acid, the tubes of a condenser last indefinitely, but where the cooling water contains sulphur, as in drainage from coal mines, or sea water contaminated by sewage, such as harbor water, the deterioration is exceedingly rapid.

The maintenance of a jet condenser is much less affected by impurities in the water.

**BIBLIOGRAPHY.** — Gebhardt, *Steam Power Plant Engineering*, contains 62 pages on condensers and a full bibliography of the subject.

Underground cables are now almost universally installed in either of glazed tile, wood or paper fiber. The pipes or conduits are joined together to form a series of continuous ducts for a length of not less than 100 feet and are terminated in brick or concrete chambers, from which the cables are pulled into the ducts.

**TERMINOLOGY.**—While there is some confusion in the definitions of conduit lines, the best recent literature, except the specifications of the American Electric Railway Engineering Association, sanction the following definitions.

**Conduit**, a pipe or tube designed or used for containing electric cables.

**Duct**, a passage or opening, designed or used for accommodating wires or cables.

**Conduit Line**, a group of installed conduits. (The expression *conduit line* is largely used for conduit line, but will not be used herein, as it is easily confused with such expressions as "the subway subway," meaning the conduit line of an underground railway.)

**Splicing Chamber**, a chamber built to give access to the duct line; frequently called a manhole. Properly, a manhole is the access to the splicing chamber.

**Manhole**, an opening giving access to an underground splicing chamber from the surface of the ground; frequently, but improperly, used to designate the entire splicing chamber.

**Service Box**, a part of a splicing chamber with facilities for distributing conductors to the mains. Service boxes are usually made of iron and set on the roof of the splicing chamber like a manhole cover.

**USE OF CONDUIT LINES.**—Conduit lines are used for the transmission of electrical energy wherever the unsightliness, danger or expense of overhead pole lines prohibits the use of the latter. It is therefore in large cities and in the suburbs where they have found their principal application. They are used for the distribution of lighting cables of lighting systems, power plants and for telephone and telegraph lines.

Since the invention of the Pupin loading-coil, the use of underground conduits for telephones has received considerable impetus. Underground conduits now extend from Boston to Washington, a distance of nearly 500 miles, a pump-log being used for the conduit the greater part of the way. A notable installation of conduit for trunk-line railroad electric

the New York Central which comprises over 1,600,000 duct feet, partly in tile conduit and partly in iron pipe.

**Advisability of Double-conduit Line.** — A conduit line of a large number of ducts should be avoided wherever possible. While a large line may be permissible for telephone work, it certainly is not desirable for light or power work. The entire output of a station or substation of considerable size should not be carried out through one conduit line, but should be divided between two or more lines kept well separated.

**TYPES OF CONDUITS.** — While tile conduit is used far more than any other kind, there are four other kinds in fairly extensive use; namely, fiber conduit, wrought-iron pipe, cement-lined iron and pump-log.

**Tile Conduit.** — Fig. 1 shows the tile conduits used in the Electric Zone of the N. Y. C. & H. R. R. R. near New York and Fig. 2, the standard of the

Fig. 1.

A.E.R.E.A. They represent what is probably the best practice up to date. The conduit shown in Fig. 1 weighs 16½ pounds per length of 18 inches. Four-

Fig. 2.

duct conduit is now comparatively little used; it weighs about 100 pounds per length of 3 feet.

**Fiber Conduit** consists of tubes, made by rolling paper saturated with asphalt or bituminous compound around a mandrel. Like iron pipe, which it resembles in appearance, lengths of fiber conduit are usually joined by screw and coupling although it is also made for socket, sleeve and drive joints. It is lighter and easier to handle than iron pipe with which it compares favorably in cost, but is more expensive than tile conduit. It is mechanically inferior to other types of conduit, and difficulty is often experienced in drawing heavy cable around bends without breaking the conduit. For some classes of work this disadvantage is entirely compensated for by superior gas and water tightness.

The dimensions of fiber conduits are given as follows by the Johns-Manville Company and substantially the same by the Fiber Conduit Company.

Socket joint				Sleeve joint			
Inside diameter, inches	Thickness of walls, inches	Approximate average weight per foot, pounds	Length of section, inches	Inside diameter, inches	Thickness of walls, inches	Approximate average weight per foot, pounds	Length of section, inches

4	7/8	3.20	60				

**Wrought-iron Pipe** is used in city streets where the conduit line has to twist about sub-surface obstructions. It is more expensive than tile conduit and does not last as long on account of rusting. The usual sizes are 3-inch and 3 1/2-inch pipe, 20 feet long, provided with threaded ends and couplings. (For weights and dimensions see article on *Pipes*.)

**Cement-lined Iron Pipe** consists of thin sheet-iron cylinders, like stovepipe, with a lining of hydraulic cement. When the conduit is old the iron usually rusts away without detriment to the construction.

**Pump-log Conduit** is used only on telephone lines, as its inflammability renders it dangerous for power work. It consists of wooden blocks with the

Fig. 3.

Fig. 4.

duct hole drilled out. A description of a typical pump-log installation is given below under *Installation*.

**SPlicing CHAMBERS.** — Splicing chambers, for straight runs, are usually built in the shapes shown in Figs. 3, 4, 5 and 6. That shown in Fig. 3 is usually regarded as ideal, as the excavation is a minimum, and the cables can

follow the walls very closely without being bent to a dangerously small radius, a frequent occurrence in chambers with square corners. The rectangular form shown in Fig. 4 is somewhat more common, but requires more excavation and more wall material than the first form, and is conducive to sharp bends in the

Fig. 5.

Fig. 6.

cable. The type shown in Fig. 5 is convenient where it is desired to have a wide chamber without occupying much space on one particular side of the duct line as, for example, where two duct lines run parallel and a short distance apart. In this case, economy may be obtained by the use of a common wall on the long side of the chamber.

Fig. 6 shows the side-wall type of chamber, which is entered from the side instead of the top. This form is used in the side walls of tunnels or in retaining walls, and usually takes the form of a long niche in the wall. When built in tunnel walls not far from the surface of the ground, it is desirable to have them open from the street above as well as from the side, in order to avoid the necessity of having the use of a tunnel track when work is to be done in the chambers.

**Material of Splicing Chambers.** — Monolithic concrete is the cheapest and best material to use where a large number of identical chambers have to be built, as the same form can be used over and over again. Where such uniformity cannot be attained, as in streets congested with sub-surface construction, brick or concrete hollow tile are better and cheaper materials.

**Dimensions of Splicing Chambers.** — The height of large splicing chambers is usually determined by the height in which a man can stand upright and is seldom less than  $6\frac{1}{2}$  feet. The width is similarly influenced by the space required to work in, which is about 4 feet. The length depends upon the length of splice and the space required to curve the cable from the ducts to the supporting shelves or racks, considerations which make a length of 8 feet the practical minimum where there are large cables.

Special chambers, such as those for bare grounded cables, for a small number of telephone or other small cables, may be made of smaller dimensions than stated above, because a man can work on his knees in a chamber 4 feet high and  $3\frac{1}{2}$  feet wide, and the length may be reduced to about 4 feet if the cables are small and flexible.

Table I gives the dimensions of standard splicing chambers used by several large traction and lighting companies. The letters refer to the dimensions on Figs. 3, 4, 5 and 6. The average volume of a splicing chamber is about 16 cubic feet per splice, although a maximum of 40 and a minimum of 6 are sometimes found.

**Spacing of Splicing Chambers.** — It is found that the greatest length of cable that can be pulled through a glazed tile conduit without injuring the cable or requiring special apparatus is about 400 or 500 feet on a straight or slightly curved run. Hence at distances of 400 or 500 feet along a conduit line it is necessary to provide splicing chambers, where the separate lengths of cable may

be pulled in and spliced. Local conditions and curves may prevent the full length being attained in all cases, but it is desirable to have no lengths greater than the standard, in order to avoid the necessity of keeping special long pieces of cable in stock.

**Service Boxes.** — Service boxes are usually iron castings similar in shape and size to an ordinary manhole casting, but provided with a completely waterproof inner cover which screws down on a gasket. The outer cover resembles that of a manhole. Inside the inner cover is a distribution board with copper bus bars, to which the main and feeder cables in the chamber connect through the bottom of the board.

**Waterproofing and Drainage.** — There is some diversity of opinion with regard to the value of waterproofing splicing chambers, although the modern tendency is to omit waterproofing and provide efficient drainage. Waterproofing is futile unless the duct lines leading to it are waterproofed. This is a very difficult and expensive process which seldom shows good results. Water will also enter chambers from the top and will be retained if the chamber is waterproof.

Every chamber should be provided with a sump into which the water can drain, Fig. 7. It is desirable to connect the sump to the sewer through a syphon and back-water valve. If this is not practicable the sump may be drained through the manhole by a hand pump.

Fig. 7.

Where natural drainage cannot be secured, as, for example, where the chamber is below the sewer level, it is good practice to provide a special drain pipe to which all the chambers are connected, the drainage being towards a general sump pit, which is kept

dry by an automatic sump pump. The cost of such a system often compares favorably with that of waterproofing, besides yielding superior results.

The sump of a splicing chamber should be covered with an easily removable grating; wooden ones are often used on account of their property of floating when the chamber is flooded, thereby leaving the sump open for the pipe of a hand pump.

**Manhole Castings.** — Manhole castings are usually made with two covers (Fig. 8), the outer of which should be made strong enough to stand the weight of the heaviest vehicle, and the inner should be as light as consistent with the rough usage they receive in handling. Both covers should be provided with means to grip them with a hook-bar. Where power cables are used it is essential to provide ventilating holes. It is usual to lock the inner cover with a substantial brass padlock with protected keyhole.

Fig. 8.

**Cable Supports.** — (See also article on *Wires and Cables, Insulated.*) Cables in splicing chambers are usually supported on iron brackets attached to the chamber walls. This construction is very satisfactory, especially if the power cables are properly wrapped with asbestos, but some engineers consider a shelf to be preferable, as it affords insulation and provides more protection between cables.

Concrete reinforced with expanded metal or wire cloth has proved satisfactory for shelves one inch thick, and is inexpensive. A good support for shelves in concrete splicing chambers is a pair of iron pins set in iron pipes, which are sunk in the chamber wall at a slight angle, so as to tilt the shelves toward the chamber

Fig. 9.

Fig. 10.

wall as shown in Fig. 9. Where splicing chambers are made of brick, the design shown in Fig. 11, is recommended by the A.E.R.E.A. Splicing chambers with shelves have to be made larger and more expensive than those with duplex racks (Fig. 10), if an equal number of cables has to be carried.

**RODDING AND WIRING OF CONDUIT LINES.** — The only test which it is usual to apply to conduit lines is rodding with a mandrel in order to ascertain whether the ducts are continuous and unobstructed.

The rods used for this purpose are of hickory about one inch in diameter

and three or four feet long and are fitted at the ends with steel couplings such as that shown in Fig. 12. The first rod is attached to a mandrel and pushed into the duct. Another rod is coupled to the first and the pair pushed further

Fig. 11.

into the duct. By successively coupling other rods and pushing them into the duct, the mandrel is made to travel from one chamber to another. As soon as the mandrel emerges into the receiving chamber, the rods are pulled through and uncoupled. If an obstruction stops the mandrel an attempt is made to force it through by repeated blows, failing which, it becomes necessary to cut into the conduit line from the side.

**Mandrels for Rodding.**— Various types of mandrels are used for testing ducts, some hollow and smooth with sharp cutting edges, others fitted with numerous sharp projections and known as hedgehogs (Fig. 13).

Fig. 12.

Fig. 13.

**“Wiring” the Ducts.**— It is usual to attach a galvanized steel wire (No. 10 or 12) to the last rod and leave the wire in the duct after the removal of the rods. The ducts may also be “wired” by the use of a conduit machine. This consists of a reel of steel tape and means for winding and unwinding the tape into the duct at the rate of about ten feet per second. This tape or “snake” having been pushed through the duct is pulled out again with the wire attached to its end.

**SPECIFICATIONS FOR CONDUIT LINES.**— (See also article on Specifications.) By far the greatest number of cable breakdowns occur from injury to the lead sheaths either by electrolysis or by abrasions during installation. Sharp projections in the ducts should therefore be carefully guarded against, as a cable pulled over such a projection will have a groove cut along its entire length and the effective thickness of the sheath will be thereby materially reduced. The specifications for inspection and rodding given below are typical of the best modern practice, but unfortunately duct inspection is usually so lax that often in a large installation scarcely a single duct conforms in every particular with the specifications. Engineers are now beginning to realize the practical importance of giving each duct a rigid inspection, and rejecting those which have any

roughness or irregularity. Scarcely less important is rigid inspection during installation, in order to assure the most perfect alignment.

**Details of Construction.** — The following items should be covered:

**Conduits.** —

Single-way, or four-way.

Holes circular or square with rounded corners.

Maximum outside dimensions.

Minimum inside dimensions.

Minimum thickness of walls.

Shall be free from blisters, cracks and other imperfections which, in the opinion of the Engineer, will tend to injure the cables to be accommodated therein.

Shall be of good quality tile, thoroughly glazed inside and outside.

Shall be straight and true.

Shall be provided with holes for dowel pins if ducts are four-way.

Dowell pins may also be called for.

The sides of single duct conduits shall be combed with two (2) sets of three (3) longitudinal combings each, each combing to have a width of one-quarter ( $\frac{1}{4}$ ) inch and a depth of one-sixteenth ( $\frac{1}{16}$ ) inch. Multiple-duct conduits shall be scored transversely near the ends.

Conduits shall be of stated length. It is usual to call for a certain percentage of shorter lengths (generally 1 per cent), in order to finish runs or stagger joints. The permissible variation from the specified length should be stated.

(If fiber conduit is to be used, substitute the corresponding requirements.)

**Cement.** —

Shall be of approved brand.

Briquettes made of neat cement and kept one day in air and six days in water shall show a stated tensile strength. A corresponding strength may be similarly required of briquettes made of one part cement and two and one-half parts sand.

Shall be protected from moisture during work.

**Sand.** —

Shall be clean and free from loam or salt.

Shall be sharp and of stated coarseness.

**Stone.** —

Shall be of crushed granite, lime stone, trap rock or other approved variety.

Shall pass through a sieve of stated mesh.

**Brick.** —

Shall be of good commercial hard-burned sewer brick, or other stated variety.

**Concrete.** —

Stated proportions of cement, sand and stone. (Usually 1 part of cement, 2 parts of sand and 4 parts of stone.)

Maximum size of aggregate. (Usually  $\frac{1}{2}$ -inch.)

Sand and cement shall be mixed dry and wetted with only sufficient water to make a stiff paste. The stone having been previously wetted shall be added while wet and thoroughly mixed until all the stones are covered with mortar. It shall then be deposited as rapidly as possible. Machine-mixed concrete will be accepted if made in a manner approved by the Engineer.

**Cement Mortar. —**

Stated proportions of cement and sand. (Usually  $2\frac{1}{2}$  to 1 of cement.) Concrete mortar shall not be laid in freezing weather, and shall not be used after initial set has taken place.

**Excavation. —**

Shall always be of such depth as to leave a stated minimum distance between the top of the concrete over the conduits and the surface of the ground.

Ground on which conduits are laid shall be rammed solid before any concrete is laid.

**Refilling Excavations. —**

The best part of the material excavated shall be used.

Surplus material shall be carted away by the contractor (or will be carted away by the company).

Filling shall be thoroughly tamped and rolled, or flushed, as seems necessary to the Engineer, and shall be done in a manner to prevent, as far as possible, a settling of the earth after completion.

**Obstructions. —**

Obstructions encountered in the course of the work shall be overcome in a manner to be approved by the Engineer.

**Laying Conduits. —**

Shall be laid with ends square so as to leave a tight, well-fitting butt joint.

Joints shall be staggered horizontally and vertically.

Conduits shall be laid in a bed of cement mortar of about  $\frac{1}{4}$ -inch thickness.

Each joint shall be wrapped with two strips of burlap 6 inches wide and coated with neat cement mortar, the ends of the wrap to lap 4 inches. (It will insure more careful work if it be specified that the contractor shall supply rubber gloves to the men who lay the burlap.)

Where conduits are laid on curves, the wraps shall be doubled if required to protect the openings between the ends of the conduits on the outside of the curve, and to exclude mortar from said openings. (This method of wrapping is not universal. If another method is to be used, corresponding details should be given.)

Conduits shall be laid with a mandrel of specified length and width and provided at the end with a rubber washer for wiping the joints.

Conduits shall be laid on a bed of concrete of stated depth, shall be covered at the top with a stated depth of concrete, and shall have a stated thickness of concrete on each side. Where the conduit line goes under railroad tracks, the concrete shall be suitably thickened and reinforced.

If conduits are four-way, they shall be laid with dowel pins at joints. The alignment horizontally and vertically shall be satisfactory to the Engineer.

**Drainage of Conduit Lines. —** The grade of all conduit lines shall be such that water cannot stand in the ducts but shall drain into one or both spring chambers.

**Repairing. —** All repairing shall be done in a manner satisfactory to the Engineer and the municipal authorities.

**Extras. —** No extras will be allowed the contractor for irregular work except

Rock blasting, if necessary.

Removal of pipes or other obstructions, if necessary.

Such work shall not be done without the consent of the Engineer. The contractor shall specify the cost of such work before it is begun.

**Details of Terminals of Conduit Lines.** — (Whether they be power stations, etc.)

**Splicing Chambers.** — Shall be built according to plans supplied by the Engineer, in which case the suggested modifications shall be approved by the Engineer.

Chambers to be not more than a stated distance apart.

State any details pertaining to the design of the chamber and its supports which may not be clear from the plans.

**Tests.** — The contractor shall notify the Engineer sufficiently in advance of the completion of the conduits to enable inspection at the factory to be arranged for.

**Rodding, Cleaning and Wiring.** — After the conduits are laid and the cement is sufficiently set, they shall be rodded and the contractor shall use after such rods, wire brushes and a mandrel of specified dimensions. All rust and other foreign matter shall be removed. If obstructions are found they cannot be removed by cleaners so as to pass the specified mandrel, they shall be removed and relaid. Any expense incurred by such work shall be borne by the contractor. A galvanized wire of stated size shall be left in each conduit from splicing chamber to splicing chamber, and sufficient length shall be left at each end to permit it to be bent in order to prevent it from slipping into the duct.

**Inspection.** — During the process of construction, the Engineer reserves the right to inspect and the right to reject any and all parts which are not standard in accordance with this specification.

**INSTALLATION OF CONDUIT LINES.** — The problems connected with the installation of conduits vary greatly with the local conditions. They involve the choice of trench excavation, drainage, removing or avoiding obstructions, concrete mixing and so on. The following details are gleaned from first-class examples of the various kinds of work described but should in no sense be regarded as standard.

**Cross-country Conduit Lines.** — The excavation for the conduit line for the American Telegraph and Telephone Company, between New York and Washington, was made partly by a trenching machine and partly by a trench plow. The trenching machine was of the Austin "caterpillar" type and made a trench 18 inches wide and 3 feet deep at the rate of 3 feet of clean trench each minute of actual working time. An engineer and two assistants were required to operate the machine, replacing, it is estimated, 50 laborers. Other sections were excavated by a trench plow drawn by two mules or horses, a furrow being made a few inches deeper at each pass, and the loose earth removed by shovelers. The conduit used in this installation was "pump-log" made of southern yellow pine  $4\frac{1}{2}$  inches square and 7 feet long with a circular hole 3 inches in diameter. These conduits were creosoted by the pressure process with 15 pounds dead oil of coal tar per cubic foot of wood. Splicing chambers having concrete-block walls were built every 500 feet.

A wheel type trenching machine made by Pawling & Hortischfeger Co. has been successfully used by the Wisconsin Telephone Co. This machine has a cutting wheel  $7\frac{1}{2}$  feet in diameter, digging a trench 15, 18 or 21 inches wide with a maximum depth of  $5\frac{1}{2}$  feet. The machine weighs 9 tons and is operated at a speed of  $3\frac{1}{2}$  feet per minute, by an operator and one helper.

**Conduit Lines for Railroads** are usually difficult to construct and operated for the following reasons:

**Four-duct Conduits** are usually provided with holes for dowels by means of which the ducts are aligned. The joints are wrapped and soaked in asphalt and afterwards painted with asphalt. No mandrel is in this type of construction.

**Concrete Covering.**— However the conduits may be laid, the entire group is always inclosed in concrete to secure rigidity and protection. After finished ducts are cleared of rubbish and obstructions by pushing a steel plunger through them by means of the rods described above. A steel plunger for this purpose is shown in Fig. 15, in which is also shown a wooden plunger with rubber washers, which should be drawn through the ducts to collect the loose particles left behind the steel plunger.

**MAINTENANCE OF CONDUIT LINES.**— The principal items of conduit-line maintenance are those relating to keeping the

line clean and safe, namely, pumping out water, blowing out gas, removing mud, opening and closing manholes for the benefit of cable workers and inspecting the line to guard against theft and injury. Large systems have used one or more wagons equipped with apparatus required for these purposes and have men ready to go out with it upon emergency calls.

**Removal of Water** is usually the most important of operating troubles, especially where no drainage system is installed. When cable accidents occur it is important to have the chambers accessible without delay and a portable pump is required. For this purpose a small gasoline or electric pump is used having a capacity of about 50 gallons per minute. Such a pump which has good service is of the horizontal centrifugal type with horizontal discharge and costs about \$200 complete with electric motor, hand priming pump and speed rheostat.

**Ventilation** does not occur naturally in conduit lines, because the cold air contained in them has no tendency to rise. Noxious gases therefore tend to accumulate in splicing chambers, endangering workers and making explosion possible. No permanent system of ventilation has proved successful, as it is found that pressure is maintained only at or near the blowing points. When it is necessary to blow out the chambers, it is therefore usual to employ a portable blower in conjunction with an air-tight false manhole cover.

Cooling duct lines is sometimes desirable in order to increase the carrying capacity of the cables in them. L. E. Inlay has accomplished this at Niagara by keeping the surrounding soil moist. The Duquesne Light Co. of Pittsburgh installed several blowers each of 600 cubic feet per min. capacity and forced air into alternate splicing chambers. A reduction of temperature from 115° F. to 96° F. was obtained.

Protection from theft of cable is secured (1) by locking the inner manhole cover and having the lock combination periodically changed; (2) by patrol

Fig. 15.

the line and (3) by using cable differing in some way from that used by neighboring companies, so that it can be easily identified if stolen.

Electrolysis is more fully treated in the article on *Electrolysis*. It should be noted that the prevention of electrolytic corrosion of cable sheaths depends more upon efficient drainage than anything else.

Maintenance of Conduit Lines Along Railroads present the following peculiar operating difficulties.

(1) Owing to the right-of-way being often on made ground, duct lines settle and crack, injuring the cables in them and preventing the removal and replacement of injured cables.

(2) Owing to the great depth of splicing chambers necessitated by railroad conditions, they are often full of water and cannot be cleared for repairs without pumping water out of as much of the system as is at the same level, a process which may take many hours to complete, possibly interfering with traffic during that time. Drainage is usually out of the question, owing to the absence of any kind of a drainage system below the surface system.

(3) The great depth of chambers requires the use of narrow chimneys connecting the chambers to the surface of the ground. This makes it almost impossible for employees to escape from chambers in case of trouble.

(4) Where improvements are made involving the raising of the right-of-way, as, for example, in eliminating grade crossings, ducts laid previous to the improvements become so deep that they are practically inaccessible for repairs and splicing chambers are correspondingly dangerous on account of their distance from the surface.

(5) The existence of water in low splicing chambers renders the cables particularly liable to electrolytic corrosion. This is a very serious matter where the grounded return is only a few feet away, as is almost invariably the case on a railroad. Electrolytic trouble cannot always be reduced by grounding the cable sheaths to the track rails, as such connections are seldom permissible where electric signals are used.

**REPAIRS.** — The principal repairs to conduit lines are those due to settlement and to damage done by adjacent building operations, such as the construction of sewers or railway tracks. It is sometimes desirable to replace the conduit line without disturbing the cables they contain. In such cases, the conduits are broken, the utmost care being taken to avoid injuring the cables. New conduits are then relaid on a firm foundation, after having been split longitudinally so as to fit over the cables. The whole construction is then rendered rigid by being inclosed in concrete.

**COSTS.** — The costs of conduit lines published from time to time are of merely local value, the labor of preparing a dry trench free from obstructions being an item whose variations are so great as to render insignificant the items of constant cost. Costs as low as 20c, and as high as \$3.00 per duct foot, are recorded.

The items to be considered in making an estimate of the cost of a conduit line are the following, the quantities all being per foot of trench.

Labor: excavating trench; excavating for splicing chambers; boxing and bracing; removing obstacles, such as gas and water pipes; mixing and placing concrete; placing conduit; carting and dumping; repaving; superintendence, outside; office expense.

Material: conduit; manhole and service boxes; covers, shelves, etc.; sand, stone and cement; brick for splicing chambers (unless made of concrete); lumber for protecting top of ducts; lumber for bracing; incidentals.

**Depreciation.** — (See also article on *Depreciation*.) Conduit lines depreciate

very slowly from the effects of deterioration or obsolescence. There are few conduit lines in existence which have lost much of their value from age unless unforeseen circumstances have deprived them of some useful association upon which their value depended. The value of conduit lines often increases with age especially where they have been laid in growing districts, where the demand for duct space increases more rapidly than the supply.

**BIBLIOGRAPHY.** — American Electric Railway Engineering Association. *Specification for Electrical Conduit Construction* A.E.R.E.A. Handbook, 1919; Meyer E. B., *Underground Transmission and Distribution for Electric Light and Power*, N. Y. 1916. Reports of Underground Systems Committee of N.E.L.A.

**CONTROL SYSTEMS FOR RAILWAY MOTORS.**—(See also *Controllers; Motors; Railways, Electric Traction Systems for.*) The function of the control equipment is to regulate the speed and direction of the motors by certain definite systematic changes in connections. The speed of direct-current railway motors is controlled in two ways: (1) by connecting suitable resistances in series with the motors, which will reduce the voltage across the motors and thereby the current which they will take; (2) by changing the connection of the motors so that they will be connected at first in series, thereby applying half of the line voltage to each motor, and then in parallel across full line voltage. In most control equipments a combination of both methods is used. For the speed control of alternating-current railway motors an auto-transformer, or compensator, is used instead of the resistances.

The direction of rotation of the motors, d-c. or a-c., is changed by changing the direction of the current in either the fields or the armatures; it is customary to connect the terminals of each field coil to a reversing switch in order to accomplish this effect.

**TERMINOLOGY.**—The following terms are in general use.

**Cylinder or Drum Control or Direct Control** are names commonly applied to an equipment in which all the connections are made by contacts on a cylinder or drum which is manually operated by the motorman and located on the platform. This may, therefore, be called direct control.

**Multiple-unit, Indirect, Remote Control or Train Control** are names applied to an equipment in which the changes in connection of the main power circuit are made by switches called "contactors," usually located underneath the floor of the car, and controlled by electric circuits coming from a small master controller on the platform. There are two systems of multiple-unit control in use in this country, viz.,

**Sprague-General Electric System.**—In this system the contactors are closed by electromagnets which force a plunger against a spring, the latter normally holding the switch open.

**Westinghouse "Unit Switch" System.**—In this system the contactors are closed by compressed air, from the air-brake cylinders, the air valves at the switches being controlled electrically from the master controller.

**Hand Control** is a term applied to that method of control in which the motorman has it in his power to regulate the current to any value he pleases by moving the controller handle, the change in connections depending only upon the motion of the latter.

**Automatic Control**, as distinguished from hand control, is a type of control in which certain automatic devices prevent the motorman from causing the motors to take a current greater than a predetermined value. With this method of control the motors start with a definite current and as soon as the current has decreased to a specified value a change in the connections is automatically made. Thus the rate of acceleration and the current are kept practically uniform throughout the period of control. It is nearly always used in connection with multiple-unit control.

**Rheostatic Control** consists in connecting a resistance in series with the motor and short-circuiting consecutively parts of this resistance. It is seldom used at present, except on mining locomotives and for single motor operation.

**Series-parallel Control**, which is used on practically all railway equipments, includes the feature of connecting two motors and their resistances in series on the first step, then short-circuiting portions of the resistance consecu-

tively until all resistance is cut out, under which condition the motors will operate efficiently at approximately half speed. On the next step of the controller the two motors with resistance in series are connected in parallel and subjected to full line voltage. There are three methods of accomplishing the change from series to parallel.

**Transition with Power Off.** — In the so-called type L controller power is entirely cut off from both motors while the change in connection is being made. This was formerly used for large-size motors and locomotives but is not at present much used.

**Transition with Series Resistance.** — During the transition from series to parallel a resistance is placed in series with one motor and the other motor is first short-circuited, then disconnected from the main circuit, and finally, placed in parallel with the other motor. This method is in general use in equipments of small motors with the so-called type K controller.

**Bridge Transition.** — The so-called "bridge" method consists in grouping the motors and their resistances like the arms of a Wheatstone bridge, so that after the two motors are in full-series position the resistances may be placed in circuit again in parallel with the motors, without opening the circuit; the two motors are then connected in parallel with each other and each in series with its own resistance. This method is preferable to either of the other two in that both motors are in operation throughout the whole control period. There is no noticeable jerk and it is not necessary to open the circuit, which would cause flashing at the switches. It is used in certain forms of the K control and in most of the multiple-unit control equipments, particularly for motors of large capacities and for locomotives.

**Series-parallel Control with Four-motor Equipment.** — Whereas the three methods just described apply particularly to two-motor equipments, they are equally applicable to four-motor equipments by connecting two motors permanently in parallel and treating them as a unit.

**TYPE K CONTROL.** — The type of control as well as the construction of the controllers for ordinary single-car equipments has been practically standardized in this country, the large manufacturers supplying control equipments which are practically identical. This type of control is known as the type K. The various sizes of type K controllers are listed in the table below.

Where type K controllers are used for motors of large capacity they are sometimes adapted with a modification of the remote control by the addition of two electrically-operated main switches placed underneath the floor of the car, the function of which is to open the main power circuit every time it is necessary that it should be opened and thus remove all flashing and arcing from the controller. This expedient makes it possible to use a smaller controller for a given capacity of motors and obviates all danger to the passengers from fire and fright. The scheme is accomplished by substituting for the main power circuit on the controller an auxiliary circuit carrying only one or two amperes and every time this auxiliary circuit is opened in the main controller the main switches underneath the car open the power circuit. When the auxiliary circuit is closed the main switches close the main circuit. By means of an overload trip operated by a coil in the main circuit these switches are also used as circuit breakers and if the current taken by the car exceeds a certain value a relay opens the auxiliary circuit which in turn causes the main switch to open.

**Capacity and Weight of Type K Controllers.** — The more usual forms of type K controllers and the capacity in motors for which they are adapted are as follows:

## TYPE K CONTROLLERS

Designation	Number of motors	Total h.p.	Number of points	Weight, pounds*
K-10-A.....	2	80	5 series 4 parallel	940
K-10-H.....	2	80	5 series 4 parallel

\* Weight includes cables, etc., but not motors.

The 10 H, 11 H, 12 D, 28 F, 34 F and 35 M have auxiliary contactors for opening the main circuit.

The K 34 and K 35 have "bridge" transition. All others short-circuit one motor during transition.

The letter "B" in the designation of a controller indicates that it has contacts added to it to make it possible to operate electric brakes by causing the motors to act as generators to energize electric brake shoes, either of the axle or rim type.

**Method of Operation of Type K Control.**—The principle of the type K control for small and moderate-size motors is shown in Fig. 1. The controller has an operating handle which moves the main cylinder and thereby changes the connections, and also a reversing handle which moves the reversing cylinder. The latter merely changes the direction of the current through the leads of all the motors with respect to the armature. These two handles or cylinders are interlocked so that the reversing handle can only be moved when the operating handle is in the off-position, thus preventing reversal with voltage on the motors.

One terminal of one of the motors is grounded throughout. The first three points are known as accelerating steps. As resistance is in circuit for each of these points the controller should not be left on any of them for a considerable

length of time, for there is a considerable power loss in the rheostats and they are not designed for continuous operation. The fourth step, full series, is efficient "running point," giving about half normal speed. The next two steps are transition steps and are not marked as points on the controller as they must be passed over rapidly. During this period one terminal of the second motor is grounded, thus short-circuiting the motor which has one terminal grounded initially; the connection between the two motors is then opened; finally the two motors are connected in parallel but in series with a part of the rheostat. Points 5, 6, and 7 are accelerating steps with motors in parallel and resistance in series and are therefore not to be used continuously. At the last point the motors are in parallel, and all resistance is cut out; it is therefore an efficient high-speed running point. The two terminals of the armatures of each motor are led to fingers on the reversing cylinder as are also one terminal of each field and the two points of the main circuit to which the motors are connected. Thus, in reversing, the current is reversed in the armatures, but in the fields.

In all controllers a magnetic blow-out and an "arc chute" are employed to interrupt the current quickly and direct it away from the contacts, in order to prevent short-circuiting other contacts. In the older types of control this was obtained from one large magnet coil and a large iron pole piece cover all the contacts. In the later forms each contact has an independent blow-out coil and small pole pieces. This gives a more powerful effect and more accurately directs the arc in the proper direction.

#### EFFICIENCY OF TWO- AND FOUR-MOTOR CONTROLLERS.

See *Railways, Energy Requirements for*.

**REASONS FOR MULTIPLE-UNIT CONTROL.**—When the capacity of the motors on a car or locomotive exceeds 300 horse-power it is advisable, and when the capacity exceeds 400 horse-power it is necessary, to use the indirect or multiple-unit control, for the cylinder type of control required to handle the large currents become too bulky and dangerous to place on the platforms of passenger cars. The cylinder control is also inadequate when it is desired to control simultaneously the motors on the several cars of a train, which is necessary in order to obtain the high tractive effort necessary for high-speed service on elevated and underground railways.

For these two reasons the system of multiple-unit or train control was developed. As originally proposed by Sprague this consisted of a large cylinder controller on each car and each controller was actuated by a small motor instead of by hand. These small motors were controlled synchronously from a single point by means of auxiliary control circuits. With the growth in the capacity

Fig. 1. Type K Control

the motors this system became inadequate and was replaced by the systems now in use.

**SPRAGUE-GENERAL ELECTRIC CONTROL.** — There are two types in use, the type MK and the type MA. The chief difference in these two types is that the type MK is non-automatic whereas the type MA is provided

Fig. 2. Sprague-General Electric Type MK Control

with a current-limiting relay. Fig. 2 is a diagram of the type MK, showing the control circuits in light lines and the motor circuits in heavy lines.

The material included in the control equipment of a motor car consists of:

- 1 master controllers;
- 1 motor controller containing 8 or 10 contactors and a reverser;
- 3 master control switches;
- 1 main switch;
- 1 main fuse box;
- 1 set of rheostats;
- Cables, Train Couplers.

**Master Controller.** — This is very similar to an ordinary railway drum-type controller but is much smaller, as the current carried by it is small. Each master controller is equipped with an operating handle, reversing handle, individual magnetic blow-outs and (optionally) a "deadman's handle," which automatically interrupts the current and applies the brakes when the motorist's hand is removed from the button located in the top of the handle.

**Motor Controller.** — This consists of an iron box lined with asbestos in which the several contactors and the reverser are placed, and is mounted under the car.

**Contactors.** — Each contactor consists of a powerful magnet operating an arm by means of a toggle joint against a spring pressure. This arm closes and opens the circuit in a strong magnetic field which acts as a blow-out. As one contactor can carry and break currents of several thousand amperes no extra circuit breakers are required. Each contactor is provided with interlocks of the form of relays so that contactor No. 2 cannot be operated until after No. 1 is closed, thus providing the proper sequence of operation under all conditions.

**Reverser.** — This is a switch with several circuits and contacts and comparable to the reverser cylinder in an ordinary controller. These contacts are mounted on a rocker-arm actuated by two electromagnets, one for moving the switch to the forward and the other to the reverse position. The electromagnets receive their current from the master controller and are interlocked so that only one can be operated at a time.

**Switches and Fuses in Control Circuit.** — Motor cut-out switches are located on the reverser to permit cutting out a disabled motor. In the control circuit there is one main control switch and fuse to protect the control circuits and near each master controller is located a "control and reset" switch, which in one position closes the circuit to the resetting coil of the overload relay in the main controller and in the other position closes the supply circuit for the master controller.

**Main Switch.** — A knife-blade switch is placed in the power circuit and is intended to disconnect the motor circuits from the trolley when it is desired to test the motor controller.

**Train Couplers** are provided where cars are to be operated in trains. These couplers or jumpers provide a means of connecting together similar control circuits of the different cars. They contain from 8 to 12 wires and are so designed that it is impossible to couple the cars together improperly.

**Current-limiting Relay.** — For automatic control, or acceleration at predetermined current, a current-limit relay is provided on each car and this prevents each successive contactor from operating until the current in the motors has decreased to a predetermined value. On roads having a fairly level profile and operating with frequent stops this refinement is desirable, as it makes it possible for the motorman to accelerate the train every time at the maximum allowable rate and yet never exceed that rate except on a down grade. When this relay is provided the control equipment is known commercially as the type MA control.

**WESTINGHOUSE "UNIT SWITCH" SYSTEM.** — The Westinghouse multiple-unit control is known as "Unit Switch Control" and is designed either for the operation of several motor cars in a train or of single cars or locomotives using either large currents or high voltage. There are four types of unit-switch control classified as follows:

**Type H. L.** — Hand-operated (non-automatic), using line voltage for the control circuits and having as many points on the controller dial as there are steps in the operation; also has a separate reverser handle. One motor or group is short-circuited during transition from series to parallel.

**Type A. L.** — Automatically operated, using line voltage for the control circuits. The controller dial shows three points forward and three reverse corresponding to switching, series running and parallel running, although there are more steps in the operation. Uses bridge transition from series to parallel.

**Type H. B.** — Hand-operated, using current from a storage battery for the control circuits. Otherwise similar to the H. L.

**Type A. B.** — Automatically operated, using current from a storage battery for the control circuits. Otherwise similar to the A. L.

**Operation of Type H. L. Control.** — As typical of all of these classes the diagram in Fig. 3 shows the connections of the H. L. type for a four-motor equipment for either a car or a locomotive (*Cole, Electric Journal, Oct. 1912*)

as many as five motor cars per train may be operated by one man with this control system.

The main-circuit connections are made by means of a number of independent pneumatically-operated switches, known as unit switches, each provided with a strong magnetic blow-out and normally held open by a powerful spring. The overload trip that controls the opening of all switches in case of overload

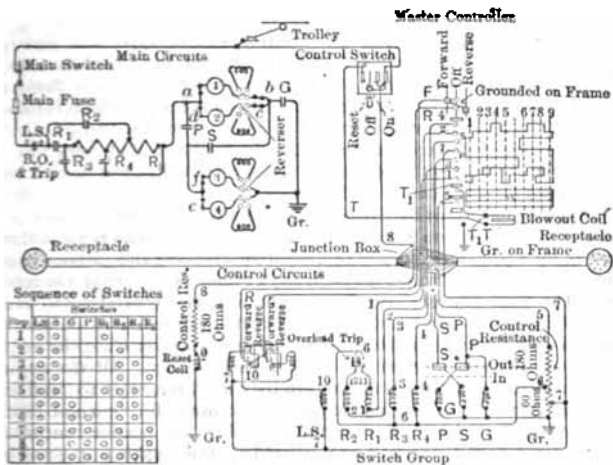

Fig. 3. Westinghouse, Type H. L. Unit Switch Control

is short-circuited is actuated by the magnetic pull produced by one of the blow-out coils, which is in the main circuit. When a predetermined current value is exceeded, a plunger carrying two contact discs breaks the control circuit, which causes certain switches to open in the line and switch group. This trip can only be reset when the controller is in the off-position.

A pneumatically-operated reverser controls the direction of operation of the motor. This reverser consists of two pistons similar to those attached to the unit switches, which serve to move the reverser drum to forward or reverse position. The air-brake system furnishes compressed air for operating the reverser and unit switches.

A multi-conductor train line extends the length of each car and is tapped off at the master controllers and at the unit switch group to form the circuits needed. This train line is made continuous throughout a number of cars by multi-conductor jumpers between cars fitted into receptacles on each car. The current for the electromagnets which operate the valves of the unit switches is taken from low-voltage taps on a resistance connected across line potential.

Operation of Type A. L. Control. — The A. L. control differs from the hand-operated control in that the acceleration of the train is automatic. The master controller has only three positions, switching, series running and parallel running. The "off" position is in the center. The unit switches are provided with interlocks which are electrically connected with the valve magnet in such a manner that the closing of one switch energizes the magnet of the next, thus producing automatic progression of the switches, under the direction of the limit switch. This limit switch controls the rate at which the resistance

is cut out of circuit so as to give uniform accelerating current. The limit switch consists of a solenoid operated by the current of one motor or a pair of motors. When this current exceeds a specified limit for which the switch is adjusted, the circuit is opened through a pair of contacts in the operating circuit. The circuit remains open so that no more unit switches can close until the accelerating current falls below the predetermined limit, when the control circuit is again closed and allows the unit switches to continue their progression.

**Operation of Type PK and PC Control.**— This type was first introduced in 1914 and is a simplification of the older Multiple Unit Systems. It uses air from the air brake system to operate the switches in groups thus requiring only two or three air cylinders and valves instead of many which is the cause of its simplicity and improved reliability. The two forms PK and PC are made by different manufacturers but are sufficiently similar so that cars with both forms may be operated in the same train. On account of its cheapness, it is quite generally used for single cars as well as trains.

The PK (manufactured by the Westinghouse Co.) is the simpler as it merely consists of a standard form K controller (which see) whose drum is rotated, not by notch, by a pair of electrically controlled air cylinders and pistons to which is added an air operated main-line switch and a cylinder for rotating the reversing drum. The small Master Controllers on the platforms control small currents at low voltage in 7 or 9 control wires which admit or exhaust air at definite intervals to the cylinders which move the reversing drum, open or close the main-line switches and advance or return the main control cylinder. All the apparatus except the master controllers is underneath the car. From start to "full series" the change is gradual and automatic under the control of a "current-limiting" device, and similarly from series to "full parallel." The master controller has three positions "Off," "Series" and "Parallel" thus making it possible to equip equipments with different numbers of steps to be operated in the same train. It is possible to adapt old "K" controllers by merely adding the "PK Head" and main line switch to one of the old controllers and placing it underneath the car.

The "PC" Control (manufactured by the General Electric Co.) uses a similar combination of electrically controlled pneumatic cylinders to rotate, notch by notch, a main cam shaft and the cams on this shaft open and close spring actuated switches or "Contactors." These cam operated switches cut out the starting resistance and change the motor connections from series to parallel. Cams also operate the main line switch while other cylinders actuate the reversing drum. The main line switches have suitable magnetic blow-out coils and serve as a circuit-breaker by means of a series trip coil.

The advantages claimed for both forms of this type of control are:

1. All power circuits and the weight of the main control apparatus are removed from the car platforms, i.e. the system is operated by remote control.
2. The main line current is always broken by large, suitably designed switches.
3. Multiple unit operation may be secured with less apparatus and therefore adapted to smaller equipments.
4. The operation of the switches being mechanical it is more positive and therefore the time element is definite.
5. Automatic or selective acceleration may be provided with less complexity.
6. A greater number of motor cars may be operated in multiple in one train (16 motor cars in one train is claimed).
7. The current from the control circuits is so small that storage batteries may be used, thus making this control easily adaptable for operation on a-c. or high voltage d-c. systems.

**SPECIFICATION FOR MULTIPLE UNIT CONTROL EQUIPMENT.**

The following memoranda are intended to assist in writing specifications for complete equipment for the electrical control for a multiple unit car or locomotive exclusive of motors and collecting shoes. See also article on *Specifications*. Give a complete description of the service in which the equipment is to be used, including the maximum number and weight of cars or locomotives per train.

Similar motion of the master-controller handle shall always produce similar train motions.

A device shall be provided (this is optional) which will limit the rate at which the controller increases the motor voltage, and will assure even acceleration without surging, at the changes from series to series-parallel, and series-parallel to parallel, etc.

A relay shall be provided (this is optional) limiting the current to a specified maximum. (The use of such a relay is more usual on heavy, than on light, equipments.)

Provision shall be made so that acceleration can be arrested at any position by the master controller and so that the motor-circuit combinations shall never be beyond the position indicated by the master controller.

The controller shall automatically return to initial or open-circuit position when the general current supply fails, and when current is restored the control shall progress, as specified, to its former advanced position.

The reverser shall be interlocked so that it cannot be thrown when the motors are taking current.

The control apparatus shall operate satisfactory with a maximum line voltage of . . . . and a minimum line voltage of . . . . and shall never take current exceeding . . . . amperes per car.

In the event of a train breaking in two, provision shall be made so that power shall be cut off from the detached rear portion without affecting the control of the front portion.

The master-controller handle shall be designed (this is optional) so that if the motorman releases it while operating a train, the power will be automatically cut off.

State whether controller is to be interlocked with air brakes.

Main circuit switch (for street cars only) shall be within easy reach of motorman at each end of car.

Each car or locomotive shall be provided with a control-circuit cut-out switch, which will enable the contactors on any car or locomotive to be disconnected from the control circuits.

Each car shall be provided with an automatic circuit breaker and devices for tripping it from any car of the train.

Number of motors	H.P. of each motor	Type of control	Weight of control equipment, pounds	Weight of each motor, pounds	Total weight of equipment, pounds	Cost of equipment, dollars
4	25	K	1200	1900	8,800	2400
4	50	K	2200	2450	12,000	3600
4	75	K	2200	3200	15,000	4800
4	75	Multi-unit	2800	3200	15,600	5100
2	125	Multi-unit	3700	4150	11,000	4000
2	200	Multi-unit	3200	6400	16,000	5600

**CAPACITY, WEIGHT AND COST OF CONTROL EQUIPMENT**

— The preceding table gives the capacity and weight and the approximate costs of some typical control equipments.

**CONTROL OF HIGH-VOLTAGE D-C. MOTORS.** — The motors operating on systems of from 1200 to 1500 volts are usually designed to operate two in series, thus each receives normally 600 or 750 volts. However, the insulation of each motor must be designed to withstand the whole line potential and each motor must be able to withstand momentarily the line voltage across its commutator, for if one motor slips the voltage will be unevenly divided between them. For operation on high voltage two motors in series are normally treated as a unit and the series and parallel connection made with the double units. The multiple-unit control is preferable with these high voltage and contactors or unit switches similar to those for 600 volts are used. To operate the control it is customary to supply a self-starting dynamotor (q.v.) which provides 600 volts for this purpose as well as for the lights and other auxiliary apparatus.

**Provision for 600-volt Operation.** — Since these equipments usually operate also over 600-volt sections of road, provision has to be made to change the connection of the dynamotor when the transfer is made. If the cars are to operate at reduced speed on the lower voltages, as is usually the case on entering the city districts, no change need be made in the motor connections. But if the cars must operate at 600 volts at high speed over an interurban section then provision must be made to separate the pairs of motors so that all motors will be in parallel for full-speed operation on 600 volts. This requires a commutating switch with automatic protection in order to provide that it is always changed when the car passes from one section to another.

**2400-volt Systems.** — For locomotive work 1200-volt motors are constructed to operate two in series on 2400 volts. The control for such a locomotive is similar to the control for a 1200-volt equipment.

**CONTROL OF A-C. COMMUTATOR MOTORS.** — A transformer or compensator is always used to transform the line voltage (3000, 6000 or 11,000 volts) to a voltage suitable for the motors, which is usually from 400 to 500 volts for two motors in series. Taps on the low-voltage side of the compensator (or auto-transformer) provide the various voltages necessary to start and control the motors and thus there is no need of series-parallel control or rheostats, as the energy lost in the rheostats is obviated. A compensator or auto-transformer is usually preferred to a transformer as it is lighter for a given capacity. It is usually placed in oil in a tank suspended from the bottom of the car body. Fewer steps (5 or 6 in all) are required for the control of a-c. motors on account of the reactance of the circuits. To avoid open circuiting the connection to the motors in changing from tap to tap or short-circuiting the portion of the transformer between the taps a "preventive resistance" is connected in the circuit momentarily during the transition. A reverser is provided to reverse the connection of the series fields or exciting windings.

The control may be either of the cylinder or multiple-unit type. In the former type a standard controller may be adapted for the work. If the multiple-unit control is used the cores of all the magnets and contactors must be laminated iron and a special design of magnet used on account of the difference in characteristics of a-c. and d-c. magnets. In some a-c. multiple-unit equipments a storage battery is used to supply current for the control circuit, in which case d-c. electromagnets may be used in the contactors.

**Provision for D-C. Operation.** — For operation on direct current as well as alternating current provision must be made to perform the following operation

(1) cut the transformer out of circuit, (2) connect the motors for series-parallel control, (3) connect rheostats in circuit, (4) change the field connection of the motors, (5) change the connections of the compressor motors, (6) change the connections of the lighting circuits. All this is done by a "commutating switch" which is thrown over at the instant the change is made. This is so arranged that it can only be moved when the controller is at the off-position. The commutating switch is frequently operated automatically, so that when the car reaches a dead section of the trolley between the a-c. and d-c. sections, a so-voltage release throws everything to off-position and when the car reaches the new live section a "selector" coil moves the commutating switch to the proper position.

**CONTROL OF THREE-PHASE INDUCTION MOTORS.** — Three-phase induction motors for railway work may be controlled by three methods, viz: (1) Changeable pole windings, (2) concatenation of two motors, (3) variable resistance in secondary.

The first two methods were given a considerable trial by German manufacturers some years ago, and have been practically abandoned on account of their complications. In addition to their complications the variable resistance method must also be used with them to provide the smaller gradations of speed.

**Variable-resistance Methods.** — The secondaries of the motors have a definite winding and the terminals are brought to collector rings by means of which a three-phase starting resistance is connected into the circuit. The speed of the motors is controlled by varying this resistance. Under these conditions the operating characteristics of the motors are similar to those of a d-c. shunt motor. At all fractional speeds a considerable amount of energy is wasted in the rheostats and there is only one efficient running speed. For prolonged running at fractional speed the rheostats must have considerable heat-dissipating capacity. To reverse the direction of the motors a reverser is employed which reverses the connections of two of the three primary leads on each motor. Either the cylinder or multiple-unit control may be used. With induction motors it is desirable to provide a separate set of resistances for each motor to avoid the tendency of the motors to exchange current and "buck," which would occur if the driving wheels were not of exactly the same diameter and one set of resistances were used for all motors. With several induction motors on one car it is desirable to accurately maintain the same diameter of driving wheels on all axles in order to divide the load equally between the motors.

Journal*, Oct. 1916, p. 462, Oct. 1917, p. 436.

**CONTROLLERS.**— (See also *Control Systems for Railway Motors; Regulators; Rheostats; Switchgear Equipment for Power Stations.*) Any device for regulating the current or voltage of an electric circuit may be called a controller. Various kinds of controllers have been given different names by users and manufacturers.

**DEFINITIONS.**— To avoid confusion the various names are used throughout this book as defined below.

**Compensator or Induction Starter,** an auto-transformer for supplying reduced voltage to the terminals of an induction motor during acceleration; see *Starters, Motor.*

**Controller,** a device which controls, in some predetermined manner, the operation of the apparatus to which it is connected; generally it controls the running speed of a motor. This article deals only with the latter type. A controller frequently combines starting with running features; see *Starters, Motor.*

**Regulator,** any device for adjusting the voltage of a circuit. A compensator is a special form of regulator. The term regulator is sometimes reserved for devices which utilize inductive action for their control properties; such a device will be designated specially as a potential regulator; see *Regulators.*

**Resistor,** the resistance portion of a controller or starter, through which flows the main current of the circuit whose voltage is controlled. A field rheostat is any device employing a variable resistance to control the voltage across the field windings of a generator or motor. The field rheostat of a d-c. motor indirectly controls the speed, because it controls the voltage and current of the field winding; see *Rheostats; Starters, Motor.*

**Motorstarter,** a controller designed for accelerating a motor to normal speed in one direction of rotation.

**FUNCTIONS OF CONTROLLERS.**— Controllers are designed to be used with motors of different kinds and to take care of the functions not incorporated in the motor design in order to enable the latter to operate under the specified conditions of load. The functions usually supplied by the controller are the following:

- To limit the current during the acceleration of the motor.
- To limit the torque during acceleration.
- To change the direction of rotation of the motor.
- To limit the load on the motor.
- To disconnect the motor on failure of voltage.
- To regulate the speed of rotation.
- To start and stop the motor at fixed points on the cycle of operation, or at the limit of travel of the load.
- To stop the motor.
- To protect the operator from injury.

Not every controller has to embody all of these features in the same degree but these are the underlying points of controller design and they must be procurable when they are needed.

**TYPES OF CONTROLLERS.**— Controllers may be divided into the following classes: Face-plate, drum, drum-contactor, and magnetic contactor, controllers.

**Face-plate Controller.**— The simplest form of controller for starting and regulating the speed of d-c. motors is the face plate type shown diagrammati-

cally in Fig. 1, and intended for use with a variable speed motor connecting resistors in the armature and field circuit. With this type of controller the contacts are mounted on the face of a suitable base and a moving arm makes the connections to the armature and field circuits, the speed of the motor being changed by varying the field strength. The rheostat arm is made in two parts, the under part making contact with the segments R-1 to R-12 and with the contact ring E, while the top arm engages the upper row of round contacts. When starting the two arms are held together by a spring. The bottom arm is provided with a notched segment engaging the plunger forming part of the low voltage release magnet. The notched segment and pawl hold the arm in any operating position after the low voltage magnet is energized. To start the motor

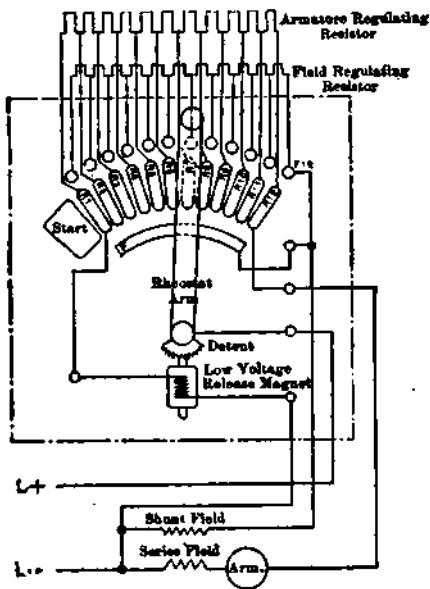

Fig. 1.

the contact arms are moved from the off position to contact R-1, and the connections can readily be traced from that point. The arms are gradually moved to the right eliminating successively each section of the armature resistor until the bottom arm makes contact with R-12. In this position the armature is connected directly across the lines and the segment E is disconnected from the rheostat arm. The shunt field circuit now is from the positive side of the line to the upper rheostat arm to the right-hand field contact F-12, thence to the field winding. This gives a motor speed due to full field strength. If it is desired to increase the speed of the motor the upper arm can be moved to the left across the field contacts to insert resistance gradually in the shunt field circuit, and thus within its range, give the increased speed desired, while the low voltage release magnet holds the lower arm on contact R-12. If the circuit is interrupted the low voltage release magnet will allow the lower arm to be carried to the off posi-

tion by means of a spring. This in turn picks up the upper arm and the two are moved quickly to the off position.

**Drum Controller.**— Another type of controller in common use is the drum controller. This is used with machine tools for varying the speed and reversing the direction of rotation of adjustable speed d-c. motors by means of armature and field resistance. On the larger sizes magnetic blowouts are used. The drum controller usually has two rows of contact fingers attached to the framework of the controller but insulated from it so as to be electrically separated from each other. Between these rows of fingers is mounted an insulated cylinder or drum which is revolved by the handle. On this drum are mounted copper segments of different lengths which engage the contact fingers. The length and location of these segments are such as to make different connections for each position of the controller handle.

**Drum-Contactor Controllers.**— A type of controller which, due to its wide application has found very extensive use, is the drum-contactor controller. It is used with series and compound wound motors for adjusting the motor speed by regulating the resistance in series and shunt with the motor armature or for crane hoist service requiring graduated dynamic braking while lowering. This controller consists of a series of spring closed contactors mounted on steel rods and a cam shaft for operating these contactors. In outward appearance it resembles an ordinary drum controller and in internal appearance and operation it is very similar to the magnetic contactor controllers, except that the contactors are operated by a cam shaft instead of by magnetic coils. The line contactors are provided with magnetic blowouts and the same type of rolling contact is used as has been so successful on magnetic contactor controllers. It has relatively quick make and break in operation, is small in size and is easy to operate and inspect. Repairs can be easily and cheaply made. Contacts have exceptionally long life.

**Magnetic Contactor Controllers.**— These controllers have many advantages which, notwithstanding their increased initial cost, recommend their use wherever rapid and frequent operation is required or where continuity of service is essential. These controllers consist of a series of magnetically operated contactors and accelerating relays which first connect the motor to the line with all resistance in circuit and gradually cut out resistance in series with the motor armature. The rate of acceleration is always dependent on the load of the motor. They are absolutely positive in operation. The motor may be completely controlled by a small master switch, field rheostat, or push button station, any one of which may be placed at a distance from the controller proper. The motor is always accelerated at the proper rate and can be provided with protection against overload and voltage failure. All safety features can easily be incorporated.

**CONTROLLERS FOR INDUCTION MOTORS.**— Controllers with squirrel cage secondaries usually operate by supplying the motors with various voltages obtained from transformer taps. If the motors are provided with wound secondaries the controllers frequently operate by varying the resistance in the secondary circuit. The resistors must then be designed to carry the running current of the motor continuously without overheating (*see Motors; Polyphase Induction; Starters, Motor*).

With a reversing motor, as in crane or rolling mill service, a similar method of control is used except that the controller is provided with two drums which are operated by a single handle. Primary reversing contacts are located on one drum so that the motor will run in one direction when the handle is turned to the right, say, and in the reverse direction when it is turned to the left. In going from the off position the first step connects the primary circuit of the motor

the line and subsequent steps cut out the secondary resistance. In passing full speed in one direction to full speed in the other the resistance is all cut circuit before reversing. In the off-position the motor is entirely disconnected from the line.

**Use of Contactors with A-C. Controllers.** — For reversing mill or hoist-work using induction motors with wound secondaries many very ingenious highly satisfactory installations have been put in service which use solenoid-actuated magnet switches, or contactors, for the secondary and occasionally in primary circuits. These are worked from a master controller or similar device, or are operated automatically by the positions of the rolls, hoist, etc. Automatic acceleration can be obtained in the same manner as with direct-current motors and various safeguards, such as dynamic breaking, can also be employed.

**Automatic Control of Input to Flywheel Motor-generator Set.** — A better application for contactor control with automatic features is with motor-generator sets which use a very heavy flywheel in connection with a d-c. generator and an a-c. motor with wound secondary. The power to the flywheel or delivered up by it depends upon the variation in speed of the motor generator. By varying the resistance in the motor secondary speed regulation can be secured. By the use of suitable relays the input to the motor and consequently the load on the a-c. system can be kept practically constant, while the output of the d-c. generator supplying power to a d-c. or rolling-mill motor is undergoing wide fluctuations, the energy in the flywheel taking care of the difference between the constant input and the variable output. See also article on *Flywheels for Load Equalization*.

**LIST OF CONTROLLERS.** — The following figures will serve as a rough indication of the cost of various sizes and types of controllers. Costs of course vary through wide limits depending upon the design, the amount of variation desired, etc.

**COST OF CONTROLLERS FOR 220-VOLT MOTORS \***

H.P. of Motor (approximate)	5	25	50	100
Plate type speed adjusting .....	\$38	\$70	\$100	\$220
Drum type .....	64	100	158	...
Drum contactor .....	85	155	145	...
Automatic contactor L.V.-O.L. Reversing .....	318	377	545	887
Reversing controllers for wound rotor induction motors .....	80	100	200	400

\* Controllers for 110 and 550 volts cost relatively the same as for 220-volt motors.

**BIBLIOGRAPHY.** — James, H. D., *Industrial Controllers*, Trans. A.I.E.E., Vol. 36, p. 253; Various Authors, on *Industrial Control*, Trans. A.I.E.E., Vol. 34-1, pp. 843, 1010.

**CONVERTERS, SYNCHRONOUS OR ROTARY.** — (See also *Generators, Alternating-current; Generators, Direct-current; Motor Generators; Motors Synchronous; Transformers; Substations, Railway.*) Since in general it is not economical to transmit electrical energy in the form of alternating current and more convenient to utilize it in the form of direct currents, some method of converting from one form of electrical energy to the other is desirable. For this purpose synchronous converters and motor-generator sets (q.v.) are available. Synchronous converters are also called "rotary converters."

A synchronous converter is a machine very similar to a d-c. generator which certain commutator segments, or the conductors connected to them, connected to 2, 3, 4 or 6 collector rings as the case may be. When the moving member is caused to rotate, the voltage between any two collector rings alternates. Such a machine, when driven by an engine or motor, may be operated as an a-c. generator or as a "double-current" generator giving an alternating current from its collector rings and direct current from its commutator. If the collector rings are connected to a source of alternating currents the machine will run as a synchronous motor and direct current may be obtained from the brushes on the commutator; i.e., the machine, with but one set of windings acts simultaneously as an alternating-current motor and a direct-current generator. It has therefore the friction, core-loss and excitation of one machine instead of two, and since the motor and generator currents in the same winding and during at least the major part of each cycle are in opposite directions, they more or less balance each other and the armature  $R I^2$  loss is much less than in either a motor or generator alone.

**Synchronous Converter versus Motor Generator.** — A converter is much more efficient and weighs and costs less than a motor-generator set of the same capacity. It also occupies less space. However, since only one winding is used, there is a definite relation between the e.m.f.s. of the a-c. and d-c. terminals. The maximum value of the alternating wave bears a definite relation to the direct e.m.f. (see below). It is therefore necessary to supply the converter with a voltage of the same order as the direct voltage and involves the use of transformers, if a high-voltage transmission line is used to supply the converter. Motors operating at voltages as high as 13,000 volts can be used in motor-generator sets.

**Relative Efficiencies.** — The efficiency of a converter is in the neighborhood of 93 per cent and of the transformers 97 per cent, thus the efficiency of the combination is about 90 per cent. The efficiency of a synchronous motor is in the neighborhood of 93 per cent and of a d-c. generator 92 per cent. Thus the combination motor-generator set has an efficiency of 85.5 per cent. If the supply voltage is greater than 13,000 volts, transformers will also be needed for the motor-generator set and the net efficiency would then be 83 per cent.

**Synchronous Converter versus Rectifiers.** — A converter differs from a rectifier (q.v.), since the former gives a direct e.m.f. of constant and uniform value and the latter gives a pulsating unidirectional voltage and current. In the former the energy is stored in the form of magnetism for an instant while in the latter there is no magnetic field and no storage of energy. A rectifier will not work satisfactorily on an inductive d-c. circuit but a converter will.

**APPLICATION OF CONVERTERS.** — The most common application of synchronous converters is in electric railway work. The great majority of motors for electric traction are direct-current series type, operating at 500 to 600 volts. The energy for these motors must be transmitted over long distances, which requires a high voltage a-c. transmission line and converter to link the d-c. distribution with the a-c. transmission. Converters have

developed for high voltage d-c. traction systems, these converters giving volts d-c. Two such converters may be connected in series for 3000 volt distribution (*Elect. J.* 12, p. 154, Apr. 1915). Synchronous converters are used for lighting and power service and for electrolytic work.

**TERMINOLOGY.** — The following terms are used to describe certain characteristic features of the various kinds of synchronous converters.

**Rings and Rings.** — A single-phase converter has two collector rings and one ring is connected to the windings by as many equally spaced taps as there are pairs of poles. The taps for the two rings alternate at equal spaces. A two-phase converter is therefore a two-ring converter.

A three-phase converter has three rings and three equally spaced taps (one tap per ring) for every pair of poles. A four-phase or quarter-phase converter has four rings and four taps for every pair of poles. A six-phase converter has six rings and six taps per pair of poles.

**Shunt and Compound-wound Converters.** — A converter may be shunt or compound wound, depending upon the service for which it is intended. In series winding is intended to make the converter take leading current when load increases and thus increase the voltage at the a-c. terminals, but the ratio of the a-c. terminal voltage to the d-c. voltage remains unaltered.

**Inverted Converter.** — Sometimes a converter is operated to convert from d-c. to a-c. It is then called an "inverted converter." The machine will run satisfactorily in this manner, but its speed depends upon the nature of the a-c. load. An inductive load in the a-c. circuit causes the armature to magnetize the fields, with a resultant increase in speed. It is therefore dangerous to operate an inverted converter on an inductive load unless it is provided with a speed-limit device. This effect does not occur when the machine is operating as an a-c. motor, since its speed is fixed by the frequency of the supply current.

**Induction Converter or Motor Converter.** — This is a combination of an induction motor and converter connected in series or concatenation (*see Motors, Induction*). The converter receives half the power in mechanical form from the motor and half the power inductively, in the form of alternating current at half frequency, from the secondary of the induction motor. By this means the steady output of a 30-cycle converter is obtained in a 60-cycle unit.

**Split-pole Converter.** — The "split-pole" or "regulating-pole" converter is used to give a variable ratio of alternating e.m.f. to direct e.m.f., for operation in parallel with storage batteries and similar purposes. The field poles are divided into sections the excitation of which may be controlled independently. The effect of the split pole is primarily to produce a third harmonic in the flux distribution curve, which increases or decreases the total flux per pole and therefore the d-c. voltage, but does not change the a-c. counter e.m.f. between slip rings since these rings are connected to the armature winding at points 120 electrical degrees apart. Split pole converters give a voltage variation of about 10 per cent.

**Converter with Series Booster.** — A synchronous converter with series winding is sometimes used for purposes similar to those of the regulating pole converter. It is merely a converter with a separately excited a-c. generator on the same shaft as the converter, and the armature of this generator is connected in series with the converter armature and the line. This generator acts as a-c. booster and raises the line voltage.

**HEATING AND PERFORMANCE.** — The standards of the A.I.E.E. require a maximum rise of 50 degrees C. on any part of the windings and

70 degrees on the commutator for continuous operation. *Sos* are more conservative in their continuous rating and give the temperature rise after operation for two hours at 25 per cent occurring immediately after a continuous run. Twenty-five per cent will give momentarily an output of three times their normal rating or injurious sparking at the commutator, but sixty cycle converters are sensitive to overloads.

**PRINCIPLES OF CONVERTER ACTION.** — In this section are treated those features of a synchronous converter, in which it differs in action from an a-c. or d-c. generator; see table on page 293 for a summary of the voltage, current and capacity relations.

**Connections and Voltage Ratios.** — The ratio of voltage on the a-c. side to that on the d-c. side depends upon the number of rings and the connection employed.

**Two-ring Converter.** — The two collector rings are connected to the same winding as the commutator; hence the alternating voltage has the same value as the direct e.m.f. at the instant that the brushes pass. As this is also the maximum value of the alternating e.m.f., the e.m.f. (i.e., the value to be indicated by a voltmeter) will be 0.707 times the direct e.m.f. Fig. 1 shows in a simple manner the action of a single-phase converter. The external circle represents a two-

Figs.

Transformer Connections and Vector Relation of Voltages in Synchronous

converters. The winding and inside is shown the supply transformer connections. The taps diametrically opposite each other. The voltage across this transformer would be  $0.707 E$ , where  $E$  is the voltage between the positive and negative brushes on the d-c. side.

**Four-ring Converter.** — If two additional collector rings are connected to conductors spaced half way between the former taps, there results the phase converter shown in Fig. 2. The voltage across each supply transformer is the same as before, but the two voltages will differ in phase by 90 degrees.

**Three-ring Converter.** — If three collector rings are connected to taps spaced 120 degrees apart the e.m.f. between adjacent collector rings will be the vector sum of  $AO$  and  $OB$  in Fig. 3. Since  $AO$  and  $OB$  each have a value of  $0.5 \times 0.707 E$  the voltage  $AB$  will be  $\sqrt{3} \times 0.5 \times 0.707 E = 0.612 E$ . In a three-ring or three-phase converter the voltage between adjacent collector rings will be 0.612 times the direct voltage and the connections of transformer are shown in Figs. 3 and 4.

**Six-ring Converter — Diametrical and Double Delta Connections.** — A six-ring converter may be connected diametrically as in Fig. 5 in which the voltage of each transformer will be  $0.707 \times E$  and the result will be the combination of three single-phase groups. A six-ring or six-phase con-

may also be connected "double delta" as shown in Fig. 6, which is similar to the combination of two groups of three-phase delta transformers. In both cases the voltage between adjacent taps of a six-phase converter is  $0.355 E$ .

**n-Ring Converter.** — In general the voltage between taps of any converter having  $n$  equally spaced taps per pair of poles is

$$E_{ac} = \frac{E \sin \frac{\pi}{n}}{\sqrt{2}}$$

**Current Ratios.** — To determine the ratio of the continuous current  $I$  to the alternating current  $I_2$  per collector ring in a three-phase converter, for example, assume the d-c. output equal to the a-c. input with unity power factor; then

$$\sqrt{3} E_2 I_2 = EI,$$

and, from preceding paragraph,

$$E_2 = 0.612 E,$$

where  $E_2$  = a-c. voltage between lines;  $I_2$  = alternating current per line;  $E$  = direct voltage;  $I$  = direct current. From these two relations

$$I_2 = 0.94 I.$$

The ratios of currents for other converters are obtained similarly, and are given in the table on page 296.

In actual practice the current on the input side must be greater than that given by these relations, in order to supply the losses in the converter, and the alternating current will also vary inversely as the power factor, which is taken as unity in the table.

**Resultant Coil-Current.** — In any machine acting simultaneously as a motor and a generator the two currents must flow in opposite directions, and the current in any particular conductor will be the difference between the two. In any particular coil the direct current is constant in amount and direction from the instant the commutator segment connected to this coil passes the positive brush to the instant it passes the negative brush, and conversely from negative to positive brush. In any coil midway between the a-c. taps the alternating current is a maximum when this coil is half way between brushes (or unity power factor), and the current falls to zero as the coil reaches the interpolar position. Therefore, for the period of time that the direct current in a coil remains constant in amount and direction there is also in it a variable current changing from zero to a maximum and back to zero again. The net or resultant current will therefore have a wave shape and frequency somewhat as shown at  $R$  in Fig. 7. The heating in this particular coil will therefore be proportional to the product of the resistance of the coil by the square of this current, and it is readily seen that the power lost is less than that due to either the direct or alternating current alone.

Fig. 7. Current in Coil Midway

Fig. 8. Current in Coil at Tap in

A coil situated very near one of the a-c. taps will carry a direct current subject to the same law as before mentioned, but the alternating current in the coil is the same as that in the middle coil and has its maximum value when the middle coil is at the middle of the poles and not when this particular end or is at the middle of the pole. The alternating current in this coil may therefore reach its maximum value soon after the coil has passed a brush, as shown in Fig. 8, and the resultant of the two currents is greater than that in the middle coil. The further a coil is situated from the middle coil of a group, the greater is the phase displacement of its alternating current, the greater is the value of the resultant current and the greater is the heating effect. Thus although the heating effect in a rotary converter winding is less than that of a direct-current machine having the same output it is different in each and every coil, is minimum in the central coil (when the power factor is unity) and is maximum in the coil nearest the tap, and the greater the angle between taps the greater the total heating effect.

**Distribution of Heat Losses in Armature Winding.** — In Figs. 9 to 12 inclusive, representing a two-ring converter, the numbers outside the circles

Component Currents in a Two-ring Converter

represent the direct current in the winding (corresponding to 100 amperes in the external d-c. circuit and unity power factor on a-c. side) and the numbers inside the circles the instantaneous alternating current in the winding. It will be seen that the resultant current in a coil midway between taps, Figs. 9 and 10, never exceeds 50 amperes. A coil 30 degrees from the middle, Fig. 10, has maximum current of 100 amperes. A coil 60 degrees from the middle, Fig. 11, has a maximum current of  $50 + 87 = 137$  amperes, and a coil 90 degrees from the middle (tap coil) may have a current of  $100 + 50 = 150$  amperes. The heating in the armature winding is therefore not uniformly distributed, though the conduction of heat from one part of the winding to another tends to equalize the temperature rise.

Fig. 13. Relative RI<sup>2</sup> in Individual Coils of Three-ring Converter

If the converter operates at a power factor different from unity, the position of minimum resultant current is no longer at the middle coil, but is moved one way with leading current and the opposite way with lagging current. Thus the end coil has improved heating conditions, and the middle coil and the other end coil have much worse heating conditions, the result being that the heating as a whole has increased and is more non-uniformly distributed than with unity power factor.

The power lost in each individual coil of a converter and the effect of the power factor on this loss is very well shown in Figs. 13 and 14, taken from a paper by J. E. Woodbridge (*A.I.E.E.*, 1908). In Fig. 13 the curved line shows the relative  $R^2$  loss in a coil having any position throughout 120 degrees of one phase of a three-phase converter when the power factor is unity. The

Fig. 14. Relative  $R^2$  in Individual Coils of Six-ring Converter

Fig. 13 shows the ratio of the loss compared to the loss in the same machine acting as a d-c. generator of the same capacity. It will be noted that the middle coil has a loss of 22 per cent of that of the generator and the end coils 120 per cent, and that the average loss is 57 per cent. For a power factor of 0.966, presenting a phase displacement of current of 15 degrees, the loss in individual coils ranges from a maximum value of 180 per cent at one tap to a minimum value of 22 per cent in the coil shifted 15 degrees to one side of the middle coil. The other end coil has a loss of a little over 80 per cent of the generator loss. The average value has been increased to 65 per cent.

In Fig. 14 the same ratios are shown for a six-phase converter, in which the loss of one phase is distributed over only 60 degrees. Consequently the conditions are better and the maximum loss due to low power factor is less.

**Dependence of Output upon Number of Phases.** — As a result of these conditions we have the following relations of the capacity of a given armature at various numbers and connections of taps, the capacity being based on an equal total amount of  $R^2$  loss.

It should be remembered that there are other losses besides coil losses in the converter, and that therefore practical figures are slightly different from those given in the table on page 296.

**Field Excitation.** — The variation of the field excitation of a synchronous converter has much the same effect as in the case of a synchronous motor (see *Part, Synchronous*); that is, if its field is under-excited the armature will draw a lagging current which assists the field and sets up the necessary flux, whereas if the field is over-excited, the armature will draw a leading current which opposes the field and reduces the flux. By this means the converter may be made to take either a leading or lagging current. A leading current flowing over a line having inductance tends to raise the voltage at the receiving end of the line.

**Line Compounding.** — If there is sufficient leading current and sufficient inductance in the line, the voltage at the receiving end may be greater than at the sending end in spite of the resistance of the line. This is some-

## VOLTAGE, CURRENT AND OUTPUT RATIOS

times called "line compounding." The relation between the voltages at two ends of the line may be expressed as follows:

Let

$E$  = voltage to neutral at sending end;

$V$  = voltage to neutral at receiving end;

$I_1$  = component of line current in phase with  $V$ , i.e., the power component of the line current;

$I_2$  = component of line current at 90 degrees to  $V$ , i.e., the leading reactive component of the line current;

$r$  = resistance of one line;\*

$x$  = inductive reactance of one line;\*

then, noting that  $I_2$  is to be taken positive when leading,

$$E^2 = (V + rI_1 - xI_2)^2 + (xI_1 + rI_2)^2.$$

**Use of Series Field.** — In practice a series field is added to the converter and the shunt excitation is adjusted so that the armature current lags at no load. As the load increases the series field increases, the adjustment being such that at about  $\frac{1}{4}$  load the proper excitation for unity power factor is given. Hence at all loads over  $\frac{1}{4}$  the field will be over-excited, current will be leading and the voltage will be raised or compounded.

**DESIGN.** — The design of a synchronous converter is very similar to the design of a d-c. generator (q.v.), except for certain special conditions due to the fact that the frequency is fixed by the frequency of the supply system, and that greater latitude is allowed in the choice of the nominal value of the armature reaction and copper density, because the real value of these quantities is the difference between their nominal d-c. values and their a-c. values.

\*  $r$  and  $x$  should include respectively the resistance and reactance not only of the line wire, but also the transformers and reactance coils through which the line current passes.

## Converters, Synchronous

**Speed and Number of Poles.**—The revolutions per minute and number of poles are definitely related to the frequency of the a.c. cycles per second, in accordance with the formula:

$$120 \times (\text{frequency}) = (\text{number of poles}) \times (\text{rev. per min.})$$

The choice of the number of poles usually depends upon the commutator. — The design of the commutator is usually the first and therefore the first to be considered. This is particularly true of low-frequency (60 cycle) machines or when the d-c. voltage is 600 or more volts. Factors must be considered in the design of the commutator to secure satisfactory commutation and life of the commutator, namely, peripheral speed, voltage between bars, thickness of bars. If the peripheral speed or the voltage between bars is too high commutation will be bad. If the commutator is too small the commutator will not retain its shape and commutation will be bad. These three limiting factors are very closely related and in a high speed machine give very little choice. The diameter of the commutator depends upon the voltage and frequency, and its minimum value is given by the following relations. Let

$s$  = pitch of commutator bars in inches. This ranges from 0.5 in low-voltage machines to 0.20 in high-voltage or high-frequency machines. These values include 1/16 in bar and about 0.03 inch insulation between bars.

$V$  = peripheral speed of commutator in feet per minute. This ranges from 3500 in liberally designed low-voltage, 25-cycle machine to 6000 in 60-cycle machines, and is extended to 6000 under computer design.

$e$  = average volts per bar = machine voltage divided by the number of bars between brush studs. Normal values are from 8 to 14. The voltage between bars is about 1.57 times this.

$f$  = frequency in cycles per second;

$E$  = voltage between d-c. terminals;

$p$  = number of poles;

$n$  = total number of commutator bars;

$d$  = diameter of commutator in inches.

Then

$$s = \frac{Vc}{10Ef}, \quad n = \frac{pE}{c}, \quad d = \frac{3n}{\pi}$$

**Armature Ampere Turns and Current Density.**—Since the armature reactions are opposed to each other the nominal value of the armature reaction ampere turns may be chosen much higher than the actual and values of from 4000 to 8000 ampere turns per pole are common. The nominal or apparent value of the ampere conductors per inch of periphery varies from 500 to 900, and the apparent current density in the armature copper from 2500 to 5000 amperes per square inch.

**Diameter of Armature.**—The diameter of the armature depends upon the number of slots, and the diameter is usually from 6 inches to 12 inches greater than the diameter of the commutator, the difference depending upon the desirability of making a good mechanical construction of the end of the armature. The number of slots in the armature and the number of segments on the commutator must be a multiple of both the number of phases and the number of poles.

**Armature Winding.** — The winding of the armature is usually of the multi-drum type, although the series winding may be used. The turns per pair poles are divided by equally spaced taps (to the slip rings) into as many groups as there are phases. The number of turns in series between brushes is adjusted for the proper direct e.m.f. and a reasonable value of flux per pole. The alternating e.m.f. bears a definite relation to the direct e.m.f. depending upon the type of connection (see above), and also to some extent upon the shape and length of pole arc.

**Flux Density in Air Gap.** — The air gap or pole-face flux density usually has a value ranging from 40 to 60 kilolines per square inch as in generators.

**Damping Copper in Pole Face.** — In the pole face of every converter squirrel-cage winding should be provided to assist in starting and to prevent hunting. The total cross-section of copper per pole ranges approximately from  $\frac{1}{16}$  to  $\frac{1}{8}$  of the armature copper per pole and the end rings must be of reasonable cross-section compared to the bars. The joints between bars and end rings must be carefully made.

**Shunt and Series Fields.** — The determination of the length of armature length of commutator and the design of the field follow the same laws as the design of these parts for a d-c. generator. The proportioning of the series field results from the considerations given above under *Field Excitation*, the problem being that a certain amount of leading current is required at a given load and to make the armature take this leading current the field excitation must be increased by a certain number of ampere turns, from which the number of turns in the series field can be determined.

**Equalizer Connection.** — In large multi-polar machines it is customary to connect to a common ring all commutator bars which are at the same potential. These "equalizer connections" avoid local cross-currents in the armature from flowing through the brushes and causing bad commutation. These cross-currents are caused by unequal or uneven air gap.

**Shaft, Bearings, Etc.** — Since the transfer of energy is in the conductors themselves, there is no mechanical torque other than that to overcome friction and core-loss. Therefore the shaft, bearings and mechanical housing of a rotary converter are quite light and present no particular mechanical difficulties in mechanical design. For the same reason converters do not require very elaborate foundations. Machines of less than 1000

kilowatt capacity are usually supplied with a base and are complete in a piece, while larger sizes are supplied with foundation plates.

Kw. rating.....	500	300
Frequency.....	25	60

Efficiency.....	96.50	94.50

machines of less than 1000 kilowatt capacity are usually supplied with a base and are complete in a piece, while larger sizes are supplied with foundation plates.

**Efficiency and Losses.** — The efficiency and distribution of losses of typical 25-cycle and 60-cycle converter are shown in the accompanying table. All values are in per cent of input at full load.

**EXAMPLES OF DESIGN.** — In the table on the next page are given design data on four representative converters of different capacities.

**TESTING OF CONVERTERS.**—The following are the usual tests made on converters to determine the efficiency, regulation, heating and to show any defects in construction.

1. **Resistance of Armature, Shunt Field and Series Field.**—The armature resistance is usually measured between points on the commutator diametrically opposite and the equivalent resistance calculated from this value by the equation

$$\text{Equiv. Res.} = \frac{4 \times (\text{diametrical resistance})}{(\text{number of poles})^2}$$

†  $U$  = amperes (d.c.) per square inch.

To obtain the true  $RI^2$  in a converter armature this equivalent resistance is multiplied by the square of the external direct current and by a constant as given in the accompanying table:

These values only hold if the converter is operating at unity power factor. For any other power factor the reactive component of the alternating current per phase must be found and the square of this component times the resistance per phase of the armature gives the additional

Three phase...	0.56	0.59
Quarter phase...	0.37	0.39
Six phase.....	0.26	0.27

$RI^2$  loss due to the lesser power factor.

2. **No-load Saturation Curves.**—The no-load saturation curve, as in a-c. generators and d-c. generators (q.v.) is usually plotted between commutator voltage and ampere turns of shunt field.

3. **Core-loss** as in a-c. and d-c. generators (q.v.).

4. **Phase Characteristic** at no load and at full load as in synchronous motors (q.v.).

5. **Synchronous Impedance** as in a-c. generators (q.v.).

6. **Starting Tests** to determine current and voltage necessary to start the converter on a-c., time to reach full speed, and voltage induced in field windings as in synchronous motors (q.v.).

7. **Heat Run.**—This may be made either with a resistance for load or two similar converters may be tested in parallel by the Hopkinson or "pump back" method; see *Transformers*. In addition to a source of d-c. power of the rated voltage of the converter to supply the losses, either a d-c. booster or an a-c. potential regulator is needed to adjust the load.

8. **Insulation Tests.**—See *Generators, Alternating-current, and Standardisation Rules of the A.I.E.E.*

9. **Pulsation Test.**—A synchronous converter is very sensitive to any change in impressed voltage or frequency. A sudden change in either of these factors will cause a pulsation which will start the machine hunting, as discussed in the article on *Motors, Synchronous*. This hunting may increase until the machine falls out of step or flashes over. To determine whether a converter has a dangerous tendency of this kind, a test is made in which two similar machines are supplied with power from a common generator. Between each converter and the common connection a resistance is placed in each a-c. line, having a value that will give with full-load current a drop in voltage of 15 per cent of the rated voltage of the machine. Thus there is 15 per cent *RI* drop between each converter and the generator and 30 per cent between the two converters. The two machines are operated at no load and at rated voltage with the shunt fields adjusted for minimum input. The voltage across the commutators is observed for any periodic variation. Then the field of one machine at a time is varied from half normal to twice the normal value and any indications of periodic variations of the direct voltage noted. If the machines have a proper damper winding in the pole faces, they should not develop any dangerous hunting, even under the above unfavorable conditions.

**SPECIFICATIONS FOR SYNCHRONOUS CONVERTER.**—The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

**Principal Characteristics and Conditions of Service.**—Use to which converter is to be put, such as railway, lighting, motor driving or battery charging. Whether it is to convert from a-c. to d-c. or vice versa. Voltages and number of phases. Nominal rating in kilowatts or Institute rating in kilowatts. Frequency and speed.

**Style and Description; Details of Construction.**—Whether interpole; whether shunt or compound wound, or whether there is a split-pole field winding; whether rheostat is to be supplied for shunt field; if so, its characteristics. Proposed method of starting and whether starting apparatus is to be supplied. Whether a speed-limit device is required; if so, the shunt field rheostat shall have sufficient resistance to speed the machine for testing the speed-limit device, the latter being set at 15 per cent over rated speed. Whether an end play device (or oscillator) is desired and if so, what type or types are acceptable.

**Work to be Done by Other Contractors.**—Whether the synchronous converter contractor is to furnish and install the following: Main wiring, field

ing, field-rheostat grids, dial plate and chains, starting panels, starting rheostat or motor generator, foundations.

**Performance and Tests.**— Temperature rises upon which nominal and stitute ratings are to be based. Overload capacity—(see *Standardisation Rules & A.J.E.E.*). Commutation limits. Efficiency at 25, 50, 75, 100, 125 and 150 per cent nominal load. High-potential tests of insulation. Requirements regarding effect of moisture upon insulation. Converters shall operate in parallel without "hunting" from no load to stated (say 100 per cent) overload, without drop in high-tension lines due to resistance between any converter and any other synchronous apparatus in the system does not exceed a stated value (say 50 per cent), and provided that the phase variation does not exceed a stated value (say 2.5°). What voltage regulation is required, how it is to be obtained and whether it is to be hand or automatic. If the converter is shunt wound, what voltage-regulation requirements. What per cent reactance between a-c. bus and converter is required?

**OPERATION OF CONVERTERS.**— In the operation of synchronous converters the points mentioned below should receive special attention.

**Transformer Connections.**— The usual methods of connecting transformers to supply converters are shown diagrammatically in Figs. 1 to 6 and are discussed above in the section on *Voltage Ratios* and also in the article on *Transformer Connections*. Of the three-phase to six-phase connections the choice must be made with some care, as all connections are not equally good for each particular use of the converter.

**Methods of Starting.**— The several methods of starting converters are as follows:

**Alternating-current Starting,** which is the same as the starting of motors; see *Motors, Synchronous*.

**Direct-current Starting.**— The machine is started as a direct-current motor and synchronized on the a-c. side after it is up to speed. This requires less power, but takes more time and more skill in order to synchronize. To secure maximum starting torque, the a-c. side should be disconnected from the transformers, which otherwise act as a shunt to a part of the starting current (Werning and Smith, *Elec. J.*, 15, p. 24, Jan. 1918).

**Starting with Auxiliary Motor.**— This involves the extra cost and the continuous loss of the auxiliary induction motor. It is no more efficient than starting by direct current and requires the same amount of time. By the use of suitable relays the starting and synchronizing may be made entirely automatic (Wensley, *R. J., El. Ry. J.* 53, p. 948, May 17, 1919).

**Combination Alternating- and Direct-current Starting.**— The machine is started up with direct current, then disconnected from the d-c. mains and connected to a low-voltage tap of the a-c. supply and brought up to full speed. This method is more economical of power and time but requires more starting apparatus than either the a-c. or d-c. methods.

**Field Break-up Switch.**— All converters are supplied with a switch to break the field in several places to avoid the strain of the high potential induced in the field during starting and to reverse the direction of current in the field after the machine is up to speed in order to reverse the polarity in case it should be at right. This is usually a double-throw switch with several poles.

**End-play Device.**— In order to prevent the brushes from wearing grooves in the commutator and collector rings a device is mounted upon one end of the shaft to move the shaft end-wise back and forth periodically. In small ma-

chines this is a mechanical device consisting of a ball running between two warped surfaces. In large machines it consists of an electromagnet which periodically pulls out the armature a short distance. The magnetic pull of the main field poles pulls the armature back.

**Speed-limiting Device.** — In case a converter should be disconnected from the main a-c. generating circuit and still remain connected so that it would tend to operate from the d-c. side there is danger of its speed becoming dangerously high. To avoid this a centrifugal governor is placed on the shaft as arranged to electrically operate the main d-c. switches of the converter.

**VOLTAGE REGULATION.** — There are several methods of regulating the voltage delivered by the commutator of a converter.

**Compound-wound Converter with External Reactance.** — This method is automatic and will give about 10 per cent variation in voltage. It is standard practice for railway work; see also *Substations, Railway*.

**Regulating or Split-pole Converter.** — With this type of converter the voltage regulation is gradual and normally accomplished by hand, but by the addition of an automatic voltage regulator may be made automatic.

**Shunt-wound Converter with Induction Regulator.** — A large variation in voltage is possible but this method does not respond to quick changes. It is quite generally used in lighting work.

**Shunt-wound Converter with Synchronous Booster.** — A synchronous generator is carried on the same shaft as the converter and connected in series between the transformers and the collector rings of the converter. The method is good but expensive. G. A. Juhlin (*Inst. El. Eng. J.* 55, p. 241, A p. 191) gives a detailed discussion of the relative advantages of reactance and boost regulation.

**Shunt-wound Converter and Taps on the Transformers.** — The voltage ratio of the transformers may be varied. This is usually accomplished by connecting the line to different taps on the primaries, which involves opening the circuit or short-circuiting a portion of the transformer at each change.

**WEIGHTS, SPEEDS AND COSTS:** — The weights, speeds and costs for four commercial lines of converters are given in the following table. The costs are based on the 1921 price level. The first group is a line of 25-cycle converters without commutating poles, the second 25-cycle converters with commutating poles. The third and fourth groups refer to 60-cycle converters without and with commutating poles respectively. It will be noted that the smaller ratings are three-phase machines while the greater ratings are six-phase machines. The six-phase connection makes possible a saving in material at the expense of increased cost in manufacturing labor. The use of commutating poles also makes possible a considerable reduction in size of machine at the expense of increased labor, therefore all the higher capacity machines have commutating poles. The costs given are only approximate, such figures vary greatly with commercial conditions. The machines listed are 600-volt converters for railway purposes. Machines for lower voltages would be somewhat less expensive.

## WEIGHTS, SPEEDS AND COSTS

## 25 Cycle non-commutating pole type, 600 volts

Poles	Kw.	R.P.M.	Phases	Weight, pounds	Cost, dollars per kw. in 1921
4	200	750	3	18,000	16
4	300	750	3	20,000	12.50
4	500	750	6	24,000	11
6	500	500	6	27,000	13

## 25 Cycle, commutating pole type, 600 volts

4	500	750	6	15,000	11
4	1000	750	6	25,000	9
6	1500	500	6	37,000	8
8	2000	375	6	54,000	8
12	4000	167	6	180,000	11

## 60 Cycle, non-commutating pole type, 600 volts

4	200	1200	3	11,000	12.50
6	300	1200	3	13,000	12
8	500	900	6	18,000	11

## 60 Cycle, commutating pole type, 600 volts

6	500	1200	6	10,000	10
8	1000	900	6	23,000	12
12	2000	450	6	70,000	17

**CONVEYORS.** — (See also *Power Stations; Telegraphs.*) A conveyor is a mechanical device for the continuous handling of materials along a horizontal or inclined plane. There are four general types of conveyors, viz., the scrape or flight, the screw, the bucket and the belt.

**THE FLIGHT CONVEYOR** consists of a trough of any desired cross section through which are pulled a series of scrapers or "flights" attached to an endless chain. The improved forms of this type of conveyor have sliding shoes or rollers attached to the flights or to the chains, supported on runways.

**Capacity.** — The following table by S. B. Peck (*Trans. A.S.M.E., 1910*) gives the capacities of flight conveyors in tons of coal per hour when the conveyor is operated at a speed of 100 feet per minute.

CAPACITY OF FLIGHT CONVEYORS

Size of flight, in.	Horizontal				Inclined		
	Flights spaced			Lb. per flight	10°	20°	30°
	18 in.	18 in.	24 in.		24 in.	24 in.	24 in.
	Tons	Tons	Tons		Tons	Tons	Tons
4 by 10	33.75	30	22.5	15	18	14.25	10.5
4 " 12	42.75	38	28.5	19	24.5	18	13.5
5 " 12	51.75	46	34.5	23	28.5	22.5	16.5
5 " 15	69.75	62	46.5	31	40.5	31.5	22.5
6 " 18	.....	80	60	40	49	40.5	31.5
8 " 18	.....	120	90	60	72	57	48
8 " 20	.....	...	105	70	84	66.5	56
8 " 24	.....	...	135	90	120	96	78
10 " 24	.....	...	172.5	113	150	120	90
10 " 30	.....	...	220	147	184	146	116
10 " 36	.....	...	268	179	225	177	142
10 " 42	.....	...	315	210	264	210	167

**Power Required.** — The following formula gives approximately the horse power at the head wheel required to operate flight conveyors:

$$H.P. = (ATL + BWS) \div 1000.$$

*T* = tons of coal per hour; *L* = length of conveyor in feet, center to center; *W* = weight of chain, flights and shoes (both runs) in pounds; *S* = speed in feet per minute; *A* and *B* constants depending on angle of incline from horizontal and have the following values.

Angle, deg.	A	B	Angle, deg.	A	B	Angle, deg.	A	B
0	0.343	0.01	10	0.50	0.01	30	0.79	0.009
2	0.378	0.01	14	0.57	0.01	34	0.84	0.008
4	0.40	0.01	18	0.63	0.009	38	0.88	0.008
6	0.44	0.01	22	0.69	0.009	42	0.93	0.007
8	0.47	0.01	26	0.74	0.009	46	0.95	0.007

For suspended flight conveyors take  $B$  as 0.8 and for roller flights as 0.6 of the values given in the table.

**Screw Conveyors.** — Screw conveyors consist of a helical steel flight, either in one piece or in sections, mounted on a pipe or shaft, and running in a steel or wooden trough. These conveyors are made from 4 to 18 inches in diameter, and in sections from 8 to 12 feet long. The speed ranges from 20 to 60 r.p.m. and the capacity from 10 to 30 tons of coal per hour. It is not advisable to use this type of conveyor for coal, except the smaller sizes, as the flights are easily damaged by any foreign substance of unusual size or shape.

**BUCKET CONVEYORS** are of two types, having rigidly connected and pivoted buckets respectively. The buckets are carried by an endless chain driven by sprockets or pawls. Rigid buckets are used to convey coal and other materials over considerable distances when there is no intermediate point of discharge. They are built to carry as much as 2 tons of coal per minute.

Pivoted buckets may be used both as conveyors and elevators, and are particularly well adapted to the handling of coal and ashes in power plants. Their advantages are slow speed, silent operation, adaptability to change of direction without transfer, high efficiency and easy renewal of worn parts. Their disadvantages are danger of buckets sticking or upsetting and jamming in the supports, and the difficulty of preventing spill at the loading and turning points. Spilling in loading may be prevented by the use of special loading devices, by providing overlapping lips on the buckets or by placing small buckets between the main buckets to catch the spill.

**Capacity.** — Buckets are usually of 2-foot pitch, and range in width from 18 to 48 inches. They run at low speeds, usually not over 50 feet per minute, 30 feet per minute being the usual speed. At the latter speed the capacities when handling coal vary from 40 tons per hour for the 18-inch width to 120 tons per hour for the 48-inch width.

**Power Required.** — Prof. E. F. Miller gives the following formula for calculating the power required for a bucket conveyor making a rectangular circuit:

$$P = 0.004 CL,$$

where  $P$  is the horse-power required,  $C$  is the capacity of the conveyor in tons of coal per hour, and  $L$  is the total lift in feet. This is an empirical formula derived from numerous data on coal conveyors having capacities of from 20 to 20 tons and operating at speeds of from 40 to 55 feet per minute, and making lifts of from 40 to 80 feet. The power given by the above formula is for the conveyor loaded to its full capacity. The conveyor when running empty will require from 40 to 60 per cent of this. The smaller the conveyor the larger the percentage of power empty to power loaded.

**BELT CONVEYORS.** — Rubber and cotton belt conveyors are used for handling coal, ore, sand, gravel, etc., in all sizes. They combine a high carrying capacity with low power consumption. In the majority of cases the belt is troughed by means of idler pulleys set at an angle from the horizontal and bent at intervals along the length of the belt. Belt conveyors may be used for elevating materials up to about 23° incline. The belt may be run at any speed from 200 to 800 feet per minute, and may be from 12 inches to 60 inches width. The most serious objection to belt conveyors is the lack of durability of the belts, their liability to destruction from accidental causes and the expense of their frequent renewals.

Link belts (see *Chains and Chain Drive*) are also used for conveying supplies.

**Capacity.** — The following table gives the capacity of the more common size of belt conveyors:

**CAPACITY OF BELT CONVEYORS IN TONS OF COAL PER HOUR**

Width of belt, in.	Velocity, feet per minute			Width of belt, in.	Velocity, feet per minute				
	300	350	400		300	350	400	450	500
12	34	..	...	20	96	112	128	...	...
14	47	..	...	24	139	162	186	210	...
16	62	72	82	30	218	254	290	326	...
18	78	91	104	36	315	368	420	472	520

For materials other than coal, the figures in the above table should be multiplied by the coefficients given in the table below:

Material	Coefficient	Material	Coefficient
Ashes (damp).....	0.86	Earth.....	1.4
Cement.....	1.76	Sand.....	1.8
Clay.....	1.26	Stone (crushed).....	2.0
Coke.....	0.60		

**Power Required** to drive a belt conveyor (*C. K. Baldwin, Trans. A.S.M.E. 1908*) depends on a great variety of conditions, as the spacing of idlers, type drive, thickness of belt, etc. In figuring the power required, the belt should run no faster than is necessary to carry the desired load. If it should be necessary to increase the speed, the load should be increased in proportion and the power figured accordingly.

For level conveyors the horse-power required is

$$P = C \times T \times L + 1000.$$

For inclined conveyors

$$P = (C \times T \times L + 1000) + (T \times H + 1000).$$

$C$  = power constant from table below;  $T$  = load, tons per hour;  $L$  = length of conveyor, center to center, feet;  $H$  = vertical height material is lifted, feet;  $S$  = belt speed, feet per minute;  $B$  = width of belt, inches.

For each movable or fixed tripper add horse-power in column 3 of table. Add 20 per cent to horse-power for each conveyor under 50 feet long. Add 10 per cent to horse-power for each conveyor between 50 and 100 feet long. The formulas above do not include gear friction, should the conveyor be gear driven.

	1	2	3	4	5
Width of belt, inches	C for material weighing from 25 lb. to 75 lb. per cu. ft.	C for material weighing from 75 lb. to 125 lb. per cu. ft.	H.P. required for each movable or fixed tripper	Minimum piles of belt	Maximum piles of belt

**COOLING SYSTEMS FOR POWER STATIONS.** — When the supply of cooling water is limited or expensive, economy requires that it should be artificially cooled and used continuously. This cooling is accomplished by natural or forced evaporation in open ponds, spray fountains, a series of artificial cascades or in cooling towers. The latter device is largely used.

**COOLING TOWERS.** — Cooling towers are usually made in the shape of large cylinders of sheet steel, filled with narrow boards or laths arranged in geometrical forms, or hollow tile, or wire network, so arranged that while the water, which is sprayed over them at the top, trickles down through the spaces it is met by an ascending air column. The air is furnished either by fans at the bottom or is drawn in by natural draft. In the latter case the tower is made very high, say 60 to 100 feet, so as to act like a chimney.

**Make-up Water.** — When used with jet condensers, the water produced by the condensation of the exhaust steam is sufficient to make up for the evaporation in the tower, and therefore only enough water for the boiler feed pump is supplied continuously. In fact, the condensed steam is, as a rule, more than sufficient to make up for the loss due to evaporation, and there results a slight overflow, which carries with it the oil from the engine cylinders and tends to clean the system of the oil that would otherwise accumulate in the hot-well.

When a cooling tower is used with a surface condenser make-up water may be added to the cooling water, the amount ranging from 3 to 15 per cent, but in this case the boiler feed water can be used over and over again with but a slight loss, provided the oil (there is none with turbines) is eliminated by suitable separators.

**Reduction in Temperature Obtainable.** — With a properly designed cooling tower the temperature of the hot water (and condensed steam in the case of a jet condenser) can be reduced 40 to 50° F. The water can usually be cooled to within 2 to 5 degrees of the wet bulb air temperature.

**Power Required for Forced Draft in Tower.** — The power required for the fan, when forced draft is used, averages 2 per cent of that developed by the main engines during the summer months, when maximum volume of steam is required, and about 1 per cent during the winter months.

**Cooling Ponds.** — Where water for condensing is scarce it is found economical to store it in reservoirs where it is cooled by evaporation. Under the conditions prevailing in northeastern United States it has been found that a surface of 250 sq. ft. is sufficient to cool the condensing water required for one boiler horsepower (34.5 lb.) at 26-inch vacuum. In countries where the evaporative coefficient is higher, smaller surfaces may be used; see Ruggles, *Transactions A.S.M.E.*, Vol. 34, p. 561.

**Spray Ponds.** — Where the area available for water storage is small recourse must be had to the spray system. Here the warm condensing water is sprayed into the air above the small pond; a portion evaporates, cooling the remaining portion, which falls to the tank to be used again. The sides of the tank are provided to prevent the spray from being carried away by the air currents. About 4 sq. ft. of surface are required for one boiler horsepower of steam condensed at 26-inch vacuum. It is even possible in small plants to have the spray pond on the roof of the power house. These ponds should not be used in crowded localities as the spray of water is likely to be a nuisance. The loss of water varies between the amount of boiler feed and twice that amount.

**COSTS (Pre-war figures).** — Cooling-tower costs vary greatly with climate and operating conditions. When these are relatively favorable the cost may be kept as low as \$2.50 per kilowatt for natural draft towers and \$3.60 for fan draft

Under ordinary central-station conditions the costs will probably average \$3.50 to \$5.00 per kilowatt respectively for the two types of towers. Assuming 24-inch vacuum, 70° air and 70 per cent humidity, forced-draft cooling towers cost about \$250 per 1000 lb. of steam condensed. For 24-inch vacuum the cost will be one-half this. Natural-draft towers cost about one-half to one-third as much as the forced-draft towers. As a general rule cooling towers do not pay for the pumping head exceeds 75 feet.

The following data on spray cooling ponds were given in the *Elec. World*, p. 808, Oct. 9, 1915:

Steam condensed lb. per hr.	Circ. water, gal. per min.	Number of nozzles	Size of pond, ft.	Total cost, pond and equipment	
				Concrete basin	Clay basin
1,000	1320	35	50 X 128	\$3385	\$2105
2,000	2420	60	90 X 90	4825	3205
3,000	4320	110	112 X 120	7710	5010

**BIBLIOGRAPHY.** — Additional data on cooling towers, ponds and spray nozzles and numerous references to original papers will be found in Gebhardt's *Power Plant Engineering*; Fernald and Orrok, *Engineering of Power Plants*; Thomas, C. C., *The Cooling of Water for Power-plant Purposes*, A.S.M.E. Trans. Vol. 39, p. 625. See also Kent's *Mechanical Engineer's Pocket-Book*.

**COPPER.** — (See also *Electrochemical Processes, Industrial; Wires and Cable Bars.*) The following discussion applies primarily to copper for electrical conductors. Copper mined in the vicinity of the Great Lakes is almost pure. That derived from the compound ores of the metal must be refined (usually electrolytically) to reduce it to the same degree of purity.

**ROLLING-MILL PROCESSES.** — The refined copper comes to the mill in bars weighing about 200 pounds each. These bars frequently have ridges along the sides, due to faults in castings, and the surface is often covered with a layer of oxide. They are heated in a furnace until sufficiently soft for rolling and are passed through a series of rolls diminishing in size until a rod of the proper diameter is obtained. The rod is then coiled up and immersed in a pickling liquid (10 per cent  $H_2SO_4$ ) in order to dissolve the oxide formed during rolling. It is then washed and dipped in a fluid tallow mixture.

**WIRE-MILL PROCESSES.** — The rods having cooled are connected together by brazing and are drawn through a series of dies of decreasing diameter. The dies give the wire a dense hard exterior coating which increases its tenacity. As the strength obtainable is almost a direct factor of the work expended upon the wire, the smaller the size the greater the tensile strength per square inch, so that the strength of the wire is readily varied by changing the size of the rod and the number of dies.

**Defects in Wire.** — One of the most serious defects occurring to wire at this point is from ridged bars as above described. Ordinarily the bar will be sufficiently heated to dissolve the copper oxide on the surface so that as the softened bar enters the first passes of the rolls, the ridges are lapped over, closing the oxide scale. The subsequent passes and the drawing through the dies obscure this flaw almost entirely, but it remains a serious menace to toughness and the resistance to wear of the copper.

A second cause of trouble arises at the same point by overheating the copper in the softening furnace, in which case copper oxide is formed on the surface and quickly dissolves through the entire bar, thereby increasing the oxide content and tending toward the production of brittleness. Both of these dangers can be avoided by careful selection of the bars and by proper regulating of the temperature of the softening furnace.

As the production of the hard surface from drawing is at best a rather delicate operation, careless handling, uneven welding of the rods and unequal temperature of the wire while passing through the dies will all produce noticeable effects in the quality of the finished wire, so that care throughout the mill is absolutely necessary for the best results.

It, therefore, appears that the most efficient wire must possess not only high conductivity but the maximum torsion and tensile strength possible in commercial copper and that to obtain this it is first necessary to use high-grade copper and to prevent an excess of cuprous oxide entering it at any stage of the manufacture, and, secondly, to select as perfect bars as possible and to observe extreme care in every treatment through which they pass. (*Adapted from article by Carl F. Woods, Electric Railway Journal, 1909, Vol. 33, p. 195.*)

**ANNEALING.** — All wire when first drawn is more or less hard. It may be softened by annealing, i. e., by heating to a temperature between 250° to 400°. The hardness is not affected by the rate of cooling. Annealed copper has a crystalline structure, whereas hard-drawn copper consists of grains elongated in the direction of drawing.

**MECHANICAL PROPERTIES.** — (See *Wires and Cables, Bars, for tests of tensile strength, etc., of various sizes of wire.*) The more important mechanical properties of copper are discussed in some detail below.

**Tensile Strength and Elongation of Soft Annealed Copper.** — The tensile strength of soft annealed copper is about 30,000 to 33,000 pounds per square inch with an elongation of about 25 per cent (in 10 inches) at the fracture. It has no true elastic limit, permanent elongation being produced by very small stresses.

**Tensile Strength and Elongation of Hard-drawn Copper.** — (*See Wires and Cables, Bare, for tensile strength of various sizes of wire.*) Modern hard-drawn copper is equally affected by drawing throughout the section, no hard skin being formed. According to D. R. Pye, hard-drawn copper in wires up to  $\frac{1}{2}$  inch diameter varies in tensile strength with the diameter according to a linear law of the form

$$T = 70,000 - 45,000 D,$$

where  $T$  = tensile strength, pounds per square inch, and  $D$  = diameter of wire, inches.

The above constants agree approximately with the tables of the American Society for Testing Materials and represent values somewhat under those usually obtained.

The elongation at fracture is approximately represented by

$$E = 4 \sqrt{D},$$

where  $E$  = per cent elongation at fracture.

Tests by G. C. Batson on 50-foot lengths of hard-drawn copper showed a tensile strength only  $\frac{1}{2}$  per cent less than that of 10-foot lengths, a fact which indicates that the material is very uniform.

**Modulus of Elasticity of Hard-drawn Copper.** — The modulus of elasticity of hard-drawn copper varies from  $16 \times 10^6$  to  $20 \times 10^6$ , the higher values being for small wires. The following tests by G. C. Batson are typical of commercial copper.

Diameter, in.	0.158	0.138	0.112	0.094	0.079	0.066	0.049
Weight, lb.							
Mod. in units	$17.7 \times 10^6$	$17.9 \times 10^6$	$17.5 \times 10^6$	$17.7 \times 10^6$	$17.1 \times 10^6$	$19.5 \times 10^6$	$19.2 \times 10^6$

An apparent modulus of  $12 \times 10^6$  is often obtained from an initial test, due to brightening-out. (*See also Wires and Cables, Bare.*) The modulus decreases at temperatures above  $150^\circ \text{C}$ .

**Elastic Limit of Hard-drawn Copper.** — The true elastic limit of hard-drawn copper, or load at which permanent set begins, is not the same as the point where the strain begins to increase more rapidly than the stress. The latter point is usually between 30,000 and 35,000 pounds per square inch and the former, somewhat below (*see Wires and Cables, Bare*).

**Compression Test.** — Copper of good quality does not fracture under compression; it yields and flattens. According to Thurston the resistance to compression may be calculated, within the limits  $\epsilon < \frac{1}{3}$ , from the formula

$$C = 145,000 \sqrt{\epsilon}$$

where  $C$  = resistance in pounds per square inch of original area,  
 $\epsilon$  = fractional compression.

**Miscellaneous Mechanical Properties.** — The torsional strength, shearing strength, hardness, resistance to impact and fatigue of copper are all discussed in Bureau of Standards Circular No. 73 on *Copper*.

**Density.** — The density of copper or, for all practical purposes, its specific gravity referred to water, is 8.89 at 20° C. This is the value which has been adopted as standard by the American Institute of Electrical Engineers, and most other authorities in the past. Recent measurements by the Bureau of Standards, the Calumet & Hecla Smelting Works, and the Reichsanstalt have indicated this as a mean.

**CONDUCTIVITY AND RESISTIVITY.** — (See also *Resistance and Conductance; Wires and Cables, Bare.*) F. A. Wolff and J. H. Dellinger give the resistivities of 89 samples of commercial copper from 14 important refiners and wire manufacturers in this and other countries. The mean for annealed wire: Resistivity in ohms per meter-gram at 20° C. = 0.15292; per cent conductivity = 100.25. (Per cent conductivity is computed on the basis of 100 per cent conductivity corresponding to the standard resistivity of 0.15328 ohm per meter-gram at 20° C.) The mean result of data furnished by a large wire manufacturing company, representing tests on more than 100,000,000 pounds of copper, is also given; for example, for annealed samples: Resistivity in ohms per meter-gram at 20° C. = 0.15263; per cent conductivity = 100.42.

**Conductivity of Hard-drawn Copper.** — The conductivity of hard-drawn No. 12 B. & S. wires was found to be less than the conductivity of annealed wires by a mean value of 2.7 per cent. The difference between the conductivity of annealed and hard-drawn wires increases as the diameter of the wire decreases. The lowest resistivity and highest conductivity found for a hard-drawn wire were: Resistivity in ohms per meter-gram at 20° C. = 0.15386; per cent conductivity = 99.62; and for annealed wire were: resistivity in ohms per meter-gram at 20° C. = 0.15045; per cent conductivity = 101.88.

**Effect of Bending on Conductivity.** — Copper wire apparently decreases in conductivity when bent, but the greater part of this is caused by local changes in cross-section. This effect is negligible unless the wire is bent to a very small radius.

**Effect of Melting.** — Electrolytic copper which is drawn without having been melted has a higher conductivity than that which has been melted, J. H. Dellinger recording copper thus drawn as having a conductivity as high as 101.71 per cent after annealing at a dull-red heat. Lake copper likewise drawn without having been melted gave conductivities as high as 101.88 after annealing.

**Temperature Coefficient of Resistivity.** — It has been found by J. H. Dellinger (*Bulletin No. 147, Bureau of Standards, 1910, Vol. 7, No. 1*) that the temperature coefficient of copper is proportional to the conductivity instead of being virtually a constant, as hitherto assumed. This fact may be expressed by saying that the change of resistivity per degree C. of a sample of copper is 0.000597 ohm per meter-gram or 0.00681 micro-ohm per centimeter cube (Dellinger's original figures were subsequently changed slightly; see *Circ. No. 1 of Bureau of Standards, 1912 ed.*) The 20° C. temperature coefficient of a sample of copper is found by multiplying the per cent conductivity by 0.0039; and dividing by 100. These rules apply only to copper furnished for electrical use and to the temperature range of 10° C. to 100° C. over which the temperature coefficient was found to be linear. The following table gives the temperature coefficients  $\alpha_T$  in the formula:

$$R_t = R_T [1 + \alpha_T (t - T)].$$

lbs per 100-grms 100° C.	Per cent conductivity	$\alpha_{75}$	$\alpha_{100}$	$\alpha_{125}$	$\alpha_{150}$	$\alpha_{175}$
1.5134	95	0.00403	0.00380	0.00373	0.00367	0.00360
1.5266	96	0.00408	0.00385	0.00377	0.00370	0.00364
1.5402	97	0.00413	0.00389	0.00381	0.00374	0.00367

**CORONA, ELECTRIC.** — (See also *Electron Theory; Spark Gap; Transmission Lines.*) If a potential difference is established between smooth parallel wires, or between concentric cylinders, and gradually increased, a voltage is finally reached at which a hissing noise is heard. If it is dark, a pale glow, called the electric "corona," will be seen to surround the wires. When wattmeters are inserted in the line a loss is noticed to start at this critical voltage. They also noted the characteristic odor of ozone, and the air around the wires becomes ionized. These phenomena are referred to as "corona effects."

The corona starts at the conductor surface, because the voltage stress per unit distance, or "voltage gradient," is highest there. The break-down or corona extends out to a point where the stress is below the break-down point of air. If the wires are close together, so that the stress is fairly uniform, the break-down immediately extends from conductor to conductor without corona, and the phenomenon is called a "spark-over." The spark and corona are exactly the same phenomenon. The corona may be considered as a spark-over from conductor to space, as distinguished from a spark-over from conductor to conductor. The spark-over does not extend to the other conductor when the separation is large compared to the wire diameter, because it reaches a point in space where the gradient is below the break-down gradient of air. Increasing the voltage after the corona point is reached causes the corona to extend until finally a spark occurs from conductor to conductor. The power loss increases very rapidly with increase in voltage above the critical point.

Corona is caused by either a-c. or d-c. voltages, and starts at approximately the same maximum stress. At the critical voltage, corona occurs only at the crest of the alternating wave. As the voltage is increased above the critical point the loss extends over a greater portion of the wave. In the a-c. corona the effect sees a superposition of the corona caused by the plus and minus half-cycles of the a-c. waves. If the effects of the half waves are viewed separately, it is noticed that a reddish haze surrounds the wire while it is negative, whereas the surface of the wire glows bluish-white while it is positive. Positive and negative d-c. corona have exactly the same appearance as the positive and negative coronas of the corresponding a-c. half-waves. When a negative wire becomes oxidized reddish tufts appear. If there are rough spots on the wire the corona starts at these points at a lower voltage. At points the positive corona extends out as a bluish-white spray; the negative corona appears as a red tuft.

Corona is also caused by transient voltages. Corona produced by voltages lasting less than a millionth of a second can be seen by the eye and distinction can be made between a positive and negative half-wave.

**Corona Voltmeter.** — For a given conductor arrangement and air density the corona always starts at the same maximum voltage. Use has been made of this fact in the corona voltmeter (*Whitehead and Ishiki, J.A.I.E.E., May, 1920*). For this purpose, a wire in the center of a cylinder is generally used. In one form the voltage is applied and the air density varied until the corona appears. The voltage is then readily calculated or read from a scale. A tapered-wire has also been used. The starting point can be detected by the glow, the noise, the odor or by the conducting ionized air.

**Laws of Corona-Formation.** — The laws of corona have been quite definitely worked out. The chief factors affecting corona formation are:

For a given spacing and air density the corona starting voltage is lowered by decreasing the wire diameter.

Increasing the spacing increases the corona starting voltage but the effect of changing the diameter is relatively much greater.

Increasing barometric pressure decreases air density and decreases the corona starting voltage.

Increasing temperature decreases air density and decreases the corona starting voltage.

Ice, water, etc., on the conductor surfaces lower the corona starting voltage increasing the stress.

The *apparent strength* of air is not constant in irregular fields but greater at surface of small conductors than large ones. The strength at the start of corona is always constant, however, at a distance from the conductor which is equal to the radius. This corresponds to the strength in a uniform field of 76 kilovolts per inch (maximum value in case of a-c. voltage), which means that the actual strength of air is 76 kilovolts per inch. In order, therefore, that a finite thickness only may be brought to this stress in an irregular field the stress at the conductor surface must be higher. At a given spacing corona always starts at a lower voltage on small wires than large ones, however, although the *apparent strength* of air at the small conductor surface is lower, the stress produced by a given voltage is relatively much higher for the smaller wires.

Corona does not start at exactly the same voltages when the wires are alternately plus and minus. The difference is at most a few per cent and is greater for small wires than large ones.

On perfectly clean, smooth wires of uniform diameter, there is no loss until the *visual critical voltage* is reached, when the loss assumes a definite value and increases as the square of the difference between the applied voltage and the *disruptive critical voltage*. The *visual critical voltage* takes into account the *apparent strength* of the air, which is a function of the wire diameter; the *disruptive critical voltage* corresponds to the constant strength of air for uniform fields, which is about 76 kilovolts per inch, maximum value. The *visual critical voltage* is always higher than the *disruptive critical voltage*. Due to irregularities there is always a loss below the *visual critical voltage*. This loss follows the probability curve, because the loss occurs at chance rough spots, but on practical transmission lines the quadratic law is generally approximated even on this portion of the curve. This is especially so for large conductors at low altitudes, where the difference between the visual and disruptive critical voltages is not great.

Corona loss increases with increasing frequency.

The formulas for calculating corona on transmission lines are given below.

**CORONA ON TRANSMISSION LINES.** — It is of great importance in the design of high voltage transmission lines to know the various factors that affect the corona formation and to be able to estimate accurately the starting stage and loss for a given line.

The various characteristics may be calculated from the following formulae:

Let  $e$  = r.m.s. value of the kilovolts to neutral ( $= \frac{E}{\sqrt{3}}$  kilovolts between wires for 3-phase;  $= \frac{1}{2}$  kilovolts between wires for single-phase).

$t$  = temperature in deg. F.,

$b$  = barometric pressure, in inches,

$s = \frac{17.9b}{459 + t}$  = specific gravity of air, referred to air at 77° F. and 29.9 inches barometric pressure,

$r$  = radius of conductor, in inches,

$g_0 = 53.6$  = disruptive critical gradient, kilovolts per inch, r.m.s. value,

$$e_v = e_0 \delta \left( 1 + \frac{0.189}{\sqrt{\delta r}} \right) = \text{visual critical gradient, kilovolts per inch, r.s. value,}$$

$s$  = distance between conductor centers, in inches,  
 $f$  = frequency, cycles per second.

Then the disruptive critical voltage, r.m.s. value of kilovolts to neutral

$$e_0 = 2.302 m_0 g_0 \delta \log_{10} \left( \frac{s}{r} \right),$$

where  $m_0 = 1$  for polished wires,  $= 0.98$  to  $0.93$  for roughened or weathered wires,  $= 0.87$  to  $0.83$  for seven-strand cables.

The visual critical voltage, r.m.s. value of kilovolts to neutral, is

$$e_v = 2.302 m_v g_v f \log_{10} \left( \frac{s}{r} \right),$$

where  $m_v = 1$  for polished wires,  $= 0.72$  for local corona all along cable,  $= 0$  for decided corona all along cable.

The power loss in fair weather, in kilowatts per mile of single conductor

$$p = \frac{390}{\delta} (f + 25) \sqrt{\frac{r}{s}} (e - e_0)^2 \times 10^{-3}.$$

The power loss in stormy weather, in kilowatts per mile of single conductor is approximately,

$$p_s = \frac{390}{\delta} (f + 25) \sqrt{\frac{r}{s}} (e - 0.8e_0)^2 \times 10^{-3}.$$

**Example.** — To illustrate the use of the above formulas consider the case of a three-phase, 60-cycle line, No. 0, A.W.G. stranded cable (diameter 0.374 in.), spacing 120 inches, length of line 100 miles, temperature  $100^\circ$  F., barometer 28.85 inches.

Then 
$$\frac{s}{r} = \frac{120}{0.187} = 642,$$

$$\log_{10} \left( \frac{s}{r} \right) = 2.81,$$

$$\sqrt{\frac{r}{s}} = \sqrt{\frac{0.187}{120}} = 0.0394,$$

$$\delta = \frac{17.9 \times 28.85}{459 + 100} = 0.925,$$

$$\sqrt{\delta r} = \sqrt{0.925 \times 0.187} = 0.426,$$

$$e_v = 53.6 \times 0.925 \left( 1 + \frac{0.189}{0.426} \right) = 71.6,$$

$$m_0 = 0.87.$$

The disruptive critical voltage is then,

$$e_0 = 2.302 \times 0.87 \times 53.6 \times 0.187 \times 0.925 \times 2.81, \\ = 52.0 \text{ kilovolts to neutral.}$$

The power loss is,

$$\begin{aligned} p &= \frac{390}{0.925} (35 + 60) \times 0.0394 (e - e_0)^2 \times 10^{-8} \\ &= 0.014 (e - e_0)^2 \text{ kw. per mile of conductor} \\ &= 0.042 (e - e_0)^2 \text{ kw. per mile of line.} \end{aligned}$$

The conductor would begin to glow ( $m_s = 0.72$ ) at

$$\begin{aligned} e_0 &= 2.302 \times 0.72 \times 71.6 \times 0.187 \times 2.81 \\ &= 62.6 \text{ kilovolts to neutral} \\ &= \sqrt{3} \times 62.6 = 108.3 \text{ kilovolts between wires.} \end{aligned}$$

The glow would be pronounced ( $m_s = 0.82$ ) for

$$e_0 = \frac{0.82}{0.72} \times 108.3 = 123.4 \text{ kilovolt between wires.}$$

The power loss per mile of line under storm conditions would be,

$$\begin{aligned} p_s &= 0.042 (e - 0.8 \times 52)^2 \\ &= 0.042 (e - 41.6)^2 \text{ kw. per mile of line.} \end{aligned}$$

This last calculation assumes a storm over the whole line at the same time; a condition that is most unlikely to occur. The storm loss will generally be less due to lower temperatures.

The loss on a transmission line will vary from day to day depending upon the temperature and weather conditions. The above losses are calculated for summer temperature. For winter the losses would be much lower.

**Methods of Increasing Size of Conductors.** — For equal conductivity an aluminum conductor has about a 25 per cent greater diameter than a copper conductor, and, therefore, approximately 25 per cent higher critical voltage.

The advantage of aluminum may be still further increased by the addition of a steel cable core. Such a cable has been in use for several years on a 165-154 kilovolt line in California.

A copper tube may also be used or a copper cable with a suitable core.

Another means of increasing the corona voltage for a given amount of metal is to arrange several conductors of the same potential close together.

**Arrangement of Conductors.** — In the above formulas it has been assumed for three-phase lines that the conductors are so arranged that they form the edges of an equilateral prism. When the conductors are not so arranged, but are placed symmetrically in a plane, corona will start at a lower voltage on the inner conductor than on the outside conductors. The actual critical voltage on the center conductor will be approximately 4 per cent lower, and on the outside conductors 6 per cent higher, than for the equilateral prism arrangement with the same spacing.

**Voltage Variation Along Line.** — In practice, due to the drop in voltage along the line, the corona loss will be different at different points on the line. This may be allowed for by calculating the loss per mile at various points, and plotting a curve with loss per mile as ordinates and length in miles as abscissa. The area of this curve then represents the total loss.

If an isolated system is operating near the critical corona voltage and one conductor becomes grounded, the corona loss will be quite high.

**The Corona Limit of High Voltage Transmission Lines. — Safe and Economical Voltages.** — It will generally be found that it is safe and economical to operate a line up to, but not above, the fair weather value: the disruptive critical voltage (that is, up to the value of  $e_0$  given by equation 1 for average barometer and summer temperatures. This will give loss during storms, but as storms do not extend over the whole line at one time, it will generally not be serious. During cold weather the critical voltage will be high and storm loss less.

Besides the loss of energy, corona loss may be undesirable from another standpoint, viz., since the loss occurs only on part of the wave, it may introduce harmonics if it is excessive.

Tables I and II give the values of the fair weather disruptive critical voltage in kilovolts between wires, for various conductors at various spacings, at a barometric pressure of 29.9 inches = 760 mm. (standard pressure at sea level) and 77° F. = 25° C.

Table III gives the factors by which these voltages must be multiplied to give the corresponding disruptive critical voltage at various elevations. The correction factor is equal to the ratio of the barometric pressure at the given altitude to the barometric pressure at sea level.

**Agreement of Calculated and Measured Losses on Actual Transmission Lines.** — In most cases where losses have been measured on transmission lines the check is in close agreement with calculated values. The agreement is in fact within the limit of error of the measurements on commercial lines. Apparent discrepancies have generally been due to the fact that the measurements are often made at voltages below the *visual critical voltage*, when the loss depends upon irregularities, as discussed above. The loss between the *visual critical voltage* and the *disruptive critical voltage* closely follows the quadratic law for large conductors, but for new conductors, and especially for small

3000	915	0.89	12,000	3660	0.63
4000	1220	0.86	14,000	4270	0.58

conductors at high altitudes, when the difference between  $e_0$  and  $e_1$  is large, the loss will generally fall below the quadratic curve.

**Special Calculations.** — For small conductors the loss, in kilowatt mile of conductor, is given by the expression,

$$p = \frac{390}{\delta} (f + 25) \sqrt{\frac{r + \frac{0.93}{s} + 0.016}{s}} (e - e_0)^2 \times 10^{-6},$$

where 
$$e_0 = e_0 \delta \left[ 1 + \frac{0.189}{\sqrt{\delta r}} \left( \frac{1}{1 + 1.48cr^2} \right) \right]$$

and 
$$e_0 = 2.302m_0g\delta \log_{10} \left( \frac{s}{r} \right).$$

**COUPLINGS, DIRECT.**—(See also *Belts and Belting.*) Couplings for connecting electrical apparatus together or to other machines can be divided into distinct classes, namely, solid and flexible.

**SOLID COUPLINGS** (Fig. 1) are usually of the flanged type and consist of two steel castings rigidly bolted together. This type should be used where two machines are mounted on a common base and where an exact alignment is possible. Large flanges should be used for overcoming bending stresses which may occur when the couplings carry part of the load such as, for example, in bearing sets. See also article on *Machine Tools, Electrical Operation of.*

Fig. 1. Solid Flange Coupling

**FLEXIBLE COUPLINGS** are mainly used to connect machines which cannot be lined up properly or where there is fear that alignment cannot be obtained. Many different kinds of flexible couplings are in use, and they may be divided in two general classes, insulated and uninsulated. The insulated couplings are composed of castings separated by leather or rubber, as a flexible and insulating medium. The principal types of flexible couplings in use are the leather link, the laced belt, the rubber buffer and the mill-type coupling.

**Leather-link Flexible Couplings** (Fig. 2) consist of two iron castings connected together through leather punchings fastened at the ends by bolts to the mate halves. For the smaller sizes the links are usually replaced by a single leather disk which connects both halves by means of bolts alternately spaced through opposite halves. The stresses are transmitted through the links or disks to the bolts which anchor them to the castings.

In order to allow sufficient play for the heads of the bolts, alternate holes are bored to a large diameter, the bolts loosely fitting the other holes in the castings. By this means flexibility is obtained and a small amount of end or side play is permissible between the flanges of the two machines to which each half coupling is securely keyed. This type of coupling is recommended for shafts up to  $3\frac{1}{2}$  inches in diameter. For shafts between  $3\frac{1}{2}$  inches and 5 inches in diameter either this type or the laced type may be used.

Fig. 2. Leather-link Flexible Coupling

**Leather-laced Flexible Couplings** (Fig. 3) are recommended for shafts over  $3\frac{1}{2}$  inches in diameter on account of their structural advantages. They consist of two steel rings, an outer and an inner, with cast-iron bolts bolted to them. Slots are made in these rings through which an endless leather belt is interwoven.

Fig. 3. Leather-laced Flexible Coupling

This construction not only gives great flexibility but, due to the two rings being concentric, it is not subjected to bending strains and therefore is espe-

cially adapted for transmitting a high torque commensurate with the strength of the belt and the size of the coupling employed.

As the outer ring of the coupling is only connected to the shaft of the machine through the coupling hub which is keyed to the shaft, machines using this form of coupling can be readily disconnected without unlacing or interfering with the coupling belt. To do this it is only necessary to remove the bolts, holding the outer ring to the hub. This partial disassembling also aids in the replacing of a worn-out belt without removing the coupling from the machine.

**Rubber-buffer Flexible Coupling.** — This coupling is made up of two cast iron spiders, the small interlocking arms of which are separated by cylinders of soft rubber. The rubber cylinders are held in place by projecting plates screw to the arms of one of the spiders. The construction of this type of coupling affords great flexibility as well as insulating qualities. This type of coupling was once much used on account of its high-insulating qualities but is now to a great extent being superseded by the two previous types.

**Mill-type Flexible Coupling (Fig. 4).** — Where the conditions are severe for the belt or rubber of the flexible couplings described above, that is, where there is much grit or hot vapor present and where noise is not objectionable, the mill-type flexible coupling shown in Fig. 4 should be used. This is a rough sturdy coupling consisting of three steel castings, two of which are identical and called the "pods," while the center is called the "box." The most extensive use for this coupling has been in steel mills. Best results are obtained from this coupling when it is used on a constant load, as the noise under these conditions is at a minimum.

Fig. 4. Mill-type Flexible Coupling.

**Leather Key Type Flexible Couplings.** — These are made in three distinct types, although all are constructed on the same fundamental principle, viz., two modified flanges, one driving the other by means of leather keys. The three types are known as the "single key," "two-piece multiple key," and "three-piece multiple key."

**Flexible Telescope Couplings.** — This coupling is specially designed for use with motor driven Jordan engine in paper and pulp mills. On the Jordan side of the set it consists of a stout split cylinder on which are mounted four radial columns of leather washers securely bolted. The motor half is a split cylinder slotted to take the columns of the other half.

**PROPER SIZE OF COUPLING.** — The selection of the proper coupling should be determined by calculation and not by the method of choosing the belt corresponding to the shaft diameter. The coupling should have sufficient capacity to take care of the overload capacity of the motor or generator, as the case may be.

Mach., 1903, Vol. 26, p. 1914; Ohnesorge, O., *Elastic Couplings*, A.S.M.E.J., 40, p. 718, 1918; Davey, H., *Flexible Couplings*, Eng., July 30, 1915.

**CRANES.** — (See also *Blocks and Tackle; Controllers; Hoists, Electric; Trolleys.*) A hoist is a machine for raising and lowering weights. A crane is a hoist with the added capacity of moving the load in a horizontal or lateral direction. That part of a crane carrying the hoist and movable with respect to the main structure of the crane is called the "trolley." Cranes are divided into two classes as to their motions, viz., rotary and rectilinear.

**Rotary Cranes** may be classified as follows:

**Swing-cranes.** — Having rotation, but no trolley motion.

**Jib-cranes.** — Having rotation, and a trolley traveling on the jib. When the jib or boom is movable, carrying a sheave on the end, the device is called a *levit*.

**Column-cranes.** — Identical with the jib-cranes, but rotating around a fixed column (which usually supports a floor above).

**Pillar-cranes.** — Having rotation only; the pillar or column being separated entirely from the foundation.

**Pillar Jib-cranes.** — Identical with the last, except in having a jib and trolley motion.

**Derrick-cranes.** — Identical with jib-cranes, except that the head of the mast is held in position by guy-rods, instead of by attachment to a roof or floor.

Rotary cranes arranged so that they may be readily moved from place to place may be classified as:

**Walking-cranes.** — Consisting of a pillar or jib-crane mounted on wheels and arranged to travel longitudinally upon one or more rails.

**Locomotive-cranes.** — Consisting of a pillar-crane mounted on a truck, and provided with a steam-engine capable of propelling and rotating the crane, as well as hoisting and lowering the load.

**Rectilinear Cranes** may be classified as follows:

**Bridge-cranes.** — Having a fixed bridge spanning an opening, and a trolley moving across the bridge.

**Tram-cranes.** — Consisting of a truck, or short bridge, traveling longitudinally on overhead rails, and without trolley motion.

**Traveling-cranes.** — Consisting of a bridge moving longitudinally on overhead tracks, and a trolley moving transversely on the bridge.

**Gantries.** — Consisting of an overhead bridge, carried at each end by trucks traveling on longitudinal tracks on the ground, and having a trolley moving transversely on the bridge.

**Rotary Bridge-cranes.** — Combining rotary and rectilinear movements and consisting of a bridge pivoted at one end to a central pier or post, and supported at the other end on a circular track, provided with a trolley moving transversely on the bridge.

For descriptions of these several forms of cranes see *Towne's Treatise on Cranes*.

**HAND-OPERATED TRAVELING CRANES.** — The weight of a hand-operated traveling crane depends not only upon the capacity of the crane and the length of the span, but also upon the particular design. The following approximate formula will serve as a rough guide when actual data are not available:

$$W = RCL,$$

where  $W$  is the weight of the crane in tons,  $C$  the capacity of the crane in tons,  $L$  the length of the span in feet and  $K$  a constant ranging from about 0.01 for  $L = 10$  feet to 0.012 for  $L = 75$  feet.

**ELECTRIC OVERHEAD TRAVELING CRANES.** — Electric travel cranes usually have 3 motors, one for the hoist, one for the trolley traveling the bridge and one for moving the bridge. Cranes of over 15 tons capacity are usually provided with an auxiliary hoist of from  $\frac{1}{10}$  to  $\frac{1}{6}$  the capacity of the main hoist. Automatic brakes are used to sustain the load when lifted and to regulate the speed when lowering, the hoist motor usually having drive the load down.

**Speeds of Electric Traveling Cranes.** — The standard speeds at which the various parts travel in the cranes manufactured by Pawling and Harnischfeger are as follows:

STANDARD SPEEDS OF ELECTRIC CRANES, IN FEET PER MINUTE  
(Pawling & Harnischfeger)

Capacity, tons (2000 lb.)	Hoisting speed, ft. per min.	Bridge travel, ft. per min.	Auxiliary hoist	
			Capacity, tons	Speed, ft. per min.
5	25-100	300-450	..	.....
10	20-75	300-450	3	30-75
25	10-40	250-350	3	50-125
			10	25-60
40	9-30	250-350	5	40-100
			10	25-60
50	8-30	200-300	5	40-100
			10	25-60
75	6-25	200-250	15	20-50
125	5-15	200-250	25	20-50
150	5-15	200-250	25	20-50

Trolley travel speed from 100 to 150 feet per minute in all cases.

**Weight and Dimensions of Electric Traveling Cranes.** — Let

$C$  = capacity of crane, in tons (2000 pounds),

$W_B$  = weight of bridge alone, in tons,

$W_T$  = weight of trolley alone, in tons,

$W$  = total weight of crane, in tons.

Then

$$W_B = K_B C L, \quad W_T = K_T C,$$

$$W = W_B + W_T = C(K_B L + K_T),$$

where  $K_B$  and  $K_T$  have the following approximate values (see paper by S. Wales, *Proc. Eng. Soc. Western Pa.*, 1902, Vol. 13, p. 146).

$L$	$K_B$	$C$	$K_T$
25	0.012	1-25	0.3
50	0.012	25-75	0.4
75	0.013	75-150	0.5
100	0.015		

For example, for a 50-ton crane for a 60-foot span, the bridge alone would weigh  $0.013 \times 50 \times 60 = 39$  tons, the trolley would weigh  $0.4 \times 50 = 20$  tons, the total weight would be 59 tons, approximately. If the bridge is equipped with 2 wheels at each end, the maximum load on each wheel when the trolley, carrying full load, is at the end of the bridge would be approximately

$$\frac{39}{4} + \frac{20 + 50}{2} = 45 \text{ tons,}$$

If there are 4 wheels at each end, the maximum wheel load would be 22.5 tons. The following table is taken from a catalogue of the Alliance Machine Co.

### DIMENSIONS AND WHEEL LOADS OF ELECTRIC TRAVELING CRANES

60-foot span and 25-foot lift; wire-rope hoist

Capacity, tons (2000 lb.)	Distance from runway rail to highest point		Distance from center of rail to ends of crane	Wheel base of end truck		Maximum load per wheel; trol- ley at end of bridge
	Feet	Inches	Inches	Feet	Inches	Pounds
5	6	0	9	9	0	20,000
10	6	6	10	10	0	27,000
25	7	4	12	11	6	51,000
40	8	0	12	12	3	82,000
50	8	9	12	12	6	48,000*

\* Has 8 track wheels on bridge.

Standard cranes are built in intermediate sizes, varying by 5 tons up to 40 tons.

**Power Required.** — The following is adapted from the paper by S. S. Wales we referred to. The frictional losses will of course depend to a certain extent on the design of the crane, the use of rope or chain, etc., but the constants below represent fair averages.

The same notation as in the previous section is used. In addition let

$R_B$  = tractive effort in pounds per ton required to move the bridge,

$R_T$  = tractive effort in pounds per ton required to move the trolley,

$S_B$  = speed of bridge in feet per minute,

$S_T$  = speed of trolley in feet per minute,

$S_H$  = speed of hoist in feet per minute.

Let  $P_B$  be the power required, at shaft of bridge motor, to drive the bridge at speed  $S_B$

$$P_B = \frac{(C + W_B + W_T) R_B S_B}{33,000} \text{ horse-power.} \quad (1)$$

Let  $P_T$  be the power required, at shaft of trolley motor, to drive the trolley at speed  $S_T$

$$P_T = \frac{(C + W_T) R_T S_T}{33,000} \text{ horse-power.} \quad (2)$$

The power required, at shaft of hoist motor, to drive the hoist at speed assuming 60 per cent efficiency of gearing and hoisting tackle, is

$$P_H = \frac{CS_H}{10} \text{ horse-power.}$$

For *constant-speed running*, Wales gives the following values for  $R_B$  and the former varying with  $L$  and the latter with  $C$ .

$L$	$R_B$	$C$	$R_T$
25	30	1-25	30
50	35	25-75	35
75	40	75-150	40
100	45	.....	....

If the moving member is *accelerating* at the rate of  $a$  ft. per sec. per to the value of  $R$  given in the above table should be added an amount

$$R_a = 64 a.$$

The power as calculated by the above formulas is the power *output* of motors; to obtain the power input divide by the motor efficiency, which ran from 80 to 90 per cent.

**Motor Equipment.** — (See also *Motors, Industrial Applications of*.) bridge motor should have a 30 minute rating, 1.8 times the calculated power for constant full-load speed, the trolley motor 1.5 times the calculated power for full-load speed, whereas the rating of the hoist motor should be 1.5 times equal to the calculated power for constant full-load speed. This is a general approximation, but for accurate work the torque capacity of the bridge motor should be checked against the rate of acceleration required. A full discussion of the motor equipment of cranes is given by McLain and Jackson in the *Elec. Rev.* 19, p. 506, June, 1916.

Both direct-current and alternating-current motors are successfully used in crane work. The series direct-current motor has speed-torque characteristics especially well adapted for crane service. At light loads the speed increases and at heavier loads the lifting is slower and the raising effect consequently stronger. This characteristic of the series motor often results in considerable saving of time, due to the fact that the majority of loads in factories are light so that the increased speed of lift enables work to be performed in a shorter time. For a-c. motors a normal operating speed about 25 to 50 per cent higher than for d-c. motors is therefore generally selected and the slowing down for heavy work is accomplished by inserting resistance in the phase-wound rotor circuit.

**Example.** — Crane of 50-ton capacity, span 70 feet, bridge speed 100 feet per minute with full load, trolley speed 100 feet per minute with full load, hoist speed 15 feet per minute with full load. Then  $C = 50$ ,  $W_B = 4$ ,  $W_T = 20$ ,  $R_B = 40$ ,  $R_T = 35$ , and

$$P_B = \frac{115.5 \times 40 \times 200}{33,000} = 28 \text{ horse-power,}$$

and the motor required for the bridge would be  $28 \times 1.5 = 42$  horse-power, the nearest commercial size over 42, say 50 horse-power.

$$P_T = \frac{70 \times 35 \times 100}{33,000} = 7.43 \text{ horse-power,}$$

If the size motor required for the trolley would be  $7.43 \times 1.25 = 9.28$  horse-power, or say 10 horse-power.

$$P_H = \frac{50 \times 15}{10} = 75 \text{ horse-power,}$$

A motor of this rating would be used for the hoist.

**Control of Crane Motors.**—The control equipments for crane motors may be of the regulating and reversible type. The starting and speed regulation of series motors is generally accomplished by inserting resistance in series with the armature and field, and with induction motors, resistance is inserted in the phase-wound secondary or rotor circuit. For cranes which do large amount of lowering, dynamic control is becoming very generally used, and is very readily accomplished with direct-current motors. This also occasionally is used with a-c. motors of 200 h.p. and above, when direct current is available for excitation. On smaller a-c. motors a system of regenerative braking in combination with solenoid load brakes is used.

**Drum Versus Magnetic Controllers.**—Both hand- and magnetic-control equipments are in general use. The former are satisfactory for small and medium-size motors, and consist simply of a drum-type controller with a set of contact resistances. For large-size motors too much physical effort would be required to move a controller of the necessary size and the magnetic control would then be selected. A magnetic-control equipment consists of a master controller, a contactor panel and the resistances. The contactor panel contains contactors for cutting in or out the resistances, the interlocks and the current-limit relays for automatically controlling the sequence and rapidity with which the contactors operate. The master-controller handle can be thrown to the full-load position quickly without causing an overload on the motor, since the current-limit relays automatically prevent the contactors from cutting out the resistances too rapidly.

**Dynamic Control.**—With dynamic control of d-c. motors the field is separately excited and the armature is connected to the line voltage with one end of a rheostat in series with it, and another section of the rheostat in parallel with it. This is accomplished by means of the controller, whose duty is to make each step on the lowering side keep the speed of the motor under control no matter whether the motor has to drive a light hook downward or hold back against a heavy load. In the former case the current which passes through the series rheostat also passes through the armature and produces the desired torque. The speed is controlled by varying the value of this rheostat as in hoisting. If the motor has to act as a brake, the power generated in the armature is expended in the parallel rheostat and the speed is controlled by varying this rheostat. In actual practice the two rheostats are varied simultaneously so that if a certain point on the controller tends to cause the motor to drive a load at a high speed it will also cause the motor to hold back at a high speed. The practical result is that an operator always has his load under control and does not have to worry about dropping his load. On the lowering side the controller, a motor holds back against its load even when power fails, because the motor then acts as a self-excited series generator, and consequently the solenoid brake alone is not depended on to prevent the load from falling. In the case of a phase-wound induction motor it is necessary to excite one end of the primary winding with direct current in order to generate a voltage in the secondary winding. A rheostat is then connected to the secondary windings of the motor and the speed can be controlled as with d-c. motors. As direct current is necessary for excitation dynamic braking is not very often used with crane motors.

Solenoid brakes are also provided for holding the load when the hoist motor is stopped. If dynamic braking is not provided, mechanical brakes must be provided in addition to the solenoid brakes to assist in holding the load when the motor is stopped and for regulating the speed when lowering.

Solenoid brakes are, as a rule, applied by gravity when the armature current is shut off and released by the solenoid which is energized when the controller is thrown on the first notch. The solenoids of direct-current motors are generally connected in series with the motor circuit, although with polyphase induction motors they are connected directly across one phase thus receiving the full line voltage.

All crane motors should also be protected by safety-limit switches arranged to cut off the supply current when the limit of motion is reached and thus automatically provide against accidents from over-travel.

**SPECIFICATION FOR ELECTRIC CRANE.** — The following measurements are intended to assist in writing specifications. See also *Specifications for Electric Cranes*.

**Principal Characteristics and Conditions of Service.** — Span between crane rails and load to be lifted on main hoist and on auxiliary hoists, if any. Characteristics of current, a-c. or d-c. (phases, cycles and voltage).

**Style and Description of Apparatus.** — Structural work of open-heel steel according to some standard steel specifications. Maximum stresses allowable. Whether hand operation is to be provided for. Distance of hook from crane rails, vertically and horizontally, when at extreme limits of its motion. Details of brake. Description and characteristics of motors to be supplied. Whether or not a foot-walk is to be supplied. Whether trolley is to be above bridge or submerged. Hoisting drum to have bronze bearings. Track wheels shall have chilled treads, ground true, with double flanges, and shall be keyed to their axles. Axle bearings shall be bronze. Details of lubrication of bearings. Location of carriage. Details of control. All gearing (except when shrouded) shall be cut, etc. Wiring details. Controller details.

**Dimensions.** — Supply a diagram of clearances.

**Work Done by Other Contractors.** — Track rail and weight thereof.

**Performance and Tests.** — Speeds of main travel, lateral travel and hoisting. Time to get up speed or acceleration rates.

**COST OF CRANES (Pre-war figures).** — The cost of cranes depends so greatly upon the design, motor equipment, etc., that no reliable average figures can be given. As a rough approximation the cost of a hand-operated traveling crane may be taken as from about 5 to 7 cents per pound of total crane weight and the cost of an electric traveling crane as from about 10 to 13 cents per pound of total crane weight.

H., *Electric Cranes*; Wilda, Herman, *Cranes and Hoists*; Brown, R. B., *Designing Electric Cranes and Brakes*, Machinery's Reference Series No. 47; Hill, C. W., *Electric Crane Construction*; Circulars of Morgan Engineering Co., Alliance, O.; Pawling & Harnischfeger, Milwaukee, Wis.; Yale and Towne Mfg. Co.

**LOSS ARMS.** — (See also *Poles for Overhead Lines; Insulator Pins; masts.*) Cross arms are usually of wood though sometimes of iron. "hook arms" or "reverse arms" are cross arms attached to a pole at right angles to the principal arms, and are used for taking off wires at right angles to the line, either at the junction of intersecting lines or at services. "Double arms" are pairs of cross arms attached to opposite sides of a pole so as to act as compound arms. Double arms are used to increase the strength of an arm and to permit the use of two pins and two insulators for supporting a wire where additional strength is required.

Cross arms are used principally for supporting pins, insulators and wires, such lightning arresters, transformers, switches and other miscellaneous devices are often mounted on them, usually for the purpose of keeping the pole free of incumbrances so that it will be more easy to climb.

**Alley Arms.** — When city distribution lines are located in alleys it is common to locate poles next to the property line. Where it is not permissible to let an arm overhang private property special arms may be used which extend on one side of the pole only. These must be well braced and should not be used for ending wires. A better construction is obtained by locating two poles on opposite sides of the alley and putting special cross arms across the alley between them.

**FORCES ON AND STRESSES IN CROSS ARMS.** — The forces which a cross arm resists are:

- (a) Vertical forces due to weight of pins, insulators, wires (with sleet) and accidental loads due to linemen standing on arms, etc.
- (b) Transverse horizontal forces due to wind pressure on the wires (with sleet) at right angles to the line.
- (c) Longitudinal horizontal forces due to the pull of the wires where the pull is unbalanced. Unbalanced pull is usually due to an angle in the line, the end of the wire at the arm, a change in the size of wire at arm and an unequal tension in the spans on the two sides of the arm.

The principal internal stresses produced in an arm from these forces are:

- (1) A bending force in a vertical plane due to vertical forces (a).
- (2) A bending force in a horizontal plane due to horizontal forces (c).
- (3) A twisting force about the longest axis of the arm due to the "pin leverage" of the horizontal forces (c). The pin leverage is the distance from the center of the wire to the axis of the arm.

Of these stresses the most destructive is probably the twisting stress which tends to split the arm in a vertical plane through the pin holes and along the grain of the wood. On this account the pin and insulator should be no taller than necessary, the pin should extend completely through the arm to give the best distribution of bearing pressure and, where stress is heavy, the arm may be strengthened by two "strengthening bolts" (machine bolts with nut and washers) put horizontally through the arm one on each side of the pin, one being at the top and the other near the bottom of the arm.

The vertical and horizontal bending stresses are of some importance and may be computed by the usual beam formula (see *Structures, Simple*). Data of tests of strength of cross arms for these stresses are given below.

**Strength Tests of Cross Arms.** — (*Forest Service, Cir. No. 204.*) Tests made on 3½ in. by 4½ in. by 6 ft., 6-pin air-dried cross arms with vertical load distributed equally at each pin hole gave the results at top of next page.

The tests showed that for ordinary use the strength, for vertical loads of 6-pin arms, need not be considered in calculations of line construction, except in the case of abrupt change of the grade of the line.

Kind of wood	Average maximum load in lb.
Longleaf pine, 75 per cent heart.....	10,180
Longleaf pine, 100 per cent heart.....	9,780
Shortleaf pine.....	9,260
Longleaf pine, 50 per cent heart.....	8,980
Shortleaf pine, creosoted.....	7,650
Douglas fir.....	7,590
White cedar.....	5,200

**DIMENSIONS AND RATING.** — Cross arms are rated in terms of number of pins they are designed to carry, 2-pin arms being the minimum and 10-pin arms the maximum ordinarily used.

**Cross-section.** — When arms are made directly from the original logs they are sometimes dimensioned in even inches, i.e., 4 in. by 5 in., 5 in. by 7 in., etc. In most cases they are made from lumber in stock and when finished are a quarter of an inch or more under the even sizes. Several "standard" dimensions have been adopted for distribution arms. In the accompanying table Standard I is that given by Miller (*American Telephone Practice*) and found in various catalogues of dealers in electrical supplies. It is the standard of the American Electric Railway Engineering Association for light service cross arms. Standard II is that given in Report of Committee on Overhead Line Construction of the National Electric Light Association, and Standard III is that of the American Electric Railway Engineering Association for heavy service cross arms.

Size of arms	Width, inches	Depth, inches
Standard I....	3 1/4	4 1/2
Standard II....	3 1/4	4 1/2
Standard III....	3 1/4	4 1/2

Fig. 1. Standard I Cross-Arms

**Distance between Pole Pins.** — It is desirable to have the space between pole pins (i.e., the two pins on opposite sides of the pole) as large as possible to give a clear space for climbing the pole. It usually varies from 16 in. to 30 in.

**Distance between Other Pins.** — This usually ranges from 10 in. to 21

Under ordinary circumstances 12 in. has been found sufficient to prevent on adjacent pins swinging in contact in the middle of the span. Where 8 wires (such as No. 10 telephone wires) are used on long spans (150 ft. or more) contact is to be expected occasionally where 12 in. spacing is used.

**Distance from End Pin to End of Arm.** — This is usually 3 or 4 in., which is about the minimum that can be used without the arm splitting due to leverage.

In order that a line may have a neat systematic appearance it is desirable that pin spacing be the same for all arms, whether 2 pin, 4 pin, etc. In the tabulations below the arms included in each standard (defined above under *Dimensions and Rating*) have been grouped on this principle which shows that Standard I only consists of one regular group and 5 odd arms while Standard II consists of 2 regular and 1 odd arm. Referring to Standards I and III it will be noted that the length of arm is always a multiple of one foot.

## STANDARD DISTANCES BETWEEN PINS

Standard	Group	Number of pins	Length of arm	End pin to end of arm	Between pole pins	Between other pins
			Pt. in.	In.	In.	In.
I	Regular	4	4 0	4	16	12
	Regular	6	6 0	4	16	12
	Regular	8	8 0	4	16	12
	Regular	10	10 0	4	16	12
	Odd	2	3 0	4	28	..
	Odd	4	5 0	4	18	17
	Odd	4	6 0	4	28	27
	Odd	4	6 0	4	24	20*
	Odd	6	8 0	4	18	17½
	Odd	8	10 0	4	17½	15½
II	Regular	4	5 7	4	30	14½
	Regular	6	8 0	4	30	14½
	Odd	8	9 2	4	30	12
III	Regular	2	3 0	4	28	..
	Regular	4	5 0	4	28	12
	Regular	6	7 0	4	28	12
	Regular	8	9 0	4	28	12
	Regular	10	11 0	4	28	12

\* Alternative found in some catalogues.

**Pin Holes.** — 1½ in. diameter is standard for wood pins. N.E.L.A. specifications require that holes shall be tested with steel gauges taking one of the usual size without forcing but not taking one ½ in. larger.

**Bolt Holes.** — For fastening the arm to the pole there is usually one 1½ in. bolt hole at the middle of the arm. For fastening cross-arm braces there are two ¾ or ¾-in. bolt holes located 38 in. apart (Standard II) or 40-42 in. apart (Standard III).

**High-tension Wooden Cross Arms.** — These are not standardized but are specially designed and made as required. They differ from distribution arms in being wider and deeper with larger pin holes and wider pin spacing. The

following tabulation will give data on some arms that have been used for different voltages.

Voltage	Number of pins	Width of arm	Depth of arm	Length of arm	Spacing of pins	Pin hole diameter
25,000	2	Inches 6	Inches 6	Inches 64	Inches 48	Inches 2 $\frac{1}{4}$
55,000	2	Inches 5	Inches 7	Inches 88	Inches 72	Inches 2 $\frac{1}{2}$

Special high-tension arms are usually unnecessary for circuits of 5500, 611,000 and 13,200 volts. Standard 2200-volt distribution arms may be used at the wire spacing being increased by not using certain pins. Thus a standard 2200-volt 6-pin arm may be used for a 11,000-volt 4-pin arm by leaving middle pin holes vacant. For higher voltages the strength of arm and size of pin hole is usually insufficient.

**SPECIFICATIONS.** — (See article on Specifications.) The points to be covered in a set of specifications are:

**Material.** — Usually pine or fir, sometimes western hemlock. (See *Poles and Overhead Lines*.)

**Quality of Material.** — Usually should be "straight grained, free from knots (or free from large, loose or unsound knots), sapwood, pitch pockets, shakes, checks, loose heart, rot, worm holes or other defects." The strictness of specifications, or of the inspection, must, however, be governed in these respects by local conditions. In some localities a quality of material can be obtained cheaply, and should be required, which would be unreasonable to expect where wood is expensive.

Wood should be dried before manufacture. (When arms are dried after drilling, the pin holes become elliptical, i.e., smaller across the grain, due to shrinkage of the wood and the pins do not fit well.)

**Dimensions, Pin holes, etc.,** as noted in preceding section.

**COST.** — The cost of cross arms is subject to considerable variation and depends largely upon the locality in which they are purchased. The following figures are rough approximations and are exclusive of freight.

#### APPROXIMATE COST OF CROSS ARMS

Cents per linear foot

Kind	Washington fir, F.O.B., Seattle	Longleaf pine, "75 per cent heart," F.O.B., New Orleans	Commercial yellow pine F.O.B., New York
3 $\frac{1}{2}$ by 4 $\frac{1}{4}$ inches.....	5	6	5
3 $\frac{1}{2}$ by 4 $\frac{1}{2}$ inches.....	7	10	...
3 $\frac{3}{4}$ by 4 $\frac{3}{4}$ inches.....	8	...	...

In car load lots about 25 per cent less than above.

**DAMS.** — (See also *Hydraulics; Hydrology; Power Stations; Structures, mple*). A dam is a structure built to interrupt a stream's flow and raise the level of the water, thereby impounding water which may be used for power development, water supply, navigation, irrigation or numerous other purposes.

**Coffer-dam.** — A dam built for the purpose of holding back water from an area which would otherwise be flooded, and making it accessible for construction purposes, is called a coffer-dam. It is generally a temporary affair.

**Diversion Dam.** — This name has been applied to dams built for the purpose of diverting the whole or a portion of a stream into a side channel or pipe by which it is conducted to one or more places where it is used for power or other purposes.

**Storage Dam.** — A storage dam is built for the purpose of storing flood waters in use during periods of low stream flow. In many power developments a large dam is essential to continuous output. Storage dams are sometimes used as diversion dams.

**Wing Dam.** — In swiftly flowing streams having steep slopes, a diversion dam is sometimes built out from one shore diagonally upstream toward the other, as cut to it. This special form of diversion dam is known as a wing dam.

**Classification with respect to Materials and Design.** — According to the materials used and the design, dams may be classified as:

Wooden dams	Masonry dams
Earth dams	Solid gravity
Rock dams	Hollow gravity
	Arched

By a **gravity dam** is meant one in which the force of gravity is relied upon for resisting the thrust and overturning moment of the water. Earth and loose rock dams, timber cribs and most masonry dams are of this type.

By an **arched dam** is meant one which in plan forms an arch, convex to the up-stream side. The ends of the arch terminate in the valley walls, which thus act as abutments to the arch so formed.

Often a gravity dam has been built in the form of an arch, using the possible arch action as a factor of safety, and depending wholly on the gravity action to resist the thrust of the water. Many of the highest dams in existence are so constructed and are generally in localities where the stream's valley is relatively narrow and deep.

**LOCATION AND HEIGHT OF DAMS.** — For power developments the location of the dam depends largely on the topography and geological formation of the site. The total fall in a stream to be utilized for power may be developed in whole by a dam or in part by a dam and in part by a canal, flume or pipe to the power-house. Thus the location and height of the dam is fixed by economic considerations to develop the whole head at the least cost, consistent with safety and reasonable operation and maintenance expense. The cost of lands to be overflowed has considerable influence.

**WOODEN DAMS.** — Wooden dams are made in a variety of forms. The most common form of wooden dams consists of a crib of timbers filled with broken rock and covered on the top and up-stream face with wooden sheeting.

**EARTH DAMS.** — A typical earth dam is indicated in Fig. 1. No dam is absolutely watertight. The successful construction of a dam of any type embodies the condition that leakage or seepage will not be sufficient to endanger

the structure or its foundation and that an excessive amount of impounded water will not be wasted.

An earth dam and its foundation must be made sufficiently tight that seepage of water through it will not be great enough to move the minute particles of which it is composed.

Fig. 1. Typical Earth Section

**Materials and Details.**—The materials used in the construction of earth dams are loam, sand, gravel and clay of various proportions. The dam is approximately trapezoidal in section, having a top width and side slopes which are determined by the materials used. The best of the available materials are used to provide a selected impervious part. The impervious part or core may be placed near the upstream face; but, as impervious materials are relatively unstable when saturated, the core is usually placed in the center of the dam and supported on each side by the more stable pervious materials. The downstream toe is often built of loose rock or otherwise well drained to prevent slipping when saturated by water seeping through the dam.

Cores of masonry, clay puddle or other materials are sometimes built in the center of the dam, extending into the foundation to an impervious stratum. Timber cores above the water gradient are not sufficiently durable for a permanent structure. Masonry core walls usually have a top width of from 2 to 4 feet with side batters of  $\frac{1}{2}$  to  $\frac{3}{4}$  inch per foot down to the foundation, but, if well reinforced may be much thinner. There is a divergence of opinion among engineers regarding the practical use of masonry corewalls for earth dams. However, it has not been shown that they impair the safety of the dam and they are often imperative to guard against burrowing animals.

The downstream slope of the dam should be protected from rain scour by sodding or seeding it. For long slopes, provision is often made for draining the rain water by building berms, a few feet wide every 30 feet or so on the slope containing gutters for lateral drainage.

Riprap, hand laid paving or masonry is used on the upstream face to protect it from the action of waves and ice. Solid paving should be laid on a layer of well-drained broken stone or gravel to prevent internal pressure on the paving when the pond is drawn down rapidly.

**Dimensions.**—The top width of the dam is often determined by requirements for a roadway. Where not so fixed it may be made approximately equal to one-fifth the height of the dam plus five feet. The top of the dam must be built sufficiently high to prevent overtopping by waves during extreme high water.

Simple rules cannot be given governing the side slopes of earth dams. From the nature of the materials available, this angle of repose when placed in the dam must be determined by tests or practical experience. The upstream face is continually saturated and the downstream face is more or less damp, rendering the materials less stable than when in a dry embankment. High dams are usually given flatter slopes than low dams and often the lower part has flatter slopes than the upper part. Low dams often have up and downstream slopes

to 1. The Ticitus Dam (New York State) is 110 feet high, has an upstream slope of 2.4 to 1 and a downstream slope of 2.5 to 1 with a 30 foot top width. Gatun Dam (Panama) is 115 feet high, has an upstream slope of 4 to 1 and a downstream slope of 16 to 1 with a top width of 100 feet. It is thus seen that the variation in practice is very great, depending upon the nature of the strata and the methods of placing them in the dam.

**Foundations.** — In preparing the foundation for earth dams the surface is stripped to a depth sufficient to reach sound material, and all loose stones, roots, etc., removed. If the foundation is rock, the surface is cleaned and treated in making a good bond with the earth. The foundation should be checked for perviousness. If deemed necessary, one or more trenches should be dug to an impervious stratum and refilled with impervious material. Between an earth dam and a rock foundation is a plane of weakness which is usually worked against, in the absence of a masonry corewall, by building several low walls of masonry across the site to resist seepage of water along the rock surface.

**Construction of Rolled Earth Dams.** — The material for rolled earth dams is placed in layers 6 inches to 12 inches thick and well rolled with a heavy roller or otherwise compacted while damp. Sprinkling may be necessary during the compacting process. It is often provided that each rolled layer shall be harrowed and dampened to provide a bond with the layer above.

**Hydraulic Fill Earth Dams.** — Hydraulic fill earth dams are constructed by slicing the materials into place. If available material is found at an elevation higher than the crest of the dam and other conditions at the site are favorable, the materials are washed out of the borrow pits by a stream of water under heavy pressure, collected by the flow of the water and transported by gravity through sluices to the site. The materials are discharged from the sluices near the edges of the dam where the coarser particles, possessing the greatest angle of repose, remain. The balance of the material is washed by the water towards the center of the dam, the particles depositing automatically and progressively according to size until only the finest particles reach the center of the dam. Here a pond of water is allowed to remain through which the fine materials settle to form an impervious core.

When the materials are not located at an elevation sufficiently high to permit slicing to the site, they are transported by cars, carts or other means to the edges of the dam and sluiced into place as above described by streams of water.

The greatest difficulty in the construction of hydraulic fill dams is to obtain a core which is composed of sufficiently fine materials to make a tight dam and still possess adequate stability for a firm structure. If the material in the core is too fine to drain properly as the construction progresses, it will exert virtually a liquid pressure on the outside embankments which may be sufficient to cause them to slip. The degree of fineness in the core can be regulated by adjusting the elevation of the pool at the center of the dam, the deeper the pool the finer the size of particles deposited in the core.

**ROCK DAMS.** — In localities where earth is not available, broken rock can be used in the construction of dams. The rock fragments are of a size that can be most conveniently quarried and handled. Such dams are made tight by a masonry corewall at the middle of the dam or on the upstream face. The natural angle of repose of loose rock is about 1 to 1 but the side slopes of rock dams should not be steeper than  $1\frac{1}{2}$  to 1 unless the face is hand laid to a considerable thickness and in any case not steeper than  $1\frac{1}{4}$  to 1.

**MASONRY CONCRETE DAMS.**— During the latter part of the century, rubble masonry was used extensively for the construction of dams, but in recent years this type has been practically superseded by plain and reinforced concrete. In massive structures cyclopean concrete is generally used, consisting of plain concrete containing a liberal percentage of large stones, called "plums." The usual mix for masonry dams consists of 1:3:6 concrete for solid gravity and large arch dams; 1:2:4 to 1:2½:5 reinforced concrete for thin arch dams; 1:2:4 reinforced concrete for decks and spillways of hollow dams and 1:2½:5 to 1:3:6 reinforced concrete for buttresses of hollow dams. Special provision for water tightness must be made, particularly for solid gravity dams where water pressure in horizontal joints increases the overturning moment to be resisted.

**Foundations for Masonry Dams.**— Most masonry dams over 30 feet high require solid rock foundations. From this all soil and disintegrated rock is removed and the surface scrubbed clean. All cracks and fissures at the foundation and for some distance above it must be located and grouted. Often, in soft rock, a longitudinal trench is taken out and refilled with masonry to form an impervious barrier to the passage of water. This is placed at the upstream face or heel of the dam (see Fig. 3).

For dams on earth foundations, a masonry or sheet piling cut-off is built into the foundation at the heel of the dam extending down to a stratum of impervious material. Where this is impractical, undermining by seepage may be prevented by providing a path of enforced percolation of sufficient length. This varies from 5 to 18 times the head on the dam according to the material of the foundations. The proper length of path may be obtained by one or more cut-offs, by a downstream apron, by an upstream apron or by a combination of these. The length of the path of percolation, as affecting uplift and erosion force is the length of the actual plane of contact between the structure and the earth including aprons and both sides of all cut-offs, providing the cut-offs are not closer together than twice their depth. The foundations below the dam must be adequately protected from wash by proper paving.

**Dimensions and Cross-sections of Solid Gravity Dams.**— Typical high solid gravity non-overflow and spillway dams are indicated in Figs. 2 and 3.

2. Typical Solid Gravity Non-Overflow Masonry Section

Fig. 3. Typical Solid Gravity Spillway Masonry Section

The top width of non-overflow dams is generally made from 10 per cent to 14 per cent of the height of the dam and is placed at or a few feet above high water sur-

1. For spillway dams the top is made approximately parabolic to conform to the natural path of the water as it leaves the crest. If the descending sheet is free of the face of the dam, a partial vacuum will occur behind it and the atmospheric pressure on the upstream side will become effective as an overturning force. The curve or "bucket" at the downstream side of the base is for the purpose of deflecting the water and protecting the foundation. This may be omitted for low dams on hard rock.

The proportions of the section below the top are possible of mathematical determination once the forces acting on it are known. A common method is "cut and try" by which a profile is first assumed and then investigated in regard to the conditions of stability previously given. It is then adjusted and again tested until it results in a satisfactory section. It is customary to start at the top and design the dam progressively towards the base.

A series of imaginary horizontal joints are arbitrarily assumed. When the dam has been tested for stability at the highest joint and has been properly designed to conform to the conditions of stability, the section of the dam is fixed and is not influenced by the design of the lower part of the dam. The section above the next lower joint is then tested and adjusted by changing the slope of the up- or down-stream faces or both between that and the next joint. The section to this joint is then fixed and other joints treated in the same manner. This method of design applies to all types of gravity dams. See section below on *Forces Acting on Dams.*

**Hollow Concrete Dams.** — A hollow concrete dam consists of an inclined wall of reinforced slabs or arches resting on a series of parallel buttresses

Fig. 4. Typical Hollow Gravity Spillway Section

which have their footings on the foundations. Fig. 4 shows a section of such a dam designed for a spillway. With a low dam and rock foundation, the downstream decking or apron may be omitted and the face made vertical.

Stability against overturning and sliding is obtained by providing a considerable batter to the upstream face, thereby obtaining a large vertical component of head water pressure to add to the weight of the structure.

**Arched Concrete Dams.** — A typical arch dam is indicated in Fig. 5. A dam of this type consists of a single masonry arch spanning the valley and is suitable for narrow sites having steep rocky sides.

Arched dams are usually treated as sections of simple cylinders and the thickness at any elevation determined by the equation

$$t = \frac{pr}{s}$$

where  $t$  = the required thickness in feet,  
 $p$  = the horizontal load on the dam in pounds per square foot,  
 $r$  = the radius of the dam in feet,  
 $s$  = the allowed unit stress in pounds per square foot.

As the arch is fixed at the base and at each end, the actual stresses are increased by expansion and contraction due to changes in temperature and mois-

Fig. 5. Typical Arch Dam

contents, contraction due to setting of the concrete and the application of loading, variations in span and radius at different elevations and other considerations. Theoretical analysis of these influences are considered by most engineers to be impractical and allowances for deviation of stress from that indicated by the foregoing equation is made in the adoption of low working stresses. These stresses should not exceed  $\frac{1}{4}$  to  $\frac{1}{2}$  the ultimate stress of the masonry or for about 30,000 to 40,000 pounds per square foot.

**FORCES ACTING ON DAMS.**—The forces usually considered in the design of dams are water pressure, earth or silt pressure, ice pressure, weight of the dam and the reaction of the foundation. One linear foot is usually considered in the design of solid dams and the distance center to center of buttress in hollow dams.

**Water Pressure.**—The weight of water per cubic foot is usually taken equal to 62.5 pounds.

It facilitates computations if the horizontal and vertical components of water pressure are considered separately instead of the resultant pressure.

When the water surface is at or above the top of the dam, the total horizontal pressure, in pounds is,

$$P = 62.5 \frac{(h_2^2 - h_1^2)l}{2},$$

where  $h_2$  and  $h_1$  are the vertical distances in feet of the bottom and the top of the dam respectively below water surface, and  $l$  is the length in feet of dam considered in the design. The location of the resultant horizontal pressure above the base of the dam is

$$x = \frac{3h_1h + h^2}{6h_1 + 3h},$$

where  $h$  is the height of the dam.

the water surface is below the top of the dam, the total horizontal pressure is

$$P = 62.5 \frac{h_1^2}{2},$$

where  $h_1$  is the depth of water in feet. The location of the resultant above the heel of the dam is

$$x = \frac{h_1}{3}.$$

On the vertical faces the vertical component of water pressure is zero; but for inclined faces the vertical component is the actual weight of water  $ABCD$  (Fig. 2), directly above the face. The resultant vertical water pressure passes through the center of gravity of  $ABCD$ .

The uplift pressure per square foot of the base of solid dams, due to water seeping through the dam, is,

$$p = 62.5 ch_0,$$

where  $c$  is the percentage of the area assumed to be subjected to uplift. The value of  $c$  is considered to vary uniformly from headwater pressure at the heel to tailwater pressure at the toe. The value of  $c$  cannot be unity unless the dam is on earth foundations. For rock it has been assumed variously from zero to 50% according to the nature of the foundation.

The resultant uplift pressure is,

$$P = 62.5cd \frac{H' + H''}{2},$$

where  $H'$  and  $H''$  are head and tail water pressures respectively,  $d$  is the width of the dam at the length of the base.

The distance of the resultant uplift pressure from the heel of the dam is,

$$x = \frac{2H' + H''}{3(H' + H'')} d.$$

It is also considered as existing in any horizontal building joint as well as at the base. Drains are sometimes placed in dams to reduce possible head water uplift pressure. Head water uplift pressure is never considered to exist to an appreciable extent in hollow dams. Uplift from tail water is always present.

**Earth Pressure.** — Submerged earth or silt deposited against dams exerts a pressure on the structure in addition to the water pressure. The amount and location of this pressure can be determined by the ordinary methods for retaining walls if the weight and angle of repose when submerged are used. An approximate method for determining silt pressure is to assume it a liquid weighing 5 pounds. It will then exert a pressure equivalent to additional water pressure of the same depth.

**Ice Pressure.** — Much uncertainty exists in the determination of ice pressure on dams. Pressures amounting to 47,000 pounds per lineal foot of dam have been used in the design of important dams in cold climates. The configuration of the gorge above the dam has considerable influence on the possible thrust. The reader is referred to the late C. L. Harrison's paper on this subject (see *Bibliography*).

**Weight of the Dam.** — The weight of masonry varies from 130 to 165 pounds per cubic foot. The weight most commonly adopted for concrete is 140 to 150 pounds per cubic foot.

**Reaction of the Foundation.** — The resultant of all forces acting on dam, including the weight of the dam, must be balanced by an equal and opposite reaction of the foundation.

**Requirements for Stability.** — A dam may fail by sliding, by overturning or by crushing of the materials in the dam or the foundations. This may occur at the base or at any horizontal plane above the base. Sliding has been known to occur on clay-filled seams below the base after the foundation near the dam has become eroded by the flowing water. A dam must therefore be investigated for stability at various elevations, considering for each elevation those forces acting above it as though the base of the dam or a horizontal joint actually existed at that elevation. The following are the fundamental conditions for the design of gravity dams.

(a) At any elevation the resistance to sliding shall be greater than the horizontal component of all forces acting on the dam above that elevation. A division of the dam at any horizontal joint or at the base is not considered except as an additional factor of safety. The angle that the resultant of all forces makes with a vertical line must therefore not exceed the angle of repose of mass on masonry or masonry on the material composing the foundation, as indicated by laboratory tests of smooth specimens. The natural or artificial roughness of rock foundations and projecting plums in horizontal joints provide the necessary margin of safety. For dams on good rock the tangent of the angle of inclination of the resultant force with the vertical should not exceed 0.75. For dams on earth foundations the tangent should not exceed 0.1 to 0.2, depending on the materials, or the dam should be well anchored to deep cut-off walls or piling.

(b) To prevent overturning, the resultant of all forces above any joint must pass inside the extremity of the joint. To provide a margin of safety against the existence of tension the resultant must intersect the joint at a distance from the extremity equal to at least one-third the width of the joint. In other words, the resultant must fall within the "middle third" of the joint, and this applies to the condition of full or empty reservoirs, as tension is always objectionable. It can be shown that, if the resultant falls within either outside of the joint, tension will exist at the opposite side of the dam.

(c) The compressive stresses in any part of the dam must not exceed working values. The unit stress on any joint is assumed to vary as a straight line from the heel to the toe. If the resultant force intersects the joint at its exact center, the unit stress will be uniform over the joint. If the resultant intersects at any other point, the stress will be a maximum at the edge of the base nearest the point of intersection and a minimum at the other end.

In Fig. 2, let

$p'$  = the unit vertical stress at  $E$ ;

$p''$  = the unit vertical stress at  $D$ ;

$x$  = the distance from the resultant to point  $E$ ;

$d$  = the width,  $DE$ , of the joint;

$l$  = the breadth of the joint;

$w$  = the vertical component of all forces on the dam above the joint including uplift at the joint;

$p'_0$  = the unit uplift at point  $E$ ;

$p''_0$  = the unit uplift at point  $D$ .

Let these quantities be expressed in feet or pounds per square foot. Then, if the resultant intersects the joint within the middle third and the joint is rectangular,

$$p' = \frac{2w}{ld} \left( 2 - \frac{3x}{d} \right) + p_1'$$

$$p'' = \frac{2w}{ld} \left( \frac{3x}{d} - 1 \right) + p_1''$$

the maximum *inclined* stress in the dam may be twice the value given by equations for *vertical* stresses. Therefore due allowance must be made in selection of working *vertical* stresses or the maximum *inclined* stresses found by extended calculations.

critical pressures should not exceed  $\frac{1}{2}$  of the ultimate strength of the masonry, or about 16,000 to 22,000 pounds per square foot.

**APPENDAGES TO DAMS.** — The more common appendages to dams are the following:

**Slide Gates.** — As their name implies, these are large gates placed in the spillway for the control of the water level, or for relieving the dam in times of flood. The common type of gate is the so-called Tainter gate, which is slightly curved and revolves about its axis of curvature. A later improvement on this is the *square*, which permits of finer regulation.

**Flap Boards.** — These are light boards, or their equivalent, placed on the spillway and held in position by light rods or frames. Their object is to temporarily increase the height of the dam during the dry season so as to save the water which would otherwise be wasted over the spillway at times when the wheels were not running. They are made light not only to facilitate raising, but also that they may give way quickly in emergency before a dangerous head could be created by sudden flood.

**Log Rans.** — On any stream where the driving of logs is practiced, it is generally a requirement that provision be made in a dam for the sluicing of logs. This is accomplished by a chute or trough placed generally near the spillway, with its upper end slightly below the pond level and closed by a sluice gate. In this the logs are guided by log booms fastened to the dam and cribs along the shore.

**Fish-ways.** — A fish-way is a gradual incline connecting the water below the dam with the pond above. A constant stream of water passes through it with a velocity against which the fish may readily swim. This is sometimes aided by using baffles across a portion of the stream, leaving a passageway on the side. The slope of a fish-way should not be greater than 1 in 4 and its bottom should be well beneath low water level. Fish-ways are generally more or less covered in order to protect the fish from interference, but should never be left dark, as they would not be used by the fish. Fish-ways are generally required by State law on all natural water ways.

**COST OF DAMS (Pre-war figures).** — It is difficult to give items of cost for dam construction, due to the great influence of local conditions. As earth bankments should not be attempted in places where material is not available at the site, the figures for unit cost may be fairly well approximated. Excavation in earth will cost from 20 to 30 cents per cubic yard; embankment 25 to 30 cents; puddle cores 45 to 70 cents; hand-laid paving \$2.00 to \$3.00; rip-rap 30 to \$2.00; sodding 20 to 30 cents per square yard. Figures for masonry will depend largely on the ease with which the materials may be brought to the site. The following figures serve to show approximately the unit costs under conditions normally favorable. Rock excavation \$1.00 to \$2.00; rubble

masonry laid in natural cement \$3.00 to \$5.00; same laid in Portland ce  
\$4.00 to \$6.00; concrete masonry, Portland cement, \$5.00 to \$7.00; reinfo  
concrete \$7.00 to \$11.00; rock-faced stone masonry \$10.00 to \$15.00; dimen  
stone masonry \$15.00 upward.

**BIBLIOGRAPHY.** — Some of the more important books treating of d  
are the following: Creager, *Engineering for Masonry Dams*; Smith, *Const  
tion of Masonry Dams*; Wegmann, *Design and Construction of Dams*; Morr

**DEMAND METERS.** — (See also *Ammeters; Ampere-hour Meters; Hour Meters; Watthour Meters.*) For some time past various attempts have been made to inaugurate systems of charging for electric energy which would be more equitable to both the consumer and the central station than a flat kilowatt or kilowatt-hour rate. The so-called "maximum demand system" has found favor with many, and may find a much more general application.

The system is based on the fundamental assumption that the charge to the consumer should be made up of two parts; one part fixed by the maximum power in watts demanded by the consumer at any time during a certain definite period, and another part fixed by the total energy in kilowatt-hours used during the same period. The object of the demand system of charging is the improvement of the load factor of the station and the more equitable distribution of fixed charges among its customers.

Demand metering cannot be regarded as an exact science, because of the large number of variables involved and the various ways in which they enter into the problem. These include the capacity of generators, lines and transformers, and the diversity factor, load factor, and power factor of the system. No practical meter can be devised to take care of all these variables, consequently charging based on the use of demand meters in addition to the usual energy meters must necessarily be somewhat arbitrary.

**Requirements of a Demand Meter.** — The kilowatt-hours supplied to the consumer are readily measured by a watthour meter (q.v.); to record the maximum power (kilowatts) taken by the consumer, various forms of "maximum demand meters," usually called simply "demand meters," have been devised. In the case of a practically constant d-c. voltage at the consumer's premises a device which measures the maximum current is as satisfactory as one which measures maximum power, but when the voltage or power factor (in case of a-c. system) varies, the maximum current indicator is not suitable.

In any case the device should be one in which the demand measured is the instantaneous peak of the load demanded by the consumer, but is the average of the power demanded over an appreciable time interval, for the maximum demand recorded should not be influenced by short-circuits, excessive current flow in starting motors, or by any abnormal consumption of energy that covers too short a time to have any real effect on the capacity which must be provided by the central station to take care of the demand.

The time interval over which the demand should be taken should theoretically differ with the character of the installation and the relation of the maximum power demanded to the maximum capacity of the central station. In relative large consumers' installations the time should be carefully chosen with reference to the time that the central station can endure an overload successfully. Hydroelectric plants have a very definite power limit which is reached with maximum gate opening, while steam-power plants have considerable thermal inertia and their boilers and generating apparatus can usually carry relative large overloads for a considerable time. These considerations require much shorter time intervals for large users of hydroelectric power than would be necessary in steam plants of corresponding magnitude.

Demand intervals of 15 minutes, 30 minutes, and 1 hour are those in general use at the present time. For very special installations, intervals as short as 1 minute and as long as 3 hours have been used. The general tendency is toward the use of a single interval for a given system, and toward the use of intervals larger than those formerly used.

On account of the desirability of improving the load factor, the offer of a system has been developed, which gives a preferential rate to customers using

current during the times of low load on the central station. Demand meters of time of day as well as demand are used for this class of metering.

The general subject of demand meters has received considerable attention in the past five years and many devices have been developed and placed on the market. The whole question of charging for electric service, including the necessary devices to be used, is still in a transition state, and is complicated by the inclusion of the power factor and balance of the customer's load as elements in determining the cost of supply.

**Classification of Demand Meters.** — Demand meters may be classified (1) as curve-drawing instruments, giving the load-time curve of the installation; (2) as integrated-demand meters, consisting of an integrating meter combined with a device which registers the energy consumption from time to time in such a way as to indicate or record the maximum demand; (3) as lagged-demand meters, which require a certain time interval for the indication to reach the value corresponding to the load. Under each of these types there are a number of other distinctions, such as length of demand interval, whether the demand intervals begin at specified times of the day or may be so chosen as to include the maximum average load during any time interval of the given length, and whether the maximum demand is simply indicated without reference to time or is recorded so that the time of its occurrence may be determined. Some of the types of demand meters in commercial use are briefly described below.

**Curve-drawing Instruments as Demand Indicators.** — (See also *Wattmeter*.) The most complete knowledge of the conditions attending the consumer's use of energy may theoretically be obtained by using a curve-drawing wattmeter, with which the average demand for any time interval may be found and also the time at which it occurred. This statement, however, requires considerable modification in practice. Unless the paper speed is fairly high, the lines will run together so as to make it difficult or impossible to determine the demand with any approach to accuracy. Curve-drawing wattmeters are expensive in first cost for any but comparatively large installations, and the simpler and cheaper devices described below is ordinarily used. The distinctions of a curve-drawing wattmeter are difficult of comprehension for the ordinary customer who knows nothing of integration. Such wattmeters are largely by central stations to accumulate demand data. Curve-drawing meters may be used on the assumption of constant voltage and power factor, but do not give as accurate information as wattmeters.

**Integrated-Demand Meters Indicating Maximum Demand Only.** — The Type M-4 demand meter of the General Electric Company consists essentially of a demand-registering and a timing mechanism mechanically connected and mounted within the same case. The demand-registering element is electrically operated by means of a contact in the register of the watthour meter in connection with which the demand meter is used. The registering element consists of a train of gears which drive a demand pointer forward over a dial. This dial is actuated by a ratchet and pawl mechanism operated by an electromagnet which receives an impulse every time a certain amount of energy is registered by the watthour meter. The speed of advance of this pointer is therefore proportional to the power. In order that the meter may show the demand for any given time interval, it is necessary that the pointer-driving mechanism shall reset to zero position at the end of each time interval, leaving the pointer itself in the highest position reached. This resetting is accomplished by a mechanism controlled by a constant-speed motor similar in construction and operation to the motor element of an induction watthour meter. This demand meter is for use on a-c. circuits, and is arranged for intervals of 15, 30, or 60 minutes. The Type M-5 demand meter for d-c. circuits is similar to the pre-

ceding, but has an 8-day keywind clock to give the time interval. The M-6 demand meter differs from the M-5 in having a small d-c. motor to keep the clock movement wound. The latest development of this series is the M-7 demand meter register, Fig. 1. This replaces the standard register of either

Fig. 1. Type M-7 Demand Meter Register.

I-14 or D-6 watthour meter. In addition to the usual four kilowatt-hour dials, it contains a demand dial. The principle of operation is the same as that of the other demand meters of the Type M series, but the timing device is a small disk-type constant speed induction motor built into the register. In the M-7 the demand registering mechanism is thus mechanically connected to the watthour meter, instead of electrically as in the preceding Type M demand meters. When new I-14 or D-6 watthour meters are supplied with this form of demand register they are called respectively Type IM-14 or DM-6 watthour demand meters.

The Type RO watthour demand meter of the Westinghouse Company is a combination of induction watthour meter, induction wattmeter, and an escapement mechanism. The auxiliary disk of the wattmeter is located in the same air gap as the watthour meter disk, and tends to move against the torque of a spring. This tendency is checked by an escapement controlled by the rotation of the watthour meter disk. The auxiliary disk thus advances step by step at a speed proportional to the load until the driving torque is equal to the spring torque. Starting from zero, the time required to reach equilibrium on a constant load is a constant, since the deflection and the rate of deflection vary in direct proportion. The auxiliary disk drives a demand pointer through a dial and a ratchet holds it in the highest point reached, until released by hand. A second ratchet allows the auxiliary disk to fall back to the position of equilibrium with the spring tension whenever the load drops, but prevents it from advancing except as controlled by the escapement.

**Integrated-Demand Meters With Arbitrary Time Interval, Recording all Demands and Time of Occurrence.** — The earliest instrument of this

was the printometer, later made by the General Electric Company as the Type P demand meter. This instrument is designed to print on a paper tape regular time intervals the time of record and the consumption of energy up to that time, the energy consumption being that registered by a watt-hour meter connected to the circuit. The instrument contains a set of cyclometer wheels which are moved forward at a rate proportional to the rate of energy consumption in the circuit. This is accomplished by a solenoid, the energizing circuit of which is closed through a contact wheel fixed to one of the spindles of the gear train of the watt-hour meter. The reading of the cyclometer is printed on paper tape (see Fig. 2) by a rubber platen and a copying ribbon, the rubber platen being actuated by a solenoid which is energized at regular time intervals by means of a contact making clock. The time is also printed opposite each

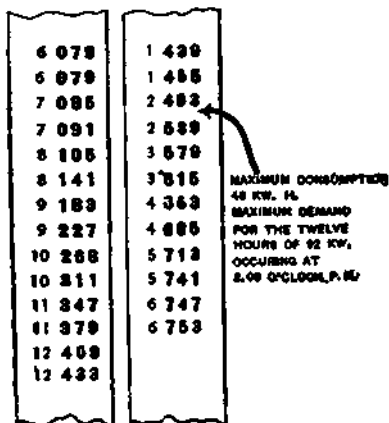

Fig. 2. Record Made by Type P Demand Meter.

meter reading. Thus, the difference between consecutive records on the tape is proportional to the energy consumption in watt hours in the circuit during a definite time interval. The average demand over a period of time, depending to the interval between successive operations of the printing mechanism, is obtained by dividing the watt-hours of energy consumption during the interval by the length of the interval.

The Type RA recording-demand watt-hour meter of the Westinghouse Company consists of a polyphase watt-hour meter combined with a mechanism for making a permanent graphic record of the integrated demand over successive determined time intervals. The total energy consumption is shown in the usual way by the register of the watt-hour meter. The time interval is controlled by a clock which requires winding once a month. A separate spring mechanism advances the record paper. The pen is moved across the paper by the gear train of the watt-hour meter, and at the end of each time interval a ratchet mechanism frees it from the gear train and allows a weight to move it back to zero where it is again meshed with the gear train to repeat its advance during the next time interval. Just before the release occurs, the record paper is advanced slightly (see Fig. 3) so that the pen makes a distinct record of the maximum travel, which is a measure of the integrated demand. The time of

occurrence is shown by the time figures printed on the paper. This meter is made with time intervals of 15, 30, or 60 minutes. It is a self-contained instrument, with the metering and demand-recording mechanisms mechanically connected.

The Piek demand instrument, which was the forerunner of the Type G demand meter, is very similar to the latter, but uses the same clock to establish the time intervals and to drive the chart.

The Type G demand meter of the General Electric Company is used in connection with a watthour meter, and gives a graphic record on a circular chart of the demands integrated over definite time intervals, with the time of occurrence and day of week of their occurrence. It consists essentially of a registering element and a timing element. The registering element is electrically connected

Fig. 3. Record Made by Type RA Recording Demand Watthour Meter.

to the watthour meter, which has a contact device on one of the spindles of the register. This contact device alternately makes and breaks the circuit of a solenoid in the registering element each time that a definite amount of energy is registered by the watthour meter. An armature operates a ratchet and pawl mechanism to advance the stylus by a small step for each operation of the contacts. At the end of each time interval a cam mechanism operated by the timing device allows the stylus to return to the zero position, where it is re-engaged ready to integrate the energy used in the following interval. The timing mechanism rotates the chart continuously, giving a record in the form of a saw-tooth polar curve. The chart gives a record for one week. The time interval is either 15, 30, or 60 minutes.

**Integrated-Demand Meters Recording Time and Equal Amount of Energy, Non-Arbitrary Time Interval.**—The Ingalls demand recorder is operated in connection with a watthour meter. It contains a clock which uniformly advances a tape upon which a mark is made by a printing solenoid energized through contact in the meter register. Each mark corresponds to a predetermined amount of energy. The number of marks in a given time interval is proportional to the average power.

**Thermal-Storage Lagged-Demand Meters.**—These meters indicate not only the maximum demand only, and the indication depends on the duration of the load as related to the "demand interval" of the meter, as well as on the previous history of the load. The demand interval of this type of meter is usually taken as the time required for the indication to reach 90 per cent of the full value of a steady load which is thrown suddenly on it. In principle, all such meters are differential thermometers.

The Wright demand indicator, manufactured by the General Electric Company, is a differential air thermometer having one of the bulbs surrounded by a heating element. The expansion of the air in this bulb drives a liquid over into a graduated tube, giving a measure of the ampere demand. It is suitable for use in constant-voltage circuits, either direct current or alternating current, and is independent of power factor. It leaves no record of the duration of the maximum demand and nor of the time at which it takes place. After the indicator has been used there is no original record of previous maximum demands.

The Type H-2 demand indicator of the General Electric Company is an ampere-demand instrument also based on the differential thermometer principle, but using a pair of strips of thermo-plastic metal. One of these is in proximity to a heating element traversed by the load current, while the other normally follows the room temperature. The two strips tend to move in opposite directions, and with no current flowing through the heating device the pointer remains at zero in spite of changes in room temperature. Current flowing through the heating device heats the adjoining strip and moves the pointer up the scale. The pointer remains at the highest point reached until manually reset.

The Westinghouse Type RH demand meter employs the principle of the hot-wattmeter, and thus takes account of watt demand. It contains two heating elements which tend to move a demand pointer in opposite directions. The electrical arrangements are such that the difference in the heating is proportional to the power in the circuit, and the thermal capacity of the heating elements makes the reading depend also upon the storage of heat in them. The demand pointer remains at the highest point reached until manually reset.

**Overdamped-Wattmeter Lagged-Demand Meter.** — The Type W polyphase demand indicator of the General Electric Company consists essentially of a polyphase watt-hour meter with a system of springs opposing the rotation of the disk and thus converting it into a polyphase wattmeter. A large number of latching magnets are used, giving heavy overdamping and preventing the meter from recording demands of short duration. The rotation of the disk against the opposing springs moves a demand pointer forward, and this pointer remains at the highest point until manually reset. This type of demand meter is not so much used.

**Demand Devices Taking Account of Power Factor.** — The increasing realization of the effect of low power factor on the cost of energy supply is leading to show in the development of demand devices taking power factor into account. For example, the Westinghouse Company has made an instrument consisting of two Type RA watt-hour demand meters in one case with their charts interlocked and driven by the same clock. One of these meters is selected to record power demand and the other records reactive-component demand. The same object is also attained by the General Electric Co. with Type P demand meter used in connection with a watt-hour meter and a five volt-ampere-hour meter.

**COSTS.** — The following figures are approximate and are intended as a rough guide.

Type	Description	P
Integrated-Demand Meters, maximum demand only:		
Types M-4 and M-5 . . . . .	15, 30, or 60 min. interval. . . . .	\$22 t
Type M-6. . . . .		
Type M-7 Demand Meter Register. . . . .		17 t
Type IM-14. . . . .	2-wire or 3-wire single-phase. . . . .	25 t
Type DM-6. . . . .	3-wire polyphase. . . . .	49 t
Type RO. . . . .	2-wire or 3-wire single-phase. . . . .	29 t
Type RO. . . . .	3-wire polyphase. . . . .	57 t
Integrated-Demand Meters, all demands and time:		
Types P-2 and PS-2. . . . .		118
Type RA (Polyphase). . . . .	15, 30, or 60 min. interval. . . . .	115 t
Type G-2. . . . .	15, 30, or 60 min. interval. . . . .	65
Logged-Demand Meters:		
Type H-2 Demand Indi- cator. . . . .	Maximum amperes 2 to 25. . . . .	6
Type RH Demand Meter. . . . .	5 to 50 amps., 110 volts; used with instrument transform- ers for higher capacities. . . . .	22 t

This section is given in the 1920 Report of the Committee on Meters of the National Electric Light Association.

**DEPRECIATION.** — Depreciation is loss of value due to expiration of usefulness. It is brought about by wear and tear and the action of the elements which eventually make replacement necessary. *Service value or serviceability* may or may not suffer diminution as depreciation accrues. Depreciation does not properly include loss of value due to accidental damage, to obsolescence, inadequacy or to price changes. Replacements due to accidents such as may be covered by insurance. If not, they should be charged directly to expense or amortized over a reasonable period. Replacements due to obsolescence or inadequacy should be financed from the savings resulting from the purchase of the more modern or adequate equipment. As for market or price changes, it is impossible to show property on the books at its value under constantly changing prices. The accounting problem involved in making replacements at changed price levels is discussed below. Depreciation as specifically defined is accrued liability to replace and it involves four problems which may be described as follows:

- First, *physical*, to determine the amount of the liability at any time and the rate of its accrual.
- Second, *financial*, to make provision for meeting the liability.
- Third, *accounting*, to keep the proper records.
- Fourth, *management or regulation*, to determine the effect of the accrued and accruing liability on the economic position of the enterprise whose assets are under consideration.

**THE PHYSICAL ASPECT.** — A piece of property whose useful life has expired has suffered depreciation to the extent of the difference between its value when new and its scrap value. This difference is called the wearing value. Various assumptions may be made as to the distribution of the depreciation over the life of the property, but the usual practice is to assume it uniform. If the annual depreciation is equal to the wearing value divided by the useful life. The accrued depreciation at any time is equal to the product of the annual depreciation and the age in years.

For the extent and rate of depreciation must be known while the property is in service, if proper provision is to be made for replacement, the life used in determining the annual depreciation must be a prediction. Such a prediction can be made only on the basis of experience, and is a subject for the best engineering judgment, since many factors, such as severity of use, quality of material and of workmanship, and climatic conditions, must be considered. Tables of lives of various classes of property have been prepared, but should be used with discretion, since they are unreliable, for the following reasons among others. First, many of the renewals considered by the compilers to be due to obsolescence were due to obsolescence or inadequacy. Second, improvements in the arts are continually increasing the durability of many classes of equipment. Third, replacements are at times postponed past the time when true engineering would dictate replacement because of the financial situation of the engineering company, and as a result, the experience recorded becomes an unreliable guide. In the bibliography appended reference is made to tables of lives which may be used as a guide to judgment.

Frequently it is desired to create a reserve which will provide for replacing property made up of parts having different lives whose independent replace-

The term "depreciation" has through use by courts and regulatory commissions come to have the specific and somewhat narrow construction defined above. In general usage, the word "depreciation" denotes decrease in value from any cause, but in this sense is here confined to the more technical use of the term.

ments are to be charged to depreciation, and it is desired to place a full piece of property as a whole. This is properly done by dividing the sum of the wearing values of the parts by the sum of their annual depreciations, the result being the composite life. The weighted average life of the parts, the weights being the wearing values of the respective parts, cannot be used as the composite life defined above. To be correct, the average life must be further weighted by the relative frequencies of renewal of the respective parts. The test of a composite life is that the wearing value of the property divided by the composite life shall, when divided by it, give the annual depreciation for the property. This the first method assures, but the second does not.

The scrap, or salvage value of a piece of property is a subject for exact estimate. The expense involved in preparing for market and marketing the scrap is a deduction from the scrap value but the cost of removing the scrap to be replaced is a charge to operation.

In certain types of property, life can better be measured in service units than in time units. However, in the case of a large and varied property, time of general application, forms the most satisfactory basis for computing depreciation.

As the operation of a property continues, the engineers responsible for determining depreciation must constantly check up and revise their opinions on the lives of various units, basing their conclusions on the frequency of renewal due to depreciation, as proved in practice. The rate of accrual of depreciation should be refigured from time to time on the basis of these studies. At the time an estimate should be made of the depreciation accrued on the property, making this estimate it must be understood that accrued depreciation or replacement liability to replace is a physical fact, independent of the assets accrued on the balance sheet, and the estimate must be a conservative and tentative statement of that physical fact, as nearly as it can be determined.

**THE FINANCIAL ASPECT.**—As depreciation and the corresponding replacement liability accrues, it is necessary to build up assets to offset this end a portion of the revenue derived from the operation of the property should be retained by the corporation for that purpose. Building up assets to offset the depreciation liability gives assurance that the property will be maintained in its full usefulness and earning power in so far as these are governed by its physical condition. In public utility mortgages, it is frequently provided that a certain percentage of the gross operating revenue shall be expended and reserved for the maintenance of the property. Such provisions have been thought to be particularly necessary where, (a) operation cannot be discontinued, (b) property cannot be removed to another location, (c) scrap or recovery of physical property is so small a proportion of original cost as to be of no importance to the creditor. These reasons, while controlling with the creditor, do not prove the value of this method of measuring maintenance and depreciation requirements.

Building up assets offsetting accruing replacement liability serves to maintain the equity of the stockholders as well as to protect the physical condition and the earning power of the creditor's security. If the funds required for care of replacement are paid out in dividends a partial liquidation takes place which may or may not be sound business, but in any event the fact should be clearly understood by all concerned, and clearly reflected by the books of the corporation.

In the case of a property made up of many parts having different lives, after the initial construction, will all parts be new at once. The assets reserved to offset depreciation will never all be needed for replacement. From this it may be argued that it is necessary to reserve enough funds to meet such abnormal amounts of replacement expenditure.

sionally occur. Under this plan no distinction would be made between maintenance and depreciation, so much each month being set aside out of net income, the amount being revised from time to time as found necessary, and all maintenance of the property paid out of the reserve. If this plan is followed it must be recognized that the company's assets have been allowed to decrease until the depreciated value of the property, plus the reserve, is less than its actual cost. This consideration is particularly pertinent in the case of a regulated utility.

In reserving funds for effecting replacement due to depreciation various methods are used for determining the amount to be periodically set aside. Sometimes it is made a fixed percentage of the gross receipts. Sometimes it is a uniform amount arbitrarily fixed. These methods have only simplicity to commend them. The correct system is to make the reservations in accordance with the accrual of depreciation as determined by the engineers. Two devices have been generally used. One is the straight line method in which the set-up for each piece of property is equal to the wearing value of that piece of property divided by its life. The other is the sinking-fund method in which the set-up for each piece of property is of such amount that, when the piece of property has reached the end of its life, the sum of the set-ups made on its life shall, with the compound interest accumulated on those set-ups, equal the wearing value. In the second case the reserve fund must be credited periodically with interest upon accumulated balances at the rate used in computing the set-ups. This interest may be charged either against income or surplus. The latter method is well adapted to the case of regulated utilities, as will be noted later.

The assets set aside or retained to offset depreciation may be handled in various ways. Specific assets, such as bank deposits and interest-bearing securities may be designated as a depreciation reserve fund, and kept equal to the depreciation liability as shown on the books, or the offsetting assets may be allowed to remain a part of the general assets and used in the business. The latter method is usually preferred, since a going concern can, as a general thing, get a larger return from capital used in the business than in that invested aside. However, care must be exercised that there is always a sufficiency of liquid assets to meet any sudden demand. In theory, when expected replacements become necessary, they may be financed by borrowing money on the security of the property in which the reserve against depreciation has been accumulated. This, however, is not generally practicable due to the provisions of rate laws.

**The Accounting Aspect.**—It is highly important that the accounting treatment of depreciation reflect accurately both the lessening of remaining life of physical plant and the financial plan by which provision is being made for replacement. The accounting processes involved are primarily: (a) Current charges to depreciation reserve either by charges to income or appropriation of surplus.\* (b) The crediting of interest to the reserve where current reservations are calculated on the sinking fund basis. (c) The segregation of assets against depreciation reserve liability or funding. (d) The auditing of charges against the reserve for the purpose of determining their propriety in the light of the basis on which the set-ups to the reserve have been made.

There is not always a clear distinction between maintenance charges to be included in current operating expenses, and replacement charges to be made

\*In the case of a company which has not from the beginning made provision for replacement of physical property, and in which considerable depreciation has already accrued, the initial charge in establishing such a reserve, if it is to cover depreciation need, must be against surplus.

against the reserve. The final test must always be whether or not the has been built up from credits calculated to cover charges such as the question. In a business where assets are progressively exhausted, as in of a mine, the reserve account may be dispensed with by making the depreciation credits direct to property. This practice is not proper in the case of a corporation enterprise.

Expenditures which serve to increase the investment in a property chargeable to construction. When a piece of property is replaced by another which by reason of greater size, superior quality, or higher price level costs more than the original piece, the procedure is as follows, assuming that an equal amount to the wearing value of the original property has been accrued in the depreciation reserve. The amount realized from scrap or salvage is credited to the depreciation reserve to bring the amount in the reserve up to the full cost of the item to be replaced. The original cost is then written out of the property and plant account and depreciation reserve concurrently reduced. The excess of the cost of the replacing unit is then added to property and plant account, the result being to increase property and plant account by the excess cost of the new property. In case the new property costs less than the old, there will be a credit to property and plant. This is sound accounting, since the property account should represent the actual cost of the existing property at all times.

In case the piece of property is replaced for reasons other than depreciation, the depreciation accrued should be charged against the reserve, and the replacement of the cost of replacement cared for in other ways. For example, if a property estimated to last 30 years is accidentally destroyed at the end of 10 years, one-tenth of its cost will have been accumulated in the reserve. The balance of the cost at which the car is carried in the property account must either be approved from surplus, charged to operation, or set up as a suspense item, and amortized over an appropriate period. The latter method would be used ordinarily in cases where large amounts are involved. The proper division of charges in such cases involves engineering judgment.

Reference has been made to periodic engineering estimates of the depreciation accrued. These estimates should be used to check the balance of the

Fig. 1.

the depreciation reserve. If the reserve has been set up on the straight line basis and the accrued depreciation estimated on the same basis, the two should be in general agreement. If the reserve has been set up on the sinking fund basis, it should be somewhat smaller than the depreciation estimated to be accrued on the straight line basis since in the case of any given piece of property, the

his including interest will be more rapid in the latter part of its life than in earlier part. (See Fig. 1.) If the reserve is found to be too large or too small by a substantial amount, the amounts currently reserved should be reduced or increased with the object of bringing the balance in the reserve into line. Usual practice does not provide for accumulating an amount as a reserve in excess of original cost less salvage, therefore cost of removing unit to be replaced must be charged to operation.

The foregoing comments on the accounting aspects of depreciation further emphasize the engineering problems involved, rather than accounting procedure.

**The Management or Regulatory Aspect.**—In the case of property in unregulated competitive business, the value at any time is the cost at current prices of a property which can be used for the same purpose, less the accumulated depreciation, the latter being computed as the product of present cost less salvage, and the percentage of expired life. It is necessary to deduct the depreciation in order to obtain a measure of the service which can still be obtained from the property. It is necessary to know the rate of accrual of depreciation in order that the management may know whether or not the business is presently profitable and to know the accrued depreciation in order that the balance sheet may show the true condition of the property.

In the case of regulated utilities, frequently, though inaccurately, described as non-competitive, value is fixed by a regulatory body subject to judicial review. No final rule of general application has been enunciated, though various standards of value have been specified and defined. It is generally agreed, however, that, in any event, the rates allowed must provide for current operating expenses and reserve for depreciation, before they can provide for return on investment fixed. Since the function of the depreciation reserve is to provide for replacement at original cost, (increases or decreases in cost being cared for through capital account) "original cost," not "present value," is considered here. The depreciation reserve accumulates and is invested either in extensions to utility's plant, or independent thereof, it furnishes a source of income aside from that earned by the original property.

If the reserve has been set up on a straight line basis, the original cost of the property plus the assets which offset the reserve, less depreciation accrued, equals the original investment. If the offsetting assets are invested so as to earn a return equal to that allowed on utility property, it is fair to fix the earnings from utility operation so as to yield a return on the property at its regulated value, but if this is done the earnings of the reserve are a part of the corporate revenues and should go to the owners. But it is seldom possible to invest so advantageously and still fulfill the essential requirement of having assets readily available for financing replacements. If a return is allowed on the undepreciated cost of the property, then the income from the invested reserve should be considered part of that return and the balance collected in the reserve. If, however, the depreciation reserve is set up on a sinking fund basis, the earnings of the reserve are needed as a part of the reserve, and are not available as return. Then the company must be allowed in rates a return on the undepreciated cost of its property. As the income from the reserve appears as corporate income, the interest payments to the reserve should be made out of corporate income. Since normally a part of the reserve will be invested in utility property, and part in quick assets, the interest rate used in calculating the return to the reserve must be a compromise between the return allowed on utility property and that obtainable from quick assets.

In cases where the depreciation reserve is less than the accrued replacement cost, to the extent that returns to investors have been excessive, it may justly be considered that partial liquidation has occurred. Where returns

have not been excessive and rates have been insufficient to permit full reparation to cover replacement liability, equitable consideration must be given that fact.

**Calculations.** — The following notes are illustrative of the calculations necessary to determine the proper amounts to be currently reserved for the purpose of financing replacements.

- Let  $C$  = cost of property,  
 $S$  = scrap value,  
 $n$  = life in years,  
 $r$  = annual interest rate,  
 $A$  = annual reserve credit,  
 $M$  = monthly reserve credit.

Then, on the *straight-line* basis:

$$A = \frac{C - S}{n},$$

$$M = \frac{A}{12} = \frac{C - S}{12n}.$$

On the *sinking fund* basis:

Assume first that the reserve credit is made annually and interest is credited annually, then:

*Case I.*—If interest is allowed each year on that year's reserve credit, set-up made at beginning of year:

$$A = (C - S) \frac{r}{(1 + r)^{(n+1)} - (1 + r)}.$$

*Case II.*—If interest is not allowed each year on that year's reserve credit, set-up made at end of year:

$$A = (C - S) \frac{r}{(1 + r)^n - 1}.$$

Assume next that the reserve credit is made monthly and interest is credited monthly, then:

*Case III.*—If interest is allowed each month on that month's reserve credit, i.e., set-up made at beginning of month:

$$M = (C - S) \frac{\frac{r}{12}}{\left(1 + \frac{r}{12}\right)^{(12n+1)} - \left(1 + \frac{r}{12}\right)}.$$

*Case IV.*—If interest is not allowed each month on that month's reserve credit, i.e., set-up made at end of month:

$$M = (C - S) \frac{\frac{r}{12}}{\left(1 + \frac{r}{12}\right)^{12n} - 1}.$$

*Illustrative Example:* Cost of property \$1000. Net scrap value \$200. Life 10 years. Interest rate on depreciation reserve 4%.

On the *straight-line* basis:

$$A = \frac{1000 - 200}{10} = \$80,$$

$$M = \frac{80}{12} = \$6.67.$$

On the sinking fund basis:

Case I.

$$A = (1000 - 200) \frac{.04}{(1.04)^{11} - 1.04} = \$64.07.$$

Case II.

$$A = (1000 - 200) \frac{.04}{(1.04)^{10} - 1} = \$66.63.$$

Case III.

$$M = (1000 - 200) \frac{.00\frac{1}{2}}{(1.00\frac{1}{2})^{121} - 1.00\frac{1}{2}} = \$5.41.$$

Case IV.

$$M = (1000 - 200) \frac{.00\frac{1}{2}}{(1.00\frac{1}{2})^{120} - 1} = \$5.43.$$

In large enterprises it is the usual accounting practice to make credits to the reserve each month. It will be seen that the difference between the monthly reserve credits determined under Case III and Case IV are less, in proportion, than the probable error in the life assigned to the property.

**Composite Life.** — A piece of property is made up of two parts. The first part has a wearing value of \$2000 and lasts 20 years; the second part has a wearing value of \$1000 and lasts 10 years. Depreciation reserve is credited on the straight-line basis:

W. V.	Life	Annual Set-up
2,000	20	100
1,000	10	100
<hr/>		<hr/>
3,000		200

The composite life is 3000 divided by 200 = 15 years. If life is weighted by wearing value, it averages as follows:

W. V.	Life	Product
2,000	20	40,000
1,000	10	10,000
<hr/>		<hr/>
3,000		50,000

The weighted average is 50,000 ÷ 3000 = 16½ years. Dividing the wearing value by this gives 300 ÷ 16½ = \$180 for the annual reserve credit which is sufficient by \$20. If frequency of renewal is introduced we have the following:

W. V.	Relative Frequency of Renewal	Product	Life	Product
2,000	1	2,000	20	40,000
1,000	2	2,000	10	20,000
<hr/>		<hr/>		<hr/>
		4,000		60,000

The weighted average is 60,000 ÷ 4000 = 15 years, which is correct.

S., in M. Merriman's *American Engineers' Handbook*, p. 269 of 1920 Edition; Wyer, *Regulation, Valuation and Depreciation*, p. 243.

Numerous Commission decisions contain data on life of physical property, those most quoted being the decisions of the California and Wisconsin Rate Commissions.

**DERIVATIVES.** — (See also *Equations, Differential; Integrals; Maxima and Minima; Series, Mathematical*).

**Differentials.** — Let  $y$  be a function of  $x$ , i.e., a quantity which varies continuously with variations of  $x$ . If  $x$  be increased or decreased by the smallest amount conceivable,  $y$  will change by a correspondingly small amount. Such small variations are called "differentials," and are symbolized thus:  $dy$  and  $dx$ , or  $\delta$  is not a quantity but a symbol meaning "the smallest conceivable amount"  $\delta y$  or  $\delta x$ .

**Derivative or Differential Coefficient.** — The ratio  $\frac{dy}{dx}$  is the rate of change of  $y$  with regard to  $x$  and is called the "derivative" or "differential coefficient" of  $y$  with respect to  $x$ .

**Geometrical Meaning of a Derivative.** — If a curve be plotted between  $x$  and  $y$  for any equation  $y = f(x)$ , and a tangent drawn to the curve at any point, Fig. 1, then the tangent of the angle  $\theta$  between

tangent and the axis of  $x$  is equal to  $\frac{dy}{dx}$ .

**Differentiation.** — Differentiation is the process of finding the derivative of a function. If  $y = f(x)$

$$\begin{aligned}\frac{dy}{dx} &= \frac{df(x)}{dx} \\ &= \frac{f(x + dx) - f(x)}{dx}\end{aligned}$$

Fig. 1

**Example.** — If

$$\begin{aligned}y &= ax^2 \\ \frac{dy}{dx} &= \frac{a(x + dx)^2 - ax^2}{dx} \\ &= \frac{a dx (2x + dx)}{dx} \\ &= a (2x + dx).\end{aligned}$$

As  $dx$  is the smallest conceivable value of  $x$ , it is so small compared to  $x$  that it may, with the smallest conceivable error, be neglected. Hence,

$$\frac{dy}{dx} = 2ax.$$

**Formulas for Differentiation.** — ( $u, v, x$  and  $z$  are variables;  $a$  is a constant.)

$$\begin{aligned}\frac{d}{dx}(u + v) &= \frac{du}{dx} + \frac{dv}{dx} \\ \frac{d}{dx}(au) &= a \frac{du}{dx} \\ \frac{d}{dx}(uv) &= v \frac{du}{dx} + u \frac{dv}{dx} \\ \frac{d}{dx}\left(\frac{u}{v}\right) &= \frac{v \frac{du}{dx} - u \frac{dv}{dx}}{v^2}\end{aligned}$$

When  $x$  is itself a function of some other variable  $s$ ,

$$\frac{du}{dx} = \frac{du}{ds} \cdot \frac{ds}{dx}$$

TABLE OF DERIVATIVES

Function $f(x)$	Derivative $\frac{d}{dx}f(x)$	Function $f(x)$	Derivative $\frac{d}{dx}f(x)$
$x^n$	$nx^{n-1}$	$\tan^{-1} ax$	$\frac{a}{1+(ax)^2}$
$\sin ax$	$a \cos ax$	$\sinh^{-1} ax$	$\frac{a}{\sqrt{1+(ax)^2}}$
$\cos ax$	$-\frac{a}{1} \sin ax$	$\cosh^{-1} ax$	$\frac{a}{\sqrt{(ax)^2-1}}$
$\tan ax$	$\frac{a}{\cos^2 ax}$	$\tanh^{-1} ax$	$\frac{a}{1-(ax)^2}$
$\sinh ax$	$a \cosh ax$	$\log_a x$	$\frac{1}{x} \log_a e$
$\cosh ax$	$a \sinh ax$	$\log_e x$	$\frac{1}{x}$
$\tanh ax$	$\frac{a}{\cosh^2 ax}$	$\log_{10} x$	$\frac{0.434294481}{x}$
$\sin^{-1} ax$	$\frac{a}{\sqrt{1-(ax)^2}}$	$a^x$	$a^x \log_e a$
$\cos^{-1} ax$	$-\frac{a}{\sqrt{1-(ax)^2}}$	$e^x$	$e^x$

Note: See also Table of Integrals in article on *Integrals* noting that the column headed "Function" is the derivative of the column headed "Integral."

**Second Derivative.** — The derivative of a derivative, i.e.,  $\frac{d}{dx} \left( \frac{dy}{dx} \right)$ , is usually written  $\frac{d^2y}{dx^2}$ . Similarly  $\frac{d}{dx} \left( \frac{d^2y}{dx^2} \right)$  is called the third derivative and is written  $\frac{d^3y}{dx^3}$ , and so on.

**DISPATCHING OF TRAINS BY TELEPHONE.** — (See also articles *Telephony*.) Up to 1907 train dispatching was done almost entirely by the telegraph. In that year the telephone began to replace the telegraph for this purpose. At the beginning of 1920, 83 railroads in the United States, having 120,000 miles of line, had abandoned telegraphic train dispatching in favor of the telephonic method.

Telephone train dispatching has many advantages over the former method. The dispatcher's work consists in the main of gathering information and issuing orders for train movements. These operations are much quicker by the use of telephone and are no less accurate. Special training in the use of the apparatus is not as necessary as when telegraphy is employed. All the agencies are brought into closer personal relations, with the result that there is better cooperation and better discipline. The dispatcher can call and speak at the same time, which is impossible by telegraph.

It is now possible to operate dispatching lines as long and with as many stations as railway conditions may permit. The length of line and number of stations are not limited by the nature of the electrical equipment. Lines of 300 miles are now in operation, and 65 stations on one line are in successful use. More than 100 stations could be operated successfully if desired.

Dispatching circuits are multi-station lines, like the telegraph-dispatching circuits they displace. Broadly speaking, they are selective party lines, but are provided with systems of apparatus which allow the placing of many more stations on a line than is possible with any other party-line system so far developed. Several train-dispatching systems are on the market, the principal ones being known as the Gill System, the Western Electric System, the Cummings-Wray System, and the Kellogg System. These are in general similar in that the dispatcher has means of calling any station selectively. In some systems he can call several stations at once by setting keys for them in advance and operating a common calling key.

Each way station is equipped with a device called a selector. These selectors are operated only by the dispatcher. They work on the step-by-step principle and the whole object of the device is to close a contact at the station called and to ring a bell. No provision is made for cutting the way-station telephone line and off the line, as secrecy is not aimed at. Any way station may communicate with the dispatcher at will by lifting the telephone receiver. The dispatcher wears a head telephone constantly and so listens upon the line at all times.

Train orders are written as given and received and are read back to the dispatcher by each station, the dispatcher underscoring each word once for each correct repetition from a way station.

**BIBLIOGRAPHY.** — See Bibliography in article on *Telephone Instruments and Circuits*.

**DISTRIBUTION LINES.**—(See also *Conduits and Conduit Lines; Distribution and Transmission Systems; Transmission Lines; Wires and Cable Wiring of Buildings.*) Two types of construction are employed, overhead and underground. Overhead construction has the following advantages (1) lowest first cost, (2) easier to repair, (3) easier to change, (4) adaptability to high voltages; while underground construction has the advantages (5) less unsightliness (6) less dangerous to the public, (7) less subject to damage by external agencies. The majority of circuits in use are overhead. Underground circuits are principally used in the central portions of the larger cities. When underground circuits are used a large part of the construction consists of a composite of underground and overhead construction.

**MATERIALS FOR LINE CONSTRUCTION.**—The principal elements for wood-pole construction are the conducting wires, insulation on the wires, insulators, tie wires, pins, cross arms, cross-arm braces, bolts, poles, guy wires and guy anchors. For underground construction, see *Wires and Cables, Insulated and Conduits and Conduit Lines.*

**Wires for Overhead Construction.**—The conducting wires are usually of copper, sometimes of aluminum. Iron is not used as it costs more than copper for equal conductivity. Aluminum is used to a much less extent than copper; see articles on *Aluminum* and on *Copper*. Soft-annealed copper is usually employed for ordinary distribution work, as it has the greatest conductivity and is the easiest to work with. Medium hard-drawn and hard-drawn wires are used in lines where great mechanical strength is necessary.

For overhead city distribution copper wires ranging in size from No. 6 B. & S. (or A. W. G.) to 500,000 circular mils are used; see *Wires and Cables*. Sizes larger than No. 0000 B. & S. are usually stranded. Conductors as small as No. 14 B. & S. have been used for overhead work but are too small, as they are frequently broken by wind and sleet.

**Standard Sizes of Wire.**—Of the gage numbers between No. 6 B. & S. and 500,000 circular mils (see *Gages, Wire*), some are but little used because (1) the difference between consecutive sizes is less than is found necessary in usual practice and (2) the difference is too small to be readily detected by an ordinary lineman or stock keeper. In practice the number of sizes to be used and carried in stock has usually been reduced by omitting certain sizes: Nos. 1 and 2 are nearly always omitted; practice regarding the omission of larger sizes varies. The most commonly used are No. 6, 4, 2, 0, 0000 B & S. and 500,000 circular mils.

**Wires for Underground Lines.**—See *Wires and Cables, Insulated*.

**Covering on Overhead Wires.**—Overhead conductors for city distribution are covered with weatherproof braid. Two grades are recognized, "double braid" and "triple braid," according to the number of coverings, though the actual thicknesses are not the same for different makes. Double braid is considered suitable for use on voltages of 600 or less, and triple braid for voltages up to 2500 constant potential and on series-arc circuits of 600 voltages. To prevent the possibility of double-braid wire being used on voltages over 600 and to reduce the number of kinds of wire used, it is good practice to have all No. 0000 wires and smaller covered with triple braid. Ordinarily cables larger than No. 0000 are not used on voltages above 600 and may therefore be double braided.

**Object of Covering on Overhead Wires.**—The covering on overhead conductors is solely for the purpose of limiting the short-circuit current due to an accidental cross or grounding. The normal insulation of the line

intended by the insulators alone (see below); any reinforcement obtained in the insulation on the conductors is neglected in practice. While weathered braid is an imperfect insulator, it serves to eliminate the greater portion of the short-circuits and arcs which would occur, due to momentary contact, if bare wires were used. Rubber and other more perfect insulators are not used on account of expense and the impossibility of maintaining perfect insulation, on account of weakness, against mechanical injury and deterioration.

Bare wire is usually used on circuits operating at 10,000 volts and over to give a false sense of security. For voltages between 2500 and 10,000 volts, weatherproof wire is often used, though the protection afforded against short-circuits is doubtful.

**Extra Cost and Weight due to Weatherproof Braids.** — In estimating the cost of a distribution line, the additional weight and cost of the weatherproof braids should be taken into account. The following is a rough comparison between bare, double-braided and triple-braided copper wire, the cost being based on price at 15 cents per pound.

#### COMPARISON OF BARE AND WEATHERPROOF COPPER WIRES

Conductor	Relative weights			Relative Costs		
	Bare	Double braid	Triple Braid	Bare	Double Braid	Triple Braid
No. 6 B. & S., solid	100	123	137	100	127	141
20000 cir. mil cable	100	112	117	100	115	124

The cost and weight of weatherproof insulation for aluminum wires are greater than for copper of the same conductance on account of the larger cross-section of conductor required.

**Insulators for Overhead Lines.** — City distribution circuits are ordinarily carried on double-petticoat deep-groove glass (D.P.D.G.) insulators; see article on *Insulators for Overhead Lines*.

**Tie Wire.** — The conductor is attached to the insulator by a tie wire of the same material as the conductor, though soft wire is usually employed even on hard-drawn conductors; the tie wire is either bare or insulated to correspond to the conductor. The size of tie wire is often the same as that of the conductor; for small wires it is merely a piece of conductor. With large conductors it may be as much as three sizes smaller. See also the section on *Insulation* in the article on *Wires and Cables, Bare*.

**Pins.** — See article on *Insulator Pins*.

**Cross Arms.** — See article on *Cross Arms*.

**Poles.** — See article on *Poles for Overhead Lines*.

**DESIGN OF CITY DISTRIBUTION LINES.** — City distributing systems should be designed so that service may be given to any building in the city and ultimately to every building present and future. On certain streets the use of lines may be omitted without defeating this object. The arrangement of lines which will serve scattered customers with the least number of poles will usually contain many poles which should not be used if the ultimate arrange-

ment were immediately constructed. Preliminary studies and designs should be made, first, of arrangements suitable for servicing the initial expected customers, second, of arrangements for ultimately servicing customers on every lot in the city, third, of a plan of extension by which the initial arrangement could be extended to the ultimate with the minimum expense in changing lines and services.

**The Pole Line.** — The pole lines perform two functions: (1) of carrying the feeders from the station to the mains and (2) of carrying the mains supplying services to buildings immediately adjacent. In the old cities of the eastern part of the United States where the streets are crooked general rules for systematic line work cannot be followed far. In the newer cities of the West and South the streets are laid out at regular intervals and at right angles, dividing the city into rectangular blocks of equal size. In such cases the following rules should be followed:

(1) A pole line should continue on the same side of the street through its entire length and disconnected lines built in the same street should be on the same side, so that they may be connected when desired without crossing the street.

(2) The spacing between poles should be an exact divisor of the length of the block (including cross street), giving a uniform number of poles per block.

(3) Whenever the line crosses a street where there is, or may be, an intersecting line there should be a corner pole on the proper side of the intersecting street for making a junction.

These rules logically lead to the use of corresponding sides of all pole lines on all streets.

When each block contains lots fronting on all four surrounding streets the servicing of every lot in the city would require poles on all streets, though on the streets in at least one direction the lines may be discontinuous. Often lots all front on the streets in one direction, which are laid out to be private streets, in which case no service lines are necessary in cross streets, though at regular intervals connecting lines are necessary.

**Trunk Lines.** — Where the location of power house or substation is fixed, trunk lines must be laid out from such point, but often a study of possible trunk-line arrangements made before the location of the power house is fixed will show that other locations are more advantageous. If the substation (power house or substation) is centrally located, there should be at least four main trunk lines (of poles) from it, say north, east, south and west. A short distance from the station they should be divided into branches which are subdivided into smaller branches and finally merge into the service lines. The trunk lines should be laid out: (1) on back streets where the large number of numerous and heavy wires and heavy guying will not be conspicuous, (2) on side streets or streets little built up so that interruption to service due to work in adjacent buildings will be infrequent, (3) on streets where there are no trees, (4) on streets where there are no jogs or offsets to weaken the line, (5) require heavy guys, (5) on streets which lead directly to the section supply lines, penetrate its center and intersect the maximum number of service lines. When the station location is excellently chosen these desirable conditions should not have to be compromised to a serious degree.

**Street and Alley Service Lines.** — With the symmetrical arrangement of lots described above there is often an alley through each block parallel with the principal streets. Under these conditions there is therefore a choice of two methods of laying out the lines: (1) run the lines on the principal streets servicing the houses from the front and (2) run the lines in the alleys serv-

houses from the rear. The disadvantages of the first are unsightliness of the poles and wires, difficulty of avoiding or of trimming shade trees; the advantages of the second are discontinuity of alleys, proximity of buildings to ramble barns and out buildings in residence districts and of windows and escapes in business districts) and lack of established grade.

**Composite Distribution.** — The most expensive and difficult part of an underground system is that for taking the current from the conduit to the customer's building. This includes underground secondary mains, transformers, shunts, service pipes and wires. Where it is necessary to remove poles from streets but not to remove overhead wires from private property the poles are replaced by conduits which contain primary feeders and mains only. In the conduit in the street a small branch runs into the interior of each block where the ducts (usually iron pipes) come to the surface at the foot of a main pole up which the cables run. At the top the cables connect to overhead wires. The interior of each block contains a complete overhead distribution system of poles, transformers, secondary mains and services. Sometimes the servicing is done from a single centrally located pole and at others there may be a pole line of several spans length running longitudinally through the block. The most serious disadvantage of this method is that the poles and wires frequently have to be on private property, where no permanent rights may be obtained. Being dependent on concessions from one or more customers, the system does not have the independent position that a public service company would in order to serve all equally and fairly. The poles and circuits are often put up of insufficient size without proper guying.

The composite system has the advantage of the overhead system in less unsightliness, less accessibility of public to high-voltage wires and less trouble with trees. In thickly built-up blocks its use results in a tangle of wires overhead and along walls which may be as dangerous in case of fires or high winds as an overhead system. The composite system is used (1) in small cities where the load density is small and (2) in large cities in an annular district between overhead and underground construction; in either case it is usually an intermediate step from overhead to underground construction.

**Crossing of Waterways; Submarine Cables.** — Where a distributing system is divided by a navigable waterway the connection is usually made by submarine cables laid on the surface of the bottom, or better, below the surface in trenches dredged for the purpose. Cables may be single or multiple conductors, the latter being usually used for alternating currents to avoid resistance due to wire armor of cable. Two conductor cables may conveniently be of concentric type to give a true circular exterior. In laying cables it is desirable to keep them approximately parallel. Where one crosses under another it may be impossible to remove it. Each cable should be in a single length without joints, and the length should be made as short as possible, as repairs are very difficult and often impossible. At ends unimportant cables may be brought to a pole and connected to overhead wires; important cables should land in a suitable house with suitable provision for disconnecting the cable or for transferring the overhead circuit to a spare cable in case of trouble, and also with lightning arresters. Submarine cables are weak links in a distribution system and may sometimes be avoided by crossing channels at sufficient height to clear the masts of ships.

**Calculation of Size of Wires.** — The size to be used depends upon the voltage drop which should be permitted, considering the probable growth of the load. The following table of per cent voltage drop in the various lines is representative of ordinary practice.

	For light
	Per cent
House wiring.....	2
Service wires.....	3
Secondary mains.....	5
Transformers.....	3
Primary mains.....	5
Primary feeders.....	10

The drop in the feeders is usually compensated for by raising the voltage at the substation or power station or by using voltage regulators; see *Distribution and Transmission Systems*.

Formulas for calculating the size of wire for a given length of line, load and given distribution of load are given in the articles on *Transmission Lines* and *Wiring of Buildings*. Due to the uncertainty regarding the possible increase of load, a close calculation of the size of wire is seldom made, the engineer relying largely on his experience and judgment, making only a rough calculation as a check. For overhead lines 500,000 circular mils is the largest size used on account of the difficulty of supporting a larger size. A greater conductance is obtained by installing parallel circuits. For ground lines No. 0000 B. & S. three-conductor cable is the largest size that can be conveniently drawn into the ducts; 1,000,000 c.m. is the usual maximum size of single-conductor cable used.

**Effect of Diversity Factor.** — It should be noted that in a distribution circuit the maximum load on a feeder is less than the sum of the maximum loads on the mains which it feeds, these in turn are less than the sum of the maximum loads on the transformers connected to these mains, and so on. Therefore, whenever a circuit divides or subdivides, the aggregate stresses on the areas should ordinarily be greater after division than before. The total drop in voltage from power house or feeding point to a customer's lamp or outlet is also usually less than the sum of the maximum drops in the parts of the circuit which are in series (such as house wiring, services, secondary mains, etc.) because these component drops do not have their maximum value simultaneously.

**Stresses on Poles.** — An overhead line is a framed structure. The poles are struts resisting the weight of wires, including sleet on the conductors, insulators, cross arms and transformers and the downward pull of the wires. The horizontal pull of the line wires is balanced by the horizontal component of the pull of the guy wires, which transmit it to the ground. In addition to being struts the poles resist certain bending stresses, but this should be but a small part of the normal horizontal tension of the wires. The principal normal bending stresses are of two classes: (1) constant stresses due to the unbalanced pull of service and other wires which do not have sufficient force to require guys, and (2) variable stresses, due to the pull of the wind at right angles to the line on both the poles and the wires. The poles also resist a twisting force where the tension on one side of an arm is greater than on the other, due to a difference in the number or weight of wires ending on the two sides. The poles, wires and guys should be so designed that the bending and twisting forces on the poles are insignificant. A calculation of the strains produced in a pole is given in the article on *Poles for Overhead Lines*.

**Arrangement of Wires on Poles.**—The arrangement of wires is governed by mechanical, electrical and practical considerations. For mechanical reasons desirable that:

1. The largest wires be on the lowest cross arm, in order to reduce the bend-stress on the pole to a minimum.

2. The largest wires be on the pins nearest the pole, in order to reduce the bending stress on the cross arm to a minimum.

3. The wires be arranged symmetrically on the two sides of the pole, especially those which end at the pole, in order to reduce the twisting stress on pole to a minimum.

For electrical reasons (which, however, are of minor importance) it is desirable that:

4. The wires of any one circuit be as close together as practicable (on adjacent pins), in order to reduce the self-inductance of the circuit.

5. The wires of a three-phase circuit be arranged to form the edges of an equilateral prism and the wires of a two-phase circuit be arranged to form the edges of a square prism, in order to render the inductances and capacities of the wires respectively equal.

6. The wires of different circuits be placed as far apart as practicable, in order to reduce their mutual inductance.

For practical reasons it is desirable that:

7. The highest voltage wires be on the top cross arms and on the pins farthest from the pole, in order to reduce the danger of accident to linemen.

8. The mains, which have the greatest number of taps, be on the lowest cross arms, in order to avoid danger of accidental crossing (with contact) of the wires.

9. The arrangement be systematic throughout; this is absolutely essential for safe and economical operation.

As it is impossible to meet all of these conditions the actual arrangements are compromises and are governed by the relative importance attached to the several desirable conditions. In some cases the electrical requirements (4) to (6) have been considered of most importance, resulting, for example, in an arrangement subordinated to the idea that the three wires of a three-phase circuit must be arranged exactly in an equilateral triangle. It appears, however, that these electrical requirements are really the least important of the considerations and that in most practical cases can be entirely neglected.

**Transpositions.**—Due to the effect of mutual electromagnetic induction (*see Inductance*) an alternating or varying current flowing in one circuit will induce a voltage, and therefore a current, in any parallel circuit; and due to the effect of mutual electrostatic induction (*see Capacity*) an alternating or varying voltage in one circuit will induce currents in a parallel circuit, even though there is no metallic connection between the two circuits. It is possible, however, by properly transposing equal alternate lengths of the wires forming the two sides of each of the parallel circuits, to neutralize these effects. Fig. 1 shows diagrammatically a scheme of transposition whereby a two-wire circuit can be protected from both electromagnetic and electrostatic induction from a parallel circuit and vice versa, provided neither circuit is grounded. The more frequent the transpositions the more thoroughly are the effects due to inequality in the spacing of wires and poles eliminated. Transpositions cannot be made effective in eliminating inductive effects when either circuit is grounded, otherwise than at the neutral point. See also *Transmission Lines*.

Fig. 1. Transposition of Two Two-wire Circuits

Methods of calculating the induced voltage and induced currents line due to currents and voltage in a neighboring line are indicated articles on *Inductance and Capacity*.

**Disturbances in Telephone Circuits** due to neighboring power are the most common results of electromagnetic and electrostatic induction. When the power circuit is grounded and carries either (1) fluctuating currents (e.g., a d-c. railway) or (2) alternating currents it may produce noise in the telephone receiver, even though both the power circuit and phone line are transposed. See also *Telephone Lines*.

**Trees.** — Trees constitute the most serious obstacle to the proper planning, construction and operation of overhead lines. The principal methods of overcoming this difficulty are (1) avoiding them, (2) going over them, (3) going under them, (4) going through them. In most cases a combination of these methods is used. Where trees are a serious factor it is necessary to examine the plan of every line in detail and the size and location of the trees may become a determining feature of the whole design. In such cases nearly all rules of good construction and systematic arrangements are violated in the name of expediency.

The methods by which trees may be avoided are: using alleys instead of streets, or vice versa, choosing streets without trees for important lines, and finally the side of street with fewest trees, and finally the very bad arrangement of crossing the street back and forth to avoid the trees either individually or in groups.

The plan of going over the trees is the proper one in the case of all trees and is perfectly satisfactory until the trees grow up and touch the wires. It is therefore only a temporary method, especially where the trees are of the quick growing varieties. In going over small trees it is well to have the poles tall enough to allow for wires clearing after several years growth. It is usually impracticable to go over large full-grown trees because of cost of poles, the unsightliness of very tall poles, and the difficulty of properly guying them to resist wind and the unbalanced pull of wires, which is magnified by the leverage. It is also difficult or impracticable to take off service wires from the tops of tall trees.

In the case of very large trees it is sometimes practicable to take the wires under the trees on short poles. Where the wires pass the trunks it may be necessary to spread them or necessary to pass between large branches. Insulators fastened to the trees to maintain clearance. While such a line may be kept fairly clear under normal conditions, there is apt to be trouble during storms from branches falling on the wires or from limbs bent by wind or frost touching them.

With trees of moderate size it is usually necessary to take the wires through the trees among the leaves and small branches. Such wires are a constant source of trouble and expense. The branches and leaves should be trimmed from around the wires as much as possible, including not only those in contact with the wires but such as will be brought into contact by wind or which will grow into contact during the season. In addition it is usual to protect the wires in the worse places by tree insulation consisting of split tubes of wood or bamboo.

**Pole Transformers.** — The primary (1100- or 2200-volt) mains are usually run to transformers mounted on poles and the voltage there stepped down to the lamp or motor voltage (110 or 220 volts), and secondary mains run from the transformer to the buildings in the immediate vicinity. These transformers usually range in size from  $\frac{1}{2}$  to 50 kw., but transformers of  $\frac{1}{4}$  kw. were formerly common and transformers larger than 50 kw. are sometimes used in factory districts where the unsightliness of the supporting structure (several poles in

(ber) does not have to be considered. Very small transformers are objectionable because of their poor regulation, lower reliability and the cost of yearly changing them as the load increases.

**Use of Single and Polyphase Transformers.** — Transformers are of the single-phase type, two being used for motors on two-phase circuits and two for small motors and three for large motors on three-phase circuits. Polyphase transformers are also used for motors on three-phase circuits, and the advantage of reducing the amount of wiring on the poles. Single-phase transformers have the advantage of being interchangeable between the three-phase lighting and polyphase power circuits where the same voltage is

**Voltage Ratios of Pole Transformers.** — Lighting transformers were standardized with voltage ratios based on multiples or submultiples of 10, that is, 1000 and 2000 volts primary to 50, 100 or 200 volts secondary, 400 and 2080 primary to 52, 104 and 208 volts secondary. It was found on account of the voltage drop in the transformers and secondary mains, motors wound for this voltage did not operate well. Instead of remedying the difficulty by winding the motors for a lower voltage or by raising the voltage at the generators and lamps, power transformers were introduced with a ratio based on a ratio of 9:1 thus giving with 1040/2080 volts primary a secondary voltage of approximately 116/230. It was soon found that many conversions followed from the use of transformers of the two ratios, so that one ratio dropped out or the other ratio and made their transformers interchangeable. Of the two ratios the 10:1 ratio is preferable, because it is the one extensively used, gives a higher voltage for primary distribution and is better with the general principles according to which voltages have been standardized.

**Service Wires.** — The service wires are those which connect the house with the main on the street. Usually these wires extend in a single line from the nearest pole to the house. At the house they are fastened to supports similar to those used on the line and mounted on brackets attached to the house. These brackets are often the ordinary wooden bracket used for the work, though the special iron brackets made for the purpose are neater and more secure. The bracket should take the strain off the service span, and where the service passes through the wall it will not be under the strain of the span. The wires should pass through the wall in porcelain bushings and should have a drip loop between the bracket and bushing so that water will not follow the wire into the building. Where service wires do not conveniently reach the house at point of entrance, they are carried along the wall to such point, being supported at intervals by insulators on brackets. See *Wiring of Buildings*.

At the pole the service wires are sometimes attached directly to the mains to supply them; while this is the easiest method it has the disadvantage that the strain in the service wire will come on the mains, which may also be increased by the attaching and detaching of numerous service wires. When the service wires do not slope upward or downward at a considerable angle they are liable to become crossed with the main of opposite polarity. Since the normal direction of the service wire is at right angles to the main, the service wire should naturally originate on a cross arm at right angles to the arm carrying the mains. In good service work consequently a cross arm is attached to the pole below the main, and all the service wires to both sides of the street come from this. One tap to each of the wires constituting the main can then be used for a number of service wires.

**Front and Rear Servicing.** — When houses are serviced from line on the street the service wires usually enter the front of the house; if serviced from alley they enter the rear. Service wires can be run to detached houses from front to rear on brackets on the wall, but this is unexpensive and increases the service wire drop. Service entrances can be changed by changing the inside wiring, but the expense is usually heavy and the to decoration of rooms sometimes makes it prohibitive. In the wiring of a building the error is frequently made of bringing out services without regard to location of supply lines.

**Attic and Basement Servicing.** — The service-wire entrance to a house is generally in the attic for houses served overhead and in basement for those serviced underground. Buildings ranged for underground service are sometimes supplied from overhead by taking service wires down poles and under sidewalks in iron pipes.

In changing an existing system from a street to an alley distribution from overhead to underground service, the center of distribution in the house must be correspondingly changed, or a connection run from the new entrance to old center of distribution large enough to carry the current without unduly increasing the drop.

**Sectionalizing of Distribution Circuits, Fuses and Cut-Outs.** — A single overhead alternating-current system supplied from a single bus is sectionalized (1) at the switchboard in power station or substation into circuits having no external interconnection by knife switches or oil switches with fuses and automatic trip; (2) at the poles where long branches leave, by transformer cut-outs, either fused or solid, or by pole-type oil switches; (3) at transformer primaries by fused cut-outs. Switches and fuses are used but sparingly on the primary mains, and in a small compact circuit none are necessary. Switches or fuses are ordinarily used on the secondary side of transformer or on secondary mains. Occasionally transformers have been provided with switches in secondary side so that part of the transformers on a network can be cut out during times of light load to save core-loss. Such sectionalizing has been little used, as the small savings have not justified the complication and hazard to service due to mistakes.

When several transformers feed the same secondary main, the operation of a primary cut-out, either by blowing of fuse or by hand, does not mean that the transformer primary is dead, as it is still alive from the secondary side. If the fuse of one transformer on a secondary network blows the additional fuse thrown on an adjacent transformer may cause the fuse of that to blow, and transformers to go out in succession. Under these conditions the fuse must be replaced in one transformer at a time. To avoid the interruption to service involved in leaving the fuses out until a time of day when one transformer can carry the whole load temporarily, or in having the whole primary network out while the fuses are replaced, it is sometimes possible to have all the transformers on a single secondary network on the same branch of the primary main, this branch being sectionalized from the rest of the primary circuit by a switch.

**Lightning Protection.** — (See also article on *Lightning Protectors*.) Practically all disturbances from lightning enter a system through the distributing circuits. The most serious effects are not to the distribution circuit itself but to the switchboard and machinery in the station. The disturbances on the circuit consist of splitting of poles, puncturing of insulators, puncturing of transformers, blowing of transformer fuses. There may also be disturbances to meters or appliances on the premises of consumers. The protection principally used includes (1) lightning arresters and choke coils in the station

(3) lightning arresters at intervals on the lines, (4) lightning rods on poles and (5)

— On alternating circuits lightning arresters are primary but not on the secondary circuits. A lightning arrester will protect is less the more it is impracticable, and probably impossible, to put together to absolutely protect a circuit. Arresters used should be such that the sum of the cost and the expense of providing and maintaining is a minimum. The effects of lightning damage due to interruption of service is too important for the distribution of arresters being determined by experience. It has been found that when no arresters are used on circuits of considerable intensity do no great amount of damage is done but that their failure is a cause of a considerable amount of damage. It is usually well to begin by using arresters and to put additional arresters on if found necessary. The number of arresters would be reached when one was reached.

Protection is greatest in a composite system, and for submarine cables should be protected by connecting to exposed overhead circuits.

Arresters are used over transmission lines but may be used on wires in exposed places. Where adjoined to the pole line, these foreign objects give an additional screening effect will be obtained.

— Overhead line construction is constantly changing and removal of poles, extension of mains, change of service, erection and changing of location of poles with which changes may be made in the records in such form that any details can be made without making a completely new record. The subject is subject to frequent change makes it impracticable to compile a system of records it is therefore a system of records should be recorded and what omitted, and a system which will be easily corrected. Written records though for most purposes the latter gives a more useful record.

Records become useless, soon after they have been prepared on account of lack of correction or unintelligible because of corrections. The following method of keeping records give good results: (1) a map of the circuits showing the circuits on the date of preparation; (2) the tracing and all changes marked in pencil and not the tracing being used for correcting the subject to wear or tear; (3) before the blue print is made or wear the accumulated corrections are made on a date blue print substituted, and the process of making the blue print can be made by line foremen at the time that the line changes are made, while the work is being done by a draftsman who will make them neatly

and with minimum damage to the cloth. If no colored inks are used parts subject to change, such a tracing will last a long time and will only have to be redrawn when changes have become so numerous or radical as to amount to a rebuilding of the circuits.

**COST OF DISTRIBUTION CIRCUITS.** — So many varying items enter into the cost of a complete distribution system that it is impossible to give comprehensive figures of general application. A cost of from \$150 to \$250 per kilowatt of maximum load at the distributing switchboard may be taken as an indication of the magnitude of the total cost of an overhead distribution system for both light and power, including all outside construction from power station or the substation to the customer's service inlet, including meters.

The design and construction of pole lines and underground circuits are treated in detail in the articles on *Distribution Lines, Conduits and Conduit Lines, Transmission Lines, and Wiring of Buildings*. Requirements regarding the grounding circuits and methods of making ground connections are treated in the articles *Grounding of Electric Circuits and Ground Connections*.

Circuits designed for transmitting relatively large amounts of power from one point to another are called transmission lines, while those for delivering small amounts at numerous points are called distribution circuits. Transmission lines usually have no or few branches, while it is characteristic of distribution circuits to have many branches. The various systems of transmitting and distributing electric energy for light and power may be classified under three general heads, viz., constant current or series and constant potential or multiple systems, and each of these may be subdivided into direct-current systems and alternating-current systems.

**CONSTANT CURRENT OR SERIES SYSTEM.** — The lamps or other devices are connected in series and the current through them is kept constant, the voltages varying automatically to increase or decrease the energy delivered. This is the principal system used in the United States for street lighting, but is little used for any other purpose. At one time such circuits were extensively used for commercial arc lighting in stores, but the series arc became obsolete for commercial use when the arc lamp was perfected for use in multiple circuits. The value of the current used for street lighting ranges from 1.75 to 2 amp., depending upon the type of lamp used.

**Source of Current.** — Direct current for series circuits is usually obtained from d-c. series generators (*see Generators, Direct-Current*) or from an a-c. circuit by rectifying the alternating current from a constant-current transformer (*see Rectifiers*); adjustable resistance in series in a constant potential d-c. circuit is sometimes used. Alternating current is usually obtained from a constant-current transformer on a constant potential a-c. circuit; other methods sometimes used are an adjustable resistance or reactance in series on constant potential a-c. circuits and by automatic regulating reactance coil on a constant potential a-c. circuit.

**Cut-Outs, By-Passes and Transformers.** — Switching out of lamp series circuits is accomplished by short-circuiting them; this leaves the lamp charged to the potential of that point in the circuit. To make them handle "absolute cut-outs" are used which also disconnect both conductors, leaving the lamp, leaving the circuit closed.

To avoid the excessively high voltage which would occur when the circuit is opened, due to series incandescent lamps burning out, an automatic fuse is provided in multiple with the lamps, sometimes consisting of a piece of wire which punctures on a moderate rise of voltage, or of a choke coil which draws but little current at normal lamp voltage. Sockets for series incandescent lamps are arranged to automatically close the circuit when the lamp is drawn.

Transformers, one at each lamp, are sometimes used to insulate the secondary circuit containing the lamp from the primary or for reducing the current in low-current lamps used in series with lamps taking higher current.

**Advantages and Disadvantages of Series Lighting.** — Constant-current or series systems have the advantage that low-voltage lamps may be used in high-voltage circuits without the expense, losses or complication of transformation. They have the disadvantage that the lamps are dangerous to touch, the efficiency is low at light loads and it is impracticable to distribute an amount of power on a single circuit. In the series system the current is the same consequently the loss in the conductor is the same irrespective of the load, while in the multiple system, the current is proportional to the load, the watts lost in the line therefore vary as the square of the load and the loss directly as the load. For this reason the series system is not an economical one where the load varies and averages much below full load, which is the case with most commercial loads. For street lighting where all the lamps are turned on and off at once the efficiency at partial loads is of no importance. In constant-current systems the resistance of the circuit does not affect the uniformity of the voltage on the lamps at different parts of the circuit, while with constant-potential systems it does. For a scattering load of lamps, such as street lighting, a uniform light can therefore be obtained from the several lamps, with a smaller weight of copper and fewer wires by using the series than by using the multiple system.

**Thury System.** — In Europe the constant-current or series system of direct current of extra high voltage, has been used for long-distance transmission under the name "Thury System." The current is obtained by connecting several generators in series, and is utilized by a number of motors in series. The advantages are simple switchboards, no transformers and no maximum strain on line insulators, the latter due first to the fact that in constant-current the effective voltage is as high as the maximum voltage, and that in a constant-current system the working voltage only remains at its minimum value during the short period when the load is also a maximum. The disadvantages are the necessity for insulating frames of generators and motors, need of speed governors on motors, necessity of converting the alternating current by moving machinery in every case where it is used for lighting and power. The Thury System is not used in the United States.

**CONSTANT-POTENTIAL OR MULTIPLE SYSTEM.** — In this system which is the one principally used for electrical distribution, the voltage on the conductors is kept as constant as practicable and the current varies as the load changes. The degree to which the voltage approximates constancy throughout the system is called the "regulation" of the system.

**Use of Direct or Alternating Current.** — Either direct or alternating current can be used equally well for certain purposes, principally those for which

ed, including the lighting of carbon and tung-  
g and heating. For certain purposes, where  
physical changes, such as charging storage bat-  
current is essential; for other purposes, such  
lum incandescent lamps, it is better; whereas  
ernst lamps, the alternating current is better.  
urrent is most favorable where acceleration,  
eed are desirable, whereas alternating current  
unvarying speed is desired. While the fields  
a large extent that either kind can be used for  
hat it is often more advantageous to use both.  
istribution, direct current is advantageous  
best be carried on single conductor cables; no  
ll, high tension fuses are required.

supplied either directly from the generators  
e secondaries of transformers in substations.  
either directly from direct-current generators  
(see *Substations, Railway*) supplied with high-

— For a load consisting of both electric lamps  
circuit may be used throughout for both classes  
independent circuits may be employed. The  
out for light and power service has the advan-  
t, transformers and meters, reduced weight of  
nsformers and meters, whereas the use of sepa-  
has the advantage of requiring less capacity of  
of less weight of wire for the same perfection  
circuits and also simplifies the problem of bal-  
distribution (*see below*). In the business dis-  
ree-wire direct-current system is used, in which  
supplied from the same circuit, the motors as  
outside wires. In business districts where the  
urrent the lighting is frequently on single-phase  
rate polyphase circuits or on 500-volt direct-  
districts, where the lighting is done by single-  
motors are usually put on same services as the  
om 1 to 5 and in some instances as large as 15  
meters, services and transformers, but the same  
ces. In factory districts when the power is the  
ed by polyphase circuits the incidental lighting  
services, but usually there are separate meters  
arge number of cases where the same polyphase  
d light with separate transformers and second-  
transformers are usually distributed as equally  
al phases, in order to balance the load, though  
ed to a single phase. In a few cases the same  
power and light usually on the four-wire three-

There are two methods of providing proper dis-  
area, known respectively as the "tree system"  
The former is the most extensively used but  
good voltage regulation as the latter.

connected Networks.—The simplest method of  
to run one set of wires through the middle of

the district to be served, running branch wires from them wherever convenient for reaching loads at the sides. At the beginning, the single set of wires is large enough to carry the whole current, but the size is diminished as the circuit branches off. In this system adjacent branches will often have widely different voltages, due to unequal drop because of varying loads. If wires are run connecting the out-lying ends, currents will flow and partially equalize the differences in voltage. This plan, if carried out systematically, develops a mesh network, usually composed of two sets of parallel mains crossing at right angles and connected at each point of crossing.

**Feeder and Main System.** — It is practicable to keep the voltage at the customers' electric lamps within 2 to 5 per cent of being constant, when it is necessary to raise the voltage of the generators from 10 to 20 per cent from no load to full load, by arranging the distribution circuits on the feeder and main plan. The area to be served is first divided into compact sections, each small enough to be fed from a central point with a voltage drop within the desired percentage. A system of wires called "mains" are run from this central point, called the "feeding point," or "distribution center," to the customers. The mains form a little circuit originating at the feeding point instead of at the power house; they may be arranged on either the tree or interconnected network plan. A set of wires called "feeders" is run from the power house to the feeding point. As no current is taken off at intermediate points these wires are not tapered and any desired drop of voltage may occur in the feeders without affecting the lamps, provided the power-house voltage is regulated proportionally.

**Two-wire System.** — The simplest multiple system is the two-wire system, where all devices are connected directly in multiple. This system is used extensively for direct-current light and power, from isolated plants, for power circuits (usually 500 volts) and railway circuits from central stations. It is also used for single-phase alternating-current distribution for both primary and secondary circuits.

**Edison Three-wire System.** — The three-wire system, Fig. 1, is obtained by replacing the out-going wire of one two-wire system and the return wire of a second two-wire system by a single wire, called the "neutral." The voltage between the outside wires is then double the voltage between the neutral and either outside wire. For example, 110-volt lamps may be connected between the neutral and either outside wire, and 220-volt motors may be connected between the two outside wires, and both the lamps and motors be supplied with their rated voltage. The neutral wire carries a current which depends only upon the *difference* in the loads on the two sides of the system and its distribution. As a rule the neutral of a three-wire main is made equal in cross-section to each outside wire. With perfectly balanced load the three-wire system with all three wires of the same size results in a saving in copper of 25 per cent as compared with a two-wire system supplying the same load with the same regulation.

The three-wire system is used very extensively for direct-current light and power distribution from central stations, also for large isolated plants and for alternating current for lighting on the secondary circuit. Three-wire systems are usually 110 volts on each side of neutral, or 220 volts between outside

Fig. 1. Three-wire System

gh there are several systems using 220 volts on each side and 440 volts on outside.

The Edison three-wire distribution system, as used in the business sections of large cities, consists of a set of interconnected three-wire mains supplied by one or more three-wire feeders from one or more power houses or substations. Different feeders feed into the same set of mains at different points. At the power house or substation end the feeders are often all supplied from a common bus, though where there is a great difference in the length of the feeders there are sometimes two busses which are run in multiple when the load is light and separated when it is heavy, the short feeders on one called the "low bus," and the long feeders on the other called the "high bus," because of the relative drops. As the feeders from the several substations connect to interconnected mains, the bus voltage in each is raised or lowered in accordance with the drop in its own feeders. All mains which connect feeding points supplied from a common bus are made large enough to allow large equalizing currents to flow through them, without requiring any great drop in the mains, in order to equalize the voltages at these points.

**ALTERNATING-CURRENT SYSTEMS.** — The simplest form of alternating-current system is the single-phase system, for which the connections are only the same as for the direct-current systems. Both two-wire and three-wire circuits are used, the former for primary circuits and small secondary circuits and branches, and the latter for large secondary circuits. The principal use of single-phase circuits is for electric lighting and auxiliary uses, such as heating or cooking, and fan motors. For delivering large amounts of power the two-phase or three-phase system is generally used.

**Two-phase Systems.** — In this system there are two single-phase currents with a difference in phase of  $90^\circ$ , or a quarter of a cycle. These currents may be distributed on the three-wire, four-wire or five-wire system; see also *via Transformer Connections* in the article on *Transformers*.

**Three-wire Two-phase Systems.** — Each single-phase current has a separate outgoing wire but unites in a common return wire. Each two-phase system has two circuits, each connected between an outside wire and the return wire. The voltage between the two outside wires is 41 per cent greater than between outside wire and return wire and the current in the return wire is 41 per cent greater than in each outside wire. This is an unsymmetrical system and has the disadvantage that even a balanced load will cause a distortion and unbalancing of the delivered voltage of the two phases because of the unsymmetrical drop in the common return wire.

**Four-wire Two-phase System.** — Each of the two single-phase circuits is a complete, independent two-wire circuit. There are two variations, first where the circuits are insulated from each other, in which case a cross between the wire of one circuit with either wire of the other will change the voltage between the wire and ground, but will not affect the delivered voltage or cause a short circuit; second, when the neutrals of the two circuits are connected. In the latter case, when each wire of one circuit to either wire of the other circuit, the voltage is 70.7 per cent of the voltage between wires of the same phase. The four-wire system with insulated phases is probably the most extensively used of the two-phase systems.

**Five-wire Two-phase System.** — This is a modification of the four-wire system, with interconnected neutral in which the common neutral is extended as a fifth wire. Lamps may be connected from each of the four wires to the neutral. The five-wire system may be considered as two three-wire two-phase systems, one for each phase, with a common neutral wire.

**Three-phase Systems.** — In this system there are three single-phase alternating currents with a phase difference of  $120^\circ$ , or of one-third of a cycle. currents may be distributed on the three-, four- or six-wire systems.

**Three-wire Three-phase System.** — Each single-phase current has a separate outgoing wire; the three return currents neutralize so that no return is required. The three wires are necessarily interconnected, the voltage is usually the same between any two and the currents equal in each of the conductors, provided the loads on the three phases are equal, i.e., provided the load is balanced. When equally loaded the voltage drops in the three conductors are equal and symmetrical. This is the most extensively used of the three-phase systems.

**Four-wire Three-phase System.** — This is a modification of the three-wire system in which a neutral wire is extended as a fourth wire. Lamps and transformers may be connected from each of the three wires to the neutral, the neutral carries only the unbalanced current, due to the differences in loading on the three phases. The voltage between the three outside wires is 73 per cent less than from each outside wire to neutral.

**Six-wire Three-phase System.** — If to a three-wire, three-phase system, three wires are added, one with voltage midway between that of each pair of outside wires, lamps may be divided into six groups, between the three outside wires and the three adjacent middle wires. The result is the same as though there were three single-phase three-wire circuits, one for each phase, with the six outside wires combined in pairs giving three common outside wires in place of the three pairs. When connected in this way, the three middle wires cease to be neutrals, as between the three there is a three-phase voltage equal to one-half of that between the three outside wires.

**Six-phase System.** — This is used for circuits in the interior of substations (q.v.), such as from transformers to rotary converters, but is not used for distribution.

**Monocyclic System.** — This is a variety of unsymmetrical polyphase system now obsolete. It may be regarded as a species of two-phase system with voltage on one phase one-fourth of that on the other and with the two wires of the smaller phase acting as a common return for the small phase.

**Star or Y, and Mesh or  $\Delta$  Connections.** — See article on *Alternating Currents*.

**Transformer Connections and Phase Transformations.** — See article on *Transformers*.

**Transformations of Systems.** — Any electric system can be transformed to any other electric system by the use of rotating machinery; see *Generators and Converters, Synchronous*. This method is used chiefly for changing from alternating to direct current and for changing the frequency of alternating current. Conversion from alternating to direct current is accomplished by means of mercury arc rectifiers, particularly for series arc lighting and for charging storage batteries; see *Rectifiers*. Conversion from any alternating voltage to any other alternating voltage at the same frequency is accomplished by means of transformers (q.v.).

**Frequencies in Use in the United States.** — At present the two frequencies in most general use and adopted as standards in most new work are 60 cycles per second or 7200 alternations per minute, used by the majority of companies operating alternating-current lighting systems.

25 cycles per second or 3000 alternations, generally used for alternating-current railway or power work or where the alternating current is to be converted into direct current before final use.

quencies used. Sometimes the two frequencies  
covers, though sometimes all current is gen-  
erated current obtained from frequency changers

#### WEIGHTS OF COPPER REQUIRED

— The comparison of the various systems  
copper required, as tabulated below, is based  
the energy delivered, (2) that the energy loss  
the strain on insulation between any wire and  
for all systems.

... of the system is grounded, then the maxi-  
mum to ground is the maximum instantaneous  
outside wire and neutral. In the case of an  
the maximum instantaneous value is equal to  
determined by a voltmeter. When the neutral is  
ground on any leg will throw full line voltage  
other leg and ground.

On this basis of comparison, assuming a sine wave of voltage and 100 per cent power factor for the alternating-current systems, the relative voltages between outside wires and the relative weights of copper are as follows:

RELATIVE VOLTAGES AND RELATIVE WEIGHTS OF COPPER

System*	Relative voltages between outers		Relative weight of copper	
	Grounded neutral	Insulated neutral	Grounded neutral	Insulated neutral
	Per cent	Per cent	Per cent	Per cent
Direct-current (2-wire) .....	100	50	100	100
Single-phase (2-wire) .....	71	35.5	200	200
Two-phase (4-wire) .....	71	35.5	200	200
Three-phase (3-wire) .....	61	35.5	200	200

\* Neutral wire not included; when neutral is added increase the figures given in the ratio of weight of neutral to combined weight of the outside wires for the system in question. For example, the addition of a neutral wire equal in size to either of the outside wires to a d-c. 2-wire system with grounded neutral gives a relative weight of  $100 \times 1.5 = 150$  per cent.

**Effect of Power Factor.** — To correct the above tabulation for alternating-current systems in cases where the power factor is less than unity divide the relative weight of copper given by the square of the power factor (i.e. for a single-phase two-wire system with insulated neutral and 70 per cent power factor the weight of copper will be  $800/0.70^2 = 1630$ ).

**VOLTAGES FOR D-C. AND A-C. SYSTEMS.** — Unless otherwise specified the "voltage" of a polyphase system refers to the potential difference between adjacent outside wires; see *Alternating Currents* for the relations between the various voltages.

A considerable number of voltages are standard or semi-standard. In fact they may be considered as derived from a lamp voltage of 50 or 100 megavolts by the factors 2, 3, 5 and 10, and increased by 4, 5, 10, 15 and 20 per cent for various reasons, principally to allow for line loss. In addition to this list of voltages there is another system which arises from the use of Y and delta connections on the three-phase system; these voltages are related to the above by the factor  $\sqrt{3} = 1.73$ , either as a multiplier or a divisor. For example, the voltage between the outside wires of a four-wire three-phase system supplying 115-volt lamps connected between each outside wire and neutral is  $115 \times \sqrt{3} = 198$  volts.

**Voltages Commonly Used.** — The voltages most used are:  
Direct current:

100 to 120 volts	Lighting, small power and field excitation.
200 to 240 volts	Power, lighting and field excitation.
500 to 600 volts	Power, electric urban railways.
1200 to 1500 volts	Interurban electric railways.
2400 to 3000 volts	Electric trunk lines.

**NOTION.** — The ratio of the energy registered ch would be so registered if all customers had the generator to the bus-bar in the generating efficiency of distribution. The losses may be loss, transformer loss, converter loss, meter ounted for. For some purposes it is useful to s of view: (1) as a loss of energy, and (2) as st may be called the energy loss and the second oning efficiencies are usually designated as he full-load or capacity efficiency respectively.

— The total energy loss consists of two com- dent of load, including the core-loss of trans- , friction and windage of rotating converting

apparatus, the loss in the shunt coils of meters, the copper loss in current circuits, and the loss in the arc of mercury arc rectifiers for current circuits; (2) a variable loss proportional to the square of the current, including the copper loss of constant potential circuits and of transformers, and the armature copper loss of rotating converting apparatus. The effect of the fixed loss on the per cent efficiency depends on the load factor of the load, and that of the variable loss depends both on the load factor and the shape of the load curve.

**Representative Losses.** — For a lighting system, the full-load losses in primary feeders, primary mains, transformers, secondary mains, services and lamps may be expected to be as much as 17.5 per cent of the power generated. The daily energy loss is 33.3 per cent of the energy generated, giving 82.5 per cent capacity efficiency and 66.7 per cent energy efficiency respectively.

**Effect of Nature of Load.** — In making estimates of the efficiency of particular systems, the effect of the following items should be considered: (1) relation of transformer capacity to maximum loads, (2) load factor, (3) shape of load curve, (4) power factor, (5) diversity factor.

**REGULATION.** — An ideal constant potential distribution would maintain one uniform, unvarying voltage, and would be said to have perfect regulation. The greater the variation from such constancy the poorer the regulation. The regulation is usually specified in per cent variation, either "above or below" a standard mentioned. The standard is usually either the nominal voltage desired or the actual average voltage obtained.

**Evil Effects of Poor Regulation.** — The evil effects of high voltage are the short life of electric lamps, excessive speed of direct-current motors, excessive exciting current of induction motors and burning out of motors and other apparatus. On the other hand, low voltage greatly diminishes both the candle-power and efficiency of electric lamps, decreases the maximum power of motors and increases the current which a motor will take for a fixed horse-power. As electric lamps are much more sensitive to change of voltage than motors, separate circuits are often used for lighting and power, the former having perfect regulation which are omitted from the latter.

The following figures give roughly the quantitative effect of voltage variation between 5 per cent below and 5 per cent above normal:

Each per cent decrease in voltage decreases candle-power of carbon incandescent lamps.....	5 Per cent
decreases torque of induction motor.....	2 Per cent
Each per cent increase in voltage decreases the life of carbon incandescent lamps*.....	13 Per cent
increases the magnetizing current of induction motors.....	2 Per cent

**Ordinary Limits of Regulation.** — Roughly, the maximum voltage variation at the lamps on a lighting system should never exceed 5 per cent, and regulation above or below normal should never be greater than 2.5 per cent, and should be as much less as is economically feasible; the voltage variation on power systems is usually 10 per cent (5 per cent above or below normal) and is sometimes considerably more.

**Calculation of Regulation.** — In order to calculate the variation in voltage at any receiving device or group of such devices from no load to full load, the voltage at the generating or substation or feeding point being assumed constant, the impedance drops in all parts of the distribution system must be calculated.

\* Average for 5 per cent increase in voltage; the first per cent increase in voltage decreases the life 18 per cent, the fifth per cent 8 per cent.

properly combined. The various parts of the system to be considered are house wiring, service wires (or leads from street mains to the house), second-mains, transformers, primary mains, primary feeders. See *Distribution*; *Transmission Lines*; *Wiring of Buildings*.

In making such calculations account should be taken of the fact that the currents in the several parts of the system seldom have their maximum at the same time. The maximum drop in house wiring will not occur simultaneously in all houses nor will the maximum service drop occur together in services, etc. Furthermore, the maximum house wiring drop for a given day may not occur at the same time as the maximum drop on the secondary transformer or primary mains to which it is connected.

**Effect of Line Reactance.**—The regulation of an alternating-current system of unity power factor will be poorer than that of a direct-current system of the same copper efficiency (see tabulation above) because of additional drop due to line reactance.

**Effect of Lagging Power Factor.**—A lagging power factor usually makes the regulation of an alternating-current system worse than it would be for unity power factor and (therefore much worse than for a direct-current system) than the same copper efficiency.

**Effect of Leading Power Factor.**—A leading power factor usually makes the regulation better than it would be for unity power factor and may give a better regulation than can be obtained from a direct-current system of the same copper efficiency.

**Effect of Currents in Neutral.**—Any current in the neutral wire of a balanced system produces a drop which tends to unbalance the voltage of the two sides. In the case of a three-wire direct-current or single-phase system *one per cent drop in neutral produces two per cent difference in the voltages on the two sides*. This drop in the neutral therefore affects more seriously the regulation than an equal amount in the outside wires. If the currents in the neutral all have the same direction, say toward the station, the voltage drops in the various sections will be cumulative, and though the drop in each section may be small the total current may actually reach the station, the aggregate effect may be serious. The individual loads on the two sides of the neutral should be controlled so that the unavoidable neutral currents flow alternately in each direction, thus causing drops in alternate directions thereby neutralizing each other over the total length of the circuit.

**Feeder Neutral in Three-wire Systems.**—When the "feeder and main" system is used with a three-wire system, two-wire feeders should be used only for the outside wires, and only a single "feeder" neutral be used. That is, with respect to the neutral, the "tree" system gives better regulation for the same weight of copper than the "feeder and main" system, but with respect to the outside wires the latter system gives the better results. This is a point which has not always been recognized in laying out three-wire systems.

**VOLTAGE CONTROL.**—(See also *Controllers*.) The more common methods of controlling the voltage at feeding points when the feeder and main system of distribution is used (see above) are the single bus system, the high and low bus system, and feeder regulators.

**Single Bus System.**—(See also *article on Bus-Bars*.) All the feeders may be connected to a single bus and the bus voltage be raised as load increases so as to compensate for average drop of all the feeders on it. This method gives a reserve voltage on such feeders as are comparatively short and low voltage on those that are long. Usually maximum voltage is carried in the evening

during the lighting peak and lower voltage during day giving very regulation on power circuits having maximum load during the day and at night. This method is used on most small direct- and alternating-current distribution systems.

**High and Low Bus System.** — The bus may consist of two parts which may be separated, and operated at different voltages, feeders of greater drop connected to the "high" (voltage) bus and the others to the "low" (voltage) bus. The voltage of each bus is raised or lowered in accordance with the average drop of feeders on it as in the single bus system. This method is used extensively on the Edison three-wire direct-current systems, as noted above. The unequal drop of the several feeders on same bus are equalized by the interconnection through mains.

**Feeder Regulators.** — A feeder may have a separate regulator at its end to compensate for its own drop. This method is sometimes used on street current railway feeders and very extensively on alternating-current railway feeders. See article on *Regulators*. A feeder or other distribution circuit which contains a voltage regulator is frequently referred to as a "boosted" circuit. Boosted circuits are not usually interconnected but may be if the boosters are of the same nature in each.

**Control of Polyphase Systems.** — In a polyphase system the load should be as equally divided among the phases as possible and the voltage regulation with respect to any one phase taken as representing the average of the whole. A lighting load may be connected on a single phase and the voltage regulated on this phase alone. The former method is more common, as it permits of the full output of all the phases of the generator being used and gives a more equal regulation on the several phases of polyphase motors.

**Transformers as Outside Boosters.** — An auto-transformer or an ordinary transformer may be connected to a feeder at any point and used as a booster to raise or lower the voltage. In the case of an ordinary transformer the primary and secondary are connected in series thus converting the transformer into an auto-transformer; see article on *Auto-Transformers*. Such boosters are usually adjustable and have a bad effect on the regulation as they give excessive regulation on the boosted part of line at light load.

To cut such a booster out of service without taking it off the circuit the primary coil must be open circuited and the secondary short circuited. Care must be taken that the main circuit must be opened before cutting out booster, because if the main circuit is opened while current is flowing in the secondary the booster becomes an induction up transformer and may give a dangerously high voltage on the primary. On the other hand the secondary is short circuited first, a destructive current may flow through it and the primary, and when the primary is opened a dangerous arc will form.

**Use of Lamps of Different Voltage.** — Attempts have been made to compensate for the difference in voltage at the various points of a network by using lamps of different rated voltage, high-voltage lamps being used near the supply and low-voltage lamps at the ends of line. This plan has not been successful because the difference in voltage between any two points is not constant. Frequently some of the high-voltage lamps are used by mistake for low-voltage lamps are intended; the results are then poorer than when no difference is made in lamp voltage. While lamps of two or more voltages may be used temporarily as an expedient when regulation is very bad, it is better to have all lamps on a system of a single uniform voltage.

**Use of Transformers of Different Ratio.** — Transformers are usually provided with taps so that a uniform secondary voltage can be obtained with a constant primary voltage. The plan is not a good one, because if the difference

correct for uniform voltage at full load it gives unequal voltages at light load. It also has the very serious disadvantage that the haphazard changing transformer ratios by ignorant linemen to compensate for dim light, due to lamps already blackened by excessive voltage, makes it impossible to carry out any systematic plan for securing the best average regulation for the system as a whole.

**BALANCING OF LOAD.**—In three-wire direct-current or single-phase systems and in all polyphase systems supplying single-phase load it is necessary to approximately balance the load between the two sides or the several phases in the case may be. Unbalanced load has two bad effects: (1) it loads the two sides or phases of the system unequally, making it impossible to get full output out of the lightly loaded side or phase without overloading the other; (2) it makes the regulation of the system worse by causing high voltage on the heavily loaded side or phase and low voltage on the other.

The first difficulty is not serious, because through the conduction of heat from the loaded to the unloaded coils of transformers and generators the machine efficiency is not reduced in proportion to the unbalance; for moderate unbalance, say up to 10 per cent greater load on one side or phase than on the other, it is doubtful if any appreciable effect could be discovered. As the total load usually consists of a great number of small parts, a very little foresight in dividing the load in the first place between the sides or phases, and in suitably distributing a separately connected load, will give a balance good enough for all practical purposes. When polyphase alternators were first installed for supplying existing single-phase lighting circuits, it was supposed to be important to have a close balance of load between the phases, and early switchboards were therefore provided with transfer switches for throwing single-phase feeders from phase to phase. It was later found that instead of being necessary to transfer the load from phase to phase, following the diurnal or annual variations of load, that the circuits could stay on the same phase indefinitely and that transfer switches were unnecessary and undesirable. The time when rebalancing of this kind is necessary is usually when new circuits are established, at which time the changes of connections are best made by changing the taps to the bus-bars.

**Motor-generator Balancer.**—On direct-current three-wire systems the difference in current on the two sides may be balanced without taking the neutral wire to the generator by a balancer consisting of two similar machines mechanically coupled and electrically connected in series. Each machine is rated for the voltage of one side of the system (110 volts for a 220-volt system); the common connection between the machines is connected to the neutral and the other two terminals to the two outside, see Fig. 2 (the field windings are omitted for clearness). The unit acts as a motor generator (q.v.), whichever machine happens to be on the light

Fig. 2. Motor-generator Balancer

side being the motor for the time being and the other the generator. By strengthening the field of the one on the side where the voltage is low and weakening that of the other, so as to keep the same total voltage, the voltages on the two sides as well as the currents may be balanced if necessary.

The output of the balancer generator and the input of the balancer motor are practically equal to each other, neglecting the losses in the machines, and each is equal to

$$\frac{P_1 - P_2}{2}$$

where  $P_1$  is the load on the heavily loaded side of the system and  $P_2$  the load on the lightly loaded side. For example, if the load on one side is 110 kw. and on the other side 90 kw., the load on each unit of the balancer is 10 kw.

It would, however, be unsafe to use a balancer as small as such calculations for the normal unbalancing would indicate as correct, because in case of a short-circuit on one side of the system, or of loss of a large amount of load on one side due say to the blowing of fuses, the balancer would be dangerously overloaded. This may not only destroy the balancer, but may burn out many lamps and motors on one side due to excessive voltage. In small systems, say up to 100 kw. total capacity, the balancer should be able to operate momentarily at any loading up to the capacity of the main generator, and in large systems should have capacity sufficient to burn off a short-circuit on one side of the system without creating an unduly high voltage on the lightly loaded side.

**Dynamotor as a Balancer.** — A smaller and cheaper balancer is obtainable by using a dynamotor (q.v.), which is a single machine with two windings, one armature and two commutators. The armatures are connected in series to balance the currents, but as there is only one field the voltages cannot be balanced.

**Alternating-current Balancing Coil.** — On alternating-current single-phase three-wire systems it is usual to obtain the neutral from the middle tap of the coil of the transformer supplying the current. It can, however, be obtained at any point of the two-wire circuit without going back to the transformer by using a balance coil. A balance coil is a transformer with two windings connected in series across the circuit and with the neutral wire connected to the common point between the windings. Whichever coil is the lightly loaded side acts as the primary and the other as the secondary, thus balancing the circuit by transferring one-half of the difference in load from the heavily loaded side to the lightly loaded side. Such coils, which are essentially auto-transformers with a 2:1 ratio, may be used in various ways: to obtain the neutral for an unbalanced three-wire circuit from a two-wire circuit; to supply a 110-volt load from a 220-volt circuit; to supply a large 110-volt load from a 220-volt circuit without connecting to the neutral. In practice balance coils are not much used as the neutral can more cheaply be obtained from the transformer.

R., *A Review of Systems of Transmission and Distribution of Lighting Service*, G. E. Review, 1914, Vol. 17; Committee reports of A.E.I. and N.E.L.A.

**DRAFT, MECHANICAL.**—(See also *Blowers and Compressors; Chimneys; Fans; Pipes and Piping.*) Any system producing draft either by steam jets or by blowers is called a mechanical draft system. The relative advantages of mechanical draft as compared with chimney draft are: (1) The supply of air may be more readily controlled; (2) a fan permits a lower temperature of flue gases, which increases the boiler efficiency; (3) the boiler may be forced to high overloads in case of emergency; (4) the draft is uninfluenced by climatic conditions; (5) the system is low in first cost. The disadvantages of mechanical draft are: (1) danger of breakdown; (2) cost of maintenance and operation; (3) a stack or other means must be provided to carry off the flue gases wherever their discharge at low levels constitutes a public nuisance. Many plants with tall stacks are provided with mechanical-draft apparatus as a means of forcing the boilers in case of heavy overloads. Mechanical draft is frequently used in connection with fuel economizers.

**Steam Jets** for producing artificial draft are simple, inexpensive and easily applied, but are very uneconomical, since they require from 6 to 11 per cent of the total steam generated (A. J. Whitham, *Trans. A.S.M.E.*, Vol. 17).

**Forced Draft.**—A blower system creating an excess of pressure beneath the boiler is known as a forced-draft system. A single fan is commonly employed to supply a number of boilers through a system of ducts beneath the floor. The draft is sometimes taken from a chamber built around the breeching, thus utilizing part of the heat energy in the exhaust gases.

**Induced-Draft.**—In the induced-draft system the fan is placed between the breeching and the stack. All leakage of air is inward, avoiding inconvenience when the doors are opened. This system is frequently used in plants which have high peak loads, being ordinarily installed in connection with fuel economizers. A by-pass directly from breeching to stack is usually provided for use when mechanical draft is not required or in case of accident. A double system of fans is also sometimes provided as a further insurance against accidental derangement.

**POWER REQUIRED—SIZE OF FANS.**—The power and size of fans required to operate either a forced-draft or induced-draft system may be roughly calculated by the method given in the article on fans. The static pressure may be roughly approximated from the data given in the article on chimneys, the figures there given for loss of draft being taken as the static pressure to be overcome. The quantity of air required per boiler horse power depends upon the quality of the coal, upon the care taken in firing and upon the efficiency of the boiler and grate (see *Boilers*).

Let  $R$  be the number of pounds of coal required per boiler-horse-power hour,  $P$  the pounds of air required per pound of coal,  $P'$  the boiler horse power and

$$v = \frac{1.31 B}{460 + t}$$
 = pounds per cubic foot of gas passing through the fan, where  $B$  is

the barometric pressure in inches of mercury and  $t$  the temperature of the gas in degrees Fahrenheit; then the volume of gas passing through the fan per

minute is  $Q = \frac{RWP}{60w}$ . This formula and the formula for  $w$  are strictly applicable

only to the case of a forced-draft fan, but the two formulas may also be used with but a small error for an induced-draft fan, taking for  $t$  in the latter case the temperature of the discharged products of combustion (about 500° F., when no economizer is used and about 300° F. with an economizer). The size of fan and the power required to operate it will be greater for induced draft than for forced draft, since in the former case the volume of gas passing through

the fan is greater. According to Gebhardt the power required to operate forced-draft system for a plant of 1000 boiler horse power or more, will run from 1 to 5 per cent of the plant capacity.

**COSTS (Pre-war figures).**— According to Gebhardt the cost of a forced-draft fan, engine and stub stack for a plant of 1000 boiler horse power or more will approximate 20 to 30 per cent of the cost of an equivalent brick chimney. The cost of a single induced fan, engine, stack, etc., will approximate 40 to 50 per cent of the cost of an equivalent brick chimney, and the double-fan outfit will be 50 to 60 per cent of that of an equivalent brick chimney. Two per cent is liberal allowance for maintenance and depreciation of a brick or concrete chimney, while for a mechanical-draft system an allowance of from 4 to 10 per cent should be made. It costs nothing to operate a chimney, while from 1 to 5 per cent of the cost of operation of a boiler plant is chargeable to a mechanical-draft system.

**BIBLIOGRAPHY.**— Gebhardt, *Steam Power Plant Engineering; Mechanical Draft*, published by B. F. Sturtevant Co., Boston.

**DREDGES, ELECTRICALLY OPERATED.** — (See also *Motors, Industrial Applications of*.) Electrically operated dredges are now used very generally, especially in connection with gold mining. This drive has indisputably won its advantages over steam drive from the standpoint of both operation and economy, as individual motors can be applied to the various units of the dredging machinery, and a larger percentage of the power input can thereby be profitably applied in useful work.

The standard form of dredge is of the continuous-chain, close-connected bucket type, ranging in capacity from 3 to 16 cubic feet and with a digging depth from 40 to 60 feet. As the power is mostly obtained by transmission from the hydroelectric power system or central generating station, alternating current is generally used for driving the dredge machinery. For a modern all-mining dredge this consists of the digger or bucket line, the winch, the high- and low-pressure pumps, the priming pump, the screen and the sluice.

**Bucket Line.** — The bucket line is supported on a sheet-steel or girder structure of massive construction, so as to resist the heavy strains while in operation, especially when striking rock. The speed varies from 50 feet (with from 16 to 25 buckets) to 75 feet (with from 35 to 50 buckets) per minute, depending upon the condition of the ground.

For operation and control of the digger a variable-speed induction motor is used. This is located on the lower deck and belted to the driving pulley, which is generally situated in the rear of the pilot house on the upper deck. The duty imposed upon this motor is severe, as it must operate under conditions calling for a power varying from 75 per cent overload down to 25 per cent of its rated capacity. A drum-type controller for forward and reverse operation is provided, including the necessary resistance for continuous operation on any notch of the controller from one-half to full speed. The maximum starting torque is required and obtained at about the fourth point of the controller, thus leaving three points on which to bring the motor up to half speed, at which time nearly all rated torque is required. As a result of these conditions the ordinary motor designed for intermittent service cannot be successfully applied.

The raising and lowering of the bucket-line ladder is generally accomplished by a friction clutch which can be connected to the digger motor. For the larger dredges, however, a separate motor is often provided to perform this duty.

**Winch.** — To keep the dredge in place and to move it about or hold it against the bank when digging, head lines are used, which are controlled from the forward end and operated by a six- or eight-drum winch driven by a variable-speed motor. The winch motor, though of smaller capacity, is of the same staunch construction as the digger motor and is equipped with a suitable controller and resistance to permit its continuous operation from one-half to full speed. It has been found advisable to equip the motors for this service with solenoid brakes, by means of which the motor can be brought to a standstill almost instantly. It is then ready for the reverse operation without the usual reversing of the motor through the controller, which is not only bad practice but may result in a burn-out due to the heavy strain on the windings.

**Pumps.** — The high- and low-pressure pumps for supplying water to the screens and sluices are generally connected to individual motors. Constant-speed squirrel-cage motors of compact construction and large overload capacity, with speed of from 600 to 900 r.p.m., are usually installed for this work.

To prevent the filling up of the basin, in which the dredge floats, when digging in shallow water, it is sometimes found necessary to install a sand pump,

which carries the fine tailings from the sluice boxes to the top of the rock way of the stacker.

**Priming Pump.**—A priming pump is required for priming the large or for supplying water on the tables during the "clean-up." It consists of a small centrifugal pump driven by a high-speed direct-connected cage induction motor.

**Screen.**—Either a shaking or revolving screen is used to separate the from the clay and permit the fine particles containing the gold to pass on to the gold tables and sluices below. For this service a constant-speed is recommended, which can be placed on the upper deck and belted down driving pulley of the screen.

**Stacker.**—After screening the large rocks are carried on a belt conveyor to the end of the stacker and deposited on the spoil in the rear of the dredge. operating this conveyor a constant speed motor is installed at the extreme end of the stacker, where it can be readily housed.

**Monitor.**—When a dredge is working in a high bank of hard material experience has demonstrated that it is advisable to lower the water level and cut the bank down with a "Giant," water being furnished by a three- or four-stage, high-pressure centrifugal pump driven by a phase-wound induction motor. The Giant is mounted on the bow of the boat, and as the dredge moves from one side of the cut to the other, the stream of water is thrown against the bank about two feet above the water level. This undermines the bank, and the material to cave into the pond where it is brought up by the bucket line. The Giant is also used in localities where the water in the pond cannot be high enough to bring the bucket line near the top when the dredge is working ahead.

**Power Required.**—The sizes of motors required for driving the machinery of some dredges of different capacities are given in the following table. The proper speeds will depend on whether the motors are to be belted or direct connected to the machines which they are to drive.

SIZES OF MOTORS FOR DREDGES

Machinery to be driven	3 cu. ft. dredge, 40-ft. digging depth		5 cu. ft. dredge, 40-ft. digging depth		7 cu. ft. dredge, 40-ft. digging depth		13½ cu. ft. dredge, 40-50 ft. digging depth		16 cu. ft. dredge, 40-ft. digging depth
	H.P.	R.p.m.	H.P.	R.p.m.	H.P.	R.p.m.	H.P.	R.p.m.	
Bucket line	75	720	100	720	150	600	300	514	400
Winch	15	720	25	720	25	720	35	600	50
High-pressure pump	40	900	50	900	50	900	150	720	150
Low-pressure pump	25	600	25	600	25	600	75	600	100
Priming pump	7½	1200	7½	1200	7½	1200	25	1200	35
Screen	25	900	25	900	25	600	75	600	150
Stacker	20	900	20	900	25	600	50	600	50

**Usage of Motors.** — The power for operating a dredge is generally transmitted from some existing power system, and the connection between the line to the dredge is, as a rule, made by means of armored cable carried on floats. In this transmission can be economically carried out at a voltage of 2200, customary to provide the motors for this voltage, thus eliminating the expense of installing step-down transformers. When the transmission voltage is more than 2200 volts, it is desirable to step it down to 440 volts and use motors for this voltage. When step-down transformers are required, their capacity is usually taken as two-thirds of the total horse-power load, allowing one kilowatt per horse-power.

**DYNAMOTORS.** — (See also *Converters, Synchronous; Motor-Generator Transformers.*) A dynamotor is a direct-current device combining both motor and generator action in one magnetic field. It has an armature having two windings and two separate commutators, one at each end of the armature. Either winding may be used as the motor winding, and the other as the generator winding. Such a machine performs the same function in a direct-current circuit that a power transformer does in an alternating-current circuit, serving as a means of transforming high-voltage direct current into low-voltage direct current, or vice versa.

**Performance Characteristics.** — The device corresponds to two machines which share a common magnetic field, in which there is only one core-loss, one friction loss, one excitation loss, and one loss due to  $R I^2$  in the two armature circuits. It is therefore more efficient than a motor-generator set, but less efficient than one machine. Since the currents in the two windings flow in opposite directions their resultant magnetic effect is zero. The machine has therefore no armature reaction, and for the slight amount due to the current to overcome the losses in the machine. It is not subject to the troubles of field distortion and bad commutation which occur in either motors or generators. It is impossible to compound a dynamotor as a motor, since any increase in field strength intended to increase the voltage of the generator would decrease the speed of the motor by the same amount, and no change would result. The ratio of the two voltages is therefore fixed by the number of turns, and only varies from this by the loss due to  $R I$  drop in the two windings. These two drops are additive, and therefore the regulation of a dynamotor machine is not very good.

**Applications.** — Dynamotors are used largely to give large currents to other motors, or to give low voltages or a fractional voltage in a multi-voltage system for speed control. The motor of the combination may be wound for the line voltage and the generator for any fraction of the line voltage. In such a case the combination supplies a large current at a low voltage, which will give good starting torque in motors connected to it with a reasonable consumption of power. They are used as equalizers or "balancers" in three or more motor circuits, but are not as desirable for this work as motor-generator sets or compound-wound machines, on account of their poor regulation. They are also used to supply a low voltage for such purposes as telephone and telegraph systems and the low voltage and large currents for electrolytic work.

Dynamotors are also used in radio work in connection with vacuum tube detectors and amplifiers, in order to obtain from a battery of 4 to 10 volts a voltage of 300 for operating the tube.

**ELECTRICITY AND MAGNETISM, PRINCIPLES OF.** — In this article are given definitions of the various electric and magnetic quantities, together with a brief statement of the fundamental principles in accord with which all electric and magnetic phenomena take place.

The following is a brief table of contents of this article:

Units and Working Hypothesis.....	p. 393
Electric Fields of Force.....	394
Electromotive Force.....	395
Flow of Electricity.....	397
Electric Energy and Power.....	404
Dielectric Flux and Electric Charge.....	405
Electrostatic Capacity and Condensers.....	408
Electrostatic Energy and Forces.....	412
Magnetic Fields of Force.....	414
Electromagnetic Induction.....	416
Self and Mutual Induction.....	424
Energy of the Magnetic Field.....	428
Forces in the Magnetic Field.....	430

**UNITS AND QUANTITATIVE LAWS.** — Three different systems of units are in use in terms of which electric and magnetic quantities are expressed. These systems are known as the c.g.s. electrostatic system, the c.g.s. electromagnetic system and the practical system (see also *Units, Practical Electric*). Various units in the practical system have been given short names which are in common use, e.g., ampere, volt, coulomb, etc. For the sake of brevity the corresponding units of the electrostatic system will be designated by these same names with the prefix "stat.," and the corresponding units in the c.g.s. electromagnetic system will be designated by these same names with the prefix "ab," the latter prefix arising from the term "absolute" sometimes applied to this system.

The use of the electrostatic and electromagnetic systems of units arises from the manner in which certain of the fundamental quantitative relations, or laws, were originally formulated. The practical system is related to the electromagnetic system, by even multiples of ten times the units in the latter, i.e., 1 volt =  $10^8$  abvolts, 1 ampere =  $10^{-1}$  abamperes, 1 ohm =  $10^9$  abohms.

The quantitative relations given below between electric quantities are independent of the system of units employed provided all the quantities involved are expressed in the same system of units. (See *Units and Conversion Factors*.) For some of the magnetic quantities, certain additional practical units have been introduced which are not related to the c.g.s. electromagnetic units by multiples of 10; consequently, to avoid confusion it is best to reduce all quantities to electromagnetic units before applying any of the formulas given.

**WORKING HYPOTHESIS REGARDING THE NATURE OF ELECTRICITY.** — The various facts of experience described as electric and magnetic phenomena can best be coordinated by assuming at the outset the existence of electricity as an actual entity, possessing the following properties:

1. Electricity exists in two forms, which for convenience may be called "positive" and "negative" electricity. These names arise from the fact that the two kinds of electricity produce certain effects which are just the opposite of each other, and, therefore, under certain conditions the external effect of one kind of electricity may completely neutralize the effect of the other kind.
2. A given quantity of electricity is called an "electric charge."
3. All matter contains electricity of both kinds, even when in the neutral or "uncharged" state. An uncharged body contains in every elementary portion (molecule) equal quantities of positive and negative electricity, so thoroughly

"mixed" that no external effects are produced, unless the two kinds of electricity are constrained to take up a definite position or to move in a definite manner.

3. A body or portion of a body can be charged with electricity of either kind either by adding to it electricity of that kind or by taking away from it electricity of the other kind. In general only the *surface* of a body can be charged, i.e. the excess or deficit of charge exists only at the surface of separation between the body and some other body, the interior elements of the body containing, as in the neutral state, equal amounts of electricity of opposite kinds.

4. It is impossible to charge a body with electricity of one sign without producing on the same or on some other body an equal charge of the opposite sign.

5. Forces can be produced on the electricity in a body by various external agents, without necessarily producing a force on the body as a whole. When such forces are produced the two kinds of electricity are either displaced relatively to each other or are constrained to move through the body in opposite directions. This displacement or motion is always opposed by forces set up within the body itself. The opposing forces are of two kinds, (1) a force analogous to the opposing force set up in an elastic body when it is stretched-compressed, and (2) a force analogous to the resisting force due to mechanical friction produced when one body moves over another.

6. When the electricity in a body is acted upon by an external force, it cannot escape from that body to another, this force is transmitted to the body itself.

7. Electricity possesses inertia, just as ordinary matter possesses inertia; i.e., force is required to change the motion of a charge of electricity just as a force is required to change the motion of a portion of matter. The "effective" inertia of a given quantity of electricity depends upon the path over which it is caused to move and upon the nature of the surrounding bodies (*see Electric Theory*).

**Unit of Charge or Quantity of Electricity.**—The unit of electric charge or quantity of electricity in the practical system of units is called the coulomb. For the relation between the coulomb, statcoulomb, abcoulomb and other units of quantity see *Units and Conversion Factors*.

**ELECTRIC FIELDS OF FORCE.**—In any portion of a substance in which the electricity is acted upon by a force tending to move it, there is said to be an "electric field of force," or briefly an "electric field." An electric field is also said to exist in any region of free space where a charge, if placed there, would have a force exerted upon it tending to move it.

**Intensity of an Electric Field ( $F$ ).**—The "intensity" of an electric field at any point is defined as the force per unit positive charge exerted on a charge at this point by the agent or agents producing the field i.e., by the agent or agents tending to move the charge. The direction of the field intensity, or the direction of the field, is defined as the direction of the force acting on a *positive* charge at this point. A positive charge then moves or tends to move in the direction of the field and a negative charge moves or tends to move in the opposite direction.

**Units of Electric Field Intensity.**—The unit of electric field intensity has not been given any special name, but since it is of the same nature as electromotive force per unit distance, the intensity at any point may be conveniently expressed as so many volts, abvolts or statvolts per centimeter or  $\frac{1}{100}$  inch; see *Units and Conversion Factors*. Hence electric field intensity is frequently called the potential, or voltage, "gradient."

**Lines of Electric Force.**—**Lines of Electric Intensity.**—A line drawn in an electric field in such a manner that its direction at each point coincides

the direction of the field at that point is called a "line of electric force." A line of force is usually a curved line, though in certain special cases it may be straight. Any number of such lines may be drawn in an electric field, but no two of these lines can intersect. The density of these lines, i.e., the number drawn through unit area perpendicular to their direction, may be chosen arbitrarily to represent the value of the field intensity at this area, and when drawn are preferably called "lines of electric intensity," as distinguished from flux lines and stream lines defined below. The term "lines of force," however, is frequently used to designate any one of these three sets of lines, but its loose use of the term is liable at times to lead to much confusion. The term "line of electric force" will be used in this article to designate merely the locus of the field at any point; in any statement involving the density of force lines the proper one of the other terms will be employed.

**Electric Equipotential Surfaces.** — A surface drawn in an electric field in such a manner that it is perpendicular at each point to the line of force through that point is called an "electric equipotential surface." The electric intensity has no component along such a surface, and therefore no work is required to move a charge from one point to another over any path in such a surface.

**ELECTROMOTIVE FORCE ( $E$ ).** — The work done by the field intensity in moving unit positive charge around any closed path or circuit (Fig. 1) in a uniform field is defined as the "electromotive force," abbreviated "e.m.f.," acting around this path. Electromotive force is not a force in the mechanical sense; it is work per unit charge. The relation between electromotive force  $E$  and field intensity  $F$  is analogous to that between work and mechanical force viz.,

$$E = \int (F \cos \theta) dl, \quad (1)$$

Fig. 1.

where  $dl$  represents an elementary length of the path,  $(F \cos \theta)$  the component of the field intensity along  $dl$  and  $\int$  represents the integral around this closed path. When the field intensity has the same value  $F$  at every point of a path and coincides in direction with the path at every point, the electromotive force acting around the closed loop is

$$E = Fl \quad (1a)$$

where  $l$  is the total length of the path.

**Units of Electromotive Force.** — The practical unit of electromotive force is the volt; see *Units, Practical Electrical*. See also *Units and Conversion Factors* for the other units and their interrelations.

**Sources of Electromotive Force.** — The primary sources of e.m.f. are (1) two dissimilar bodies in contact (see *Batteries; Electrochemistry, Principles*) and (2) a varying magnetic flux linking the circuit (see the articles on *Generators; Transformers, etc.*). The e.m.f. is said to be "located" at the surface of contact in the case of a "contact" e.m.f., or in that portion of the circuit which is linked by the varying magnetic flux in the case of an "induced" e.m.f., for experience shows that the value of the work integral, equation (1), around any circuit passing through a given surface of contact or linking a given varying flux is always the same, irrespective of the shape of the circuit and of the nature of substance through which the path passes, provided there are no other sources of e.m.f. in this path. Contact e.m.f.'s are usually extremely

small (of the order of 0.001 volt) except in the case of metallic substance in contact with electrolytes, in which case they may amount to several volts. *Batteries; Electrochemistry, Principles of.* E.m.f.'s of 500,000 volts or more may be produced by a varying magnetic flux.

**Direction of an Electromotive Force.** — The direction of the e.m.f. in any portion of a circuit is taken as the direction in which a positive charge would be forced around a circuit containing only this one source of e.m.f. A circuit may contain several sources of e.m.f.; in this case the resultant e.m.f. acting around in the circuit is the algebraic sum of all these e.m.f.'s, the e.m.f. acting around the circuit in one direction being taken as positive and the e.m.f. acting around the circuit in the opposite direction being taken as negative. e.m.f.'s which act in the opposite direction to the resultant e.m.f. are called "back" or "counter" e.m.f.'s.

A convenient symbol for a source of constant e.m.f. is shown in Fig. 2. A long light line represents the positive terminal and the short heavy

Fig. 2.

Fig. 3.

Fig. 4.

negative terminal. Fig. 3 shows two e.m.f.'s acting around a circuit in the same direction, and Fig. 4 shows two e.m.f.'s acting around the circuit in opposite directions. In the first case the resultant e.m.f. is  $E_1 + E_2$  and the two e.m.f.'s are said to be "in series," and in the second case the resultant e.m.f. acting around the circuit in the right-handed direction is  $E_1 - E_2$  and the two e.m.f.'s are said to be "in opposition." When  $E_2$  is less than  $E_1$  then  $E_2$  is a counter e.m.f.

**DIFFERENCE OF ELECTRIC POTENTIAL ( $V$ ).** — Consider a path  $A$  between any two points 1 and 2 in an electric field. The total work done on unit charge, by the e.m.f.'s external to this portion of the path when unit charge moves from 1 to 2, is called the "drop of electric potential" from 1 to 2. The term "difference" of electric potential is also commonly used to designate this quantity; the term "drop" is preferable since it indicates the direction of the difference. Electric potential drop is of the same nature as electromotive force and is expressed in the same units. It is frequently designated "p.d." Potential drop may be due either (1) to a "back" electromotive force, analogous to the back pressure of a pump, or (2) to an opposing force, analogous to that due to the resistance of a pipe to the flow of water.

Let the path from 1 to 2 be in the direction of the line of force from the source; let  $E_{12}$  be an e.m.f. whose source is between 1 and 2 and whose direction is from 1 to 2, then the general expression for the potential drop from 1 to 2 is

$$V_{12} = \int_1^2 F \, dl - E_{12}.$$

The first term represents the "resistance" drop and  $-E_{12} = E_{21}$  represents the "back" pressure. If the field intensity along the path from 1 to 2 is constant, then  $V_{12} = -E_{12}$ ; hence an e.m.f. in a given direction is equivalent to a drop of potential, i.e., is equivalent to an actual rise of potential. Con-

with equation (1) it is evident that the total drop of potential around a closed path is always zero. This relation is conveniently expressed by the formula

$$\oint \mathcal{E} \cdot d\mathbf{s} = 0 \quad (3)$$

which holds for every closed path or circuit. This is one way of stating Kirchhoff's second "law."

**Voltage and Voltage Gradient.** — The term "voltage" is commonly used either as an e.m.f. or a potential difference, particularly when these quantities are expressed in volts. Since from equation (2) the field intensity  $F$  is equal in value to the drop in voltage per unit length, the electric field intensity is also frequently called the voltage "gradient."

**Positive and Negative Terminals.** — That terminal of a device which is at the higher potential is called the positive terminal, the other terminal being called the negative terminal. The drop of potential is always from the positive to the negative terminal, irrespective of the direction of flow of electricity through the device.

**FLOW OF ELECTRICITY.** — Whenever an electric field is set up in a substance by any means whatever a displacement of the electricity in that substance always takes place, the nature of the displacement depending upon the nature of the substance. In every case the positive electricity within the substance is displaced in the direction of the field intensity and the negative electricity in the opposite direction, until an opposing force of some kind is set up which just balances the forces due to the impressed field.

**Conductors and Insulators or Dielectrics.** — A substance in which a constant electric field is always accompanied by a continuous displacement or flow of electricity through the substance is called an "electric conductor;" when there is no flow of electricity through a conductor the field within the conductor is always zero. Every substance is a conductor of electricity, at least to a slight extent, but some substances are far better conductors than others. A substance in which a constant electric field produces only a relatively small continuous flow of electricity is called an "electric insulator" or "dielectric." A perfect dielectric may be defined as a substance through which it is impossible to set up a continuous flow of electricity; no such substance exists, but very poor conductors are approximately such. Free space may be considered a perfect dielectric, but free space differs from a substance in that it does not contain electricity.

Metals are the best conductors, carbon and most moist substances are fair conductors; dry non-metallic bodies such as air and other gases (at normal pressure), porcelain, glass, rubber, and dry paper are very good insulators.

A wire covered with an insulating substance or supported on insulating substances is said to be "insulated," even though its ends are connected to a source of e.m.f.

**Electric Current (I).** — The displacement of the electricity within a substance cannot be measured directly, but only in terms of some effect produced thereby. Two effects which always occur when a displacement of electricity is produced are (1) a magnetic field is established around the path along which the displacement takes place (but disappears when the electricity comes to rest) and (2) heat is developed in the path of the displacement. The magnetic field produced by a displacement or flow of electricity is usually taken as the measure of the rate of flow, i.e., of the quantity of electricity displaced per unit time through a surface perpendicular to the direction of the displacement. This rate of flow is called the "intensity" of the electric current, or simply the "electric current," and is usually represented by the symbol  $I$ .

**Direction of the Electric Current.**—A flow of positive electricity in one direction is equivalent magnetically to a flow of an equal amount of negative electricity in the opposite direction; hence the total flow along a given path is the sum of the positive electricity displaced per unit time in one direction at any point in this path plus the negative electricity displaced per unit time past that point in the opposite direction. The "direction" of the electric current is defined as the direction in which the positive electricity is displaced, and is, therefore, the same as the direction of the field intensity.

**Current due to Varying Electric Field.**—When the electric field in any substance is *varying*, the total magnetic effect produced is found to depend not only upon the rate of displacement of the electricity within the substance, but also upon the *rate of change* of the electric field. In fact, a magnetic field is produced around a path in *free space* along which the intensity of the electric field is *varying*, see *Waves, Electromagnetic*. In dealing with *varying electric fields* it is found convenient to consider the variation of the field intensity as equivalent to an actual flow of electricity, and to take as the total equivalent electric current the flow of electricity which would produce the same magnetic field as that actually observed; the *actual* flow of electricity is then in general less than this equivalent current, but the difference is negligible except in substances which are good insulators.

**Units of Electric Current.**—The practical unit of electric current is the ampere; see *Units, Practical Electrical*. For the relation between this unit and the statampere and abampere see *Units and Conversion Factors*.

**Continuity of an Electric Current.**—When a *varying electric field* is considered as equivalent to an electric current, it is found that the total equivalent current coming up to any point or surface in any network of circuits, no matter how complicated, is *always* equal to the total current leaving that point or surface, irrespective of the nature of the substances through which the currents are established and irrespective of whether the currents are constant or are *varying*. For example, in Fig. 5,

$$I_1 + I_2 = I_3 + I_4 + I_5. \quad (4)$$

Fig. 5.

Or, calling the currents coming up to any point positive, and the currents leaving that point negative, the *algebraic* sum of all the currents at any point in a network of circuits is always zero. This fundamental principle is conveniently expressed by the formula

$$\Sigma I = 0$$

which holds at every junction point both for variable and for continuous currents. This is Kirchhoff's first "law."

**Stream Lines of Electric Current.**—**Current Density ( $\sigma$ ).**—As a consequence of the continuity of an electric current, the total current in any substance of any size or shape may be looked upon as made up of a number of small streams of electricity flowing side by side, the strength (quantity of electricity per second) of each stream being constant throughout its length. If the cross-section of each stream at any point is so chosen that each stream represents unit current (unit quantity per second), then the number of streams crossing unit area of a surface perpendicular to their direction will be equal to the current per unit area of this surface, or to the "current density" at this surface. Each such stream may be represented graphically by a line coinciding with its axis; such lines are called "stream lines." When the stream lines are drawn as described their direction at any point gives the direction

current at this point and the number of these lines per unit area perpendicular to their direction is equal to the current density at this point.

In the case of an insulated wire the stream lines are parallel to the axis of the wire, except in the immediate vicinity of its ends; this non-uniformity at the ends is in the case of a long wire negligible. The stream lines in an ordinary wire may also, in most practical cases, be considered as all coinciding, and the wire may, therefore, be treated as a geometrical line as regards external effects. However, in the case of a short rod or strip (such as an ammeter shunt) connected in the circuit by wires attached to its ends, the stream lines are not in general parallel but diverge from one terminal and converge toward the other.

**Continuous, Direct, Pulsating, Alternating and Oscillatory Currents.**—A "continuous" electric current is defined as a current which does not vary with time. A "direct" current is a current which is always in the same direction but may vary or pulsate in value. The term "direct current" is ordinarily used to designate either a continuous current or a current which varies but pulsates only by an inappreciable amount, such as the current from a battery or direct-current generator (d.c.). A "pulsating" current is a direct current which pulsates by an appreciable amount, such as the current from a rectifier (r.f.). An "alternating" current is a current which reverses in direction, being first positive and then negative, but alternates between constant maximum positive and negative values; see article on *Alternating Currents*. An "oscillatory" current is a current which reverses in direction, oscillating between positive and negative values which either decrease or increase with time.

**Conduction Current and Displacement Current.**—Experience shows that when an electric field is established in any substance, the total equivalent electric current set up depends (1) upon the value of the field intensity, (2) upon the rate of change of the field intensity, and (3) upon the nature of the substance in which the field is established. The current density  $\sigma$  at any point at any instant may in general be expressed by the relation

$$\sigma = \gamma F + \frac{1}{4\pi} \frac{d}{dt} (kF), \quad (6)$$

where  $F$  is the field intensity,  $\gamma$  and  $k$  are coefficients depending upon the chemical nature and physical condition of the substance at the point in question, and  $\frac{d}{dt}$  means the rate of change with respect to time, the factor  $4\pi$  arising from the historical definition of the quantity  $k$ , see below. The total current may then be considered as the sum of two components having respectively the densities

$$\sigma_1 = \gamma F \quad \text{and} \quad \sigma_2 = \frac{1}{4\pi} \frac{d}{dt} (kF). \quad (6a)$$

The first of these components ( $\sigma_1$ ) is called the "conduction" current, and the second ( $\sigma_2$ ) is commonly called the "displacement" current. The term "displacement" current, however, is somewhat a misnomer, for both components of the total current are probably due, in part at least, to a displacement of electricity; whereas a displacement current is set up by a varying electric field in a free space, although there is probably no electricity in free space to be displaced. The conduction current is the only appreciable component in substances usually classed as conductors, and the displacement current is appreciable only in substances ordinarily classed as dielectrics. The conduction current in a dielectric is usually small, though measurable; it is frequently called the "leakage" current. When the electric field in a dielectric is rapidly varying the displacement current may be many times greater than the conduction or leakage current through the dielectric.

**Conductivity ( $\gamma$ ) and Resistivity ( $\rho$ ).** — The quotient of the density  $\sigma$  of the conduction current by the field intensity  $F$ , i.e., the coefficient  $\gamma$  in expression  $\sigma = \gamma F$  is called the "conductivity" of the substance at the point in question. Since in an ordinary conductor the displacement current is appreciable, the conductivity of an ordinary conductor is also equal to the density of the total current divided by the field intensity, i.e., for a conductor

$$\sigma = \gamma F, \quad (7)$$

where  $\sigma$  represents the density of the total current. Experience shows that: a given conductor at constant temperature (and also at constant pressure, in case of a gas) this coefficient  $\gamma$  is a constant irrespective of the strength, distribution or time variation of the current. The value of  $\gamma$  for a dielectric, however, is not in general a constant but depends upon the time variation of the field intensity; see below under *Capacity and Condensers*.

The above relation between  $\sigma$  and  $F$  may also be written

$$F = \rho \sigma, \quad (7)$$

where  $\rho$  is the reciprocal of the conductivity  $\gamma$ . The constant  $\rho$  is called the "resistivity" or "specific resistance" of the substance. Values of  $\gamma$  and  $\rho$  for various conductors are given in the article on *Resistance and Conductance*, and also the methods of measuring these quantities. The values of  $\gamma$  and  $\rho$  for some of the more common insulating materials are given in the article on *Insulating Materials, Properties of*. For the units of conductivity and resistivity see *Units and Conversion Factors* and also the next two paragraphs.

**Conductance ( $g$ ) and Resistance ( $r$ ).** — To cause a *continuous* current  $I$  to flow through a given conductor in which there is no source of e.m.f. a difference of potential must be established by some external agent between the ends of the conductor. Let  $V$  be the potential drop established through the conductor from any point 1 to any other point 2, then the quotient

$$g = \frac{I}{V} \quad (8)$$

is defined as the "conductance\*" from 1 to 2, and the quotient

$$r = \frac{V}{I} \quad (8a)$$

is defined as the "resistance\*" from 1 to 2. Conductance is the reciprocal of resistance and vice versa. The practical unit of resistance is called the ohm and the practical unit of conductance is called the mho; see *Units and Conversion Factors*.

It should be carefully noted that the definitions expressed by equations (8) and (8a) hold only when there is no e.m.f. in the portion of the circuit under consideration; this condition is realized only when the current remains constant in value (i.e., a *continuous* current) and the conductor is of uniform material and at constant temperature throughout. Also, the definition is meaningless unless the same current flows through each cross-section of the conductor and the drop of potential is the same between all points in the two end surfaces; i.e., the end surfaces must be equipotential surfaces.

**Factors Upon Which Conductance and Resistance Depend.** — The resistance or conductance of a given portion of a conductor included between

equipotential surfaces and bounded laterally by a surface through which stream line passes, depends upon (*a*) the conductivity of the conductor the dimensions of this portion of the conductor, and (*c*) the distribution of stream lines over each cross-section perpendicular to them. Consider now a straight wire or bar over the cross-section of which the current is evenly distributed. Let  $l$  be the length of the bar,  $A$  its cross-section and resistivity. Then from equation (2) the drop of potential along the length  $V = RI$ ; from equation (7a)  $R = \rho l / A$ ; therefore  $V = \rho l I / A$ . The total current is  $I$ ; whence the resistance and conductance are

$$r = \rho \frac{l}{A} \quad \text{and} \quad g = \gamma \frac{A}{l} \quad (9)$$

hence, the conductivity of a substance is equal to the conductance, and the resistivity is equal to the resistance, of a unit cube of this substance when the current through this cube is parallel to four edges of the cube and is uniformly distributed over the section at right angles to these four edges. Hence conductivity is frequently expressed as mhos per centimeter cube or inch cube; see *Units and Conversion Factors*.

Equation (9) is applicable only to a conductor in which the stream lines are evenly distributed and parallel to each other, such as in insulated wires carrying sinusoidal or comparatively slowly varying currents. When the stream lines are not parallel to each other, let  $dl$  represent an elementary length along a stream line and  $\sigma$  the current density at  $dl$ ; then taking the integral along a stream line from one end surface to the other, the resistance is

$$r = \frac{\rho \int \sigma dl}{I} \quad (9a)$$

where  $I$  is the total current. The calculation of the value of  $\sigma$  at each point along the line from one surface to the other is difficult except in certain special cases of symmetry; see however, equation (22) below.

**Ohm's Law and Resistance Drop.** — From the relations noted above it is seen that, in a conductor (*a*) which remains at constant temperature, (*b*) in which there is no internal e.m.f., and (*c*) in which the distribution of stream lines remains unaltered, the quotient of the voltage by the current is a constant. This constant is known as Ohm's Law; it holds only when the three conditions specified above are fulfilled.

The above relation may also be written  $V = rI$  which is merely another form of equation (2); i.e., if  $r$  is the resistance between any two points 1 and 2 in an electric circuit in which the current is  $I$ , then the integral of the electric field intensity along the path from 1 to 2 is equal to  $rI$ . This drop of potential is solely to resistance between 1 and 2 is called the "resistance drop" from 1 to 2, and is always in the direction of the current. When there is an e.m.f. in the circuit between 1 and 2 and the distribution of current remains unaltered, the total drop from 1 to 2, from equation (2), is

$$V_{12} = rI_{12} - E_{12} \quad (10)$$

where the subscripts indicating the directions of the various quantities. Equation (10) is sometimes referred to as the "modified" Ohm's law.

In general, the distribution of current depends upon the time variation of the voltage. See article on *Skin Effect*.

**Terminal and Impressed Voltages.** — The application of this eq. is best shown by considering a simple circuit containing a generator and one or other receiving device, Fig. 6. Let  $I$  be the current in this circuit,  $R_g$  the internal resistance of the generator,  $R_m$  the internal resistance of the motor and  $R_l$  the total resistance of the "line" or connecting wires, let  $E_g$  be the e.m.f. developed by the generator and  $E_m$  the back e.m.f. developed by the motor, and let  $V_g$  be the terminal voltage of the generator and  $V_m$  the terminal voltage of the motor. Through the generator the current flows from the - to the + terminal, the e.m.f. is from the - to the + terminal, and the drop of potential is from the + to the - terminal. Hence

$$V_g = E_g - R_g I,$$

i.e., the terminal voltage is less than the generator e.m.f. by an amount equal to the resistance drop in the armature. Through the motor the current flows from the + to the - terminal, the e.m.f. is from the - to the + terminal, and the drop of potential is from the + to the - terminal. Hence

$$V_m = E_m + R_m I,$$

i.e., the terminal voltage is greater than the back e.m.f. of the motor by an amount equal to the resistance drop through the motor.

The terminal voltage of the motor is less than that of the generator by an amount equal to the resistance drop in the line, i.e.,

$$V_m = V_g - R_l I.$$

The expression "impressed" electromotive force is also used to designate the rise of potential from the negative to the positive terminal of any device, whether it be a motor, bank of lamps, or any "straight" resistance containing no source of electromotive force.

**Series Circuits.** — When several conductors are connected end to end so that the same current flows through each of them (Fig. 7), they are said to be connected "in series." Let  $I_{12}$  be the current in each conductor in the direction from 1 to 2, let  $R'$ ,  $R''$ ,  $R'''$ , etc., be the resistances of the various conductors and  $E'_{12}$ ,  $E''_{12}$ ,  $E'''_{12}$ , etc., be the e.m.f.'s in the circuit between 1 and 2 in the direction from 1 to 2. Then the potential drop from 1 to 2 is

$$V_{12} = R' I_{12} - E'_{12} + R'' I_{12} - E''_{12} + R''' I_{12} - E'''_{12}, \text{ etc.}$$

Therefore, the resistances between the points 1 and 2 are equivalent to a single resistance

$$R = R' + R'' + R''', \text{ etc.},$$

and the e.m.f.'s between the points 1 and 2 are equivalent to a single e.m.f.

$$E_{12} = E'_{12} + E''_{12} + E'''_{12}, \text{ etc.}$$

Fig. 6.

Fig. 7.

equivalent conductance of several conductances  $G'$ ,  $G''$ ,  $G'''$ , etc., in series there are no e.m.f.'s in the path, is  $G$  where

$$\frac{1}{G} = \frac{1}{G'} + \frac{1}{G''} + \frac{1}{G'''} + \dots \quad (11b)$$

**Parallel Circuits.** — When several conductors are connected to two common points so that the same potential drop is established through each (Fig. 8), they are to be "in parallel." Let the currents, e.m.f.'s, resistances be as designated in the figure. From equation (5)

$$I_{12} = I'_{12} + I''_{12} + I'''_{12} + \text{etc.}$$

from equation (10a)

$$V_{12} = R'I'_{12} = E'_{12} = R''I''_{12} = E''_{12} = R'''I'''_{12} = E'''_{12} = \text{etc.},$$

which relations the currents in the individual branches may be calculated. If there are no e.m.f.'s in the various branches, the combined resistance of several branches from 1 to 2 is  $R$  where

$$\frac{1}{R} = \frac{1}{R'} + \frac{1}{R''} + \frac{1}{R'''} + \dots, \quad (12)$$

the combined conductance is

$$G = G' + G'' + G''' + \dots, \quad (12a)$$

or  $G_1, G_2, G_3$ , etc., are the individual conductances.

**Two Parallel Circuits.** — In the special case of two conductors in parallel, no e.m.f. in either, the combined resistance is

$$R = \frac{R_1 R_2}{R_1 + R_2}. \quad (12b)$$

**Series-parallel Circuits.** — When a circuit is made up of several conductors some of which are in series and some in parallel, it is called a "series-parallel" circuit. The total resistance or conductance of such a circuit can be calculated if the constants of the several branches by applying successively the formulas for series and for parallel circuits.

**Kirchhoff's Network Laws.** — The relations given above for conductors in series and in parallel are special cases of two general laws already stated, namely:

The algebraic sum of the currents coming up to any junction in a network of conductors is always zero (equation 5).

The algebraic sum of the potential drops around any closed loop in a network of conductors is always zero (equation 3).

These two laws are known as Kirchhoff's Laws, from the name of the scientist who first clearly enunciated them. By making use of them one can always determine (a) the current in each branch of a network when the resistance of each branch and the e.m.f. in each branch are known, or (b) the e.m.f. in each branch when the current in each branch and the resistance of each branch are known.

It should be carefully borne in mind in applying these laws that a current entering a point is equivalent to a negative current entering that point, and that

Fig. 8.

an e.m.f. in any chosen direction is equivalent to a rise of potential in that direction. In working out any problem concerning a network of circuits it is convenient to make a diagram of the network and to place on each branch of this diagram a number or symbol to represent the value of the current in that branch and an arrow or subscript to indicate the direction of the current. The current represented by this number or symbol, and wherever there is an e.m.f. in a branch, a number or symbol to represent the value of this e.m.f. and an arrow or subscript to indicate its direction. Then at any junction point those currents represented by arrows pointing toward the point are to be considered positive (say) and those represented by arrows pointing away from the point are to be considered negative; and for any closed loop those currents and e.m.f.'s represented by arrows pointing around the loop in the clockwise direction (say) are to be considered positive and those pointing around the loop in the counter-clockwise direction are to be considered negative. With this understanding, these laws may be written

$$\Sigma I = 0 \text{ at every point,}$$

$$\Sigma E = \Sigma rI \text{ for every closed loop,}$$

where  $I$ ,  $r$  and  $E$  represent the current, the resistance and the e.m.f. in each branch of the loop, and the symbol  $\Sigma$  indicates the algebraic sum of the quantities following it.

These equations enable one to write down a set of simultaneous equations for the given network, but it will be found that at least one of the current equations may be derived directly from the other current equations, and that at least one of the potential equations may be derived from the other potential equations. That is, the number of independent equations of each form will be one less than the number which it is possible to write down. It should also be noted that it is frequently unnecessary to write down formally all the possible independent equations; many of the simpler problems can be solved by writing down independent expressions for the potential drop between each pair of points and equating these two expressions.\*

When the currents and e.m.f.'s are varying, the first law applies to all currents (conduction and displacement current), but the second law is given in (13b) applies only to closed loops of conduction current; in such cases the instantaneous values of the currents and e.m.f.'s must be taken when the quantities are varying.

**ELECTRIC ENERGY AND POWER.** — From the definition of potential drop it follows that the total work done by the external agents in forcing a unit of electricity from any point 1 in a circuit to any point 2 is  $W = V$ . From the definition of electric current the quantity of electricity carried from point 1 to point 2 when the current  $I$  is established from 1 to 2 is  $Q = It$ , where  $t$  is the time during which the current exists. Hence when a current  $I$  is established through a device for a time  $t$  by an impressed voltage  $V$ , the energy input to this device is

$$W = VIt$$

and the power input, i.e., energy input per unit time, is

$$P = VI.$$

When  $V$  and  $I$  are expressed in volts and amperes respectively the power is in watts; if  $t$  is in seconds, the energy input is in joules or watt-seconds; if  $V$  and  $I$  are in statvolts and statamperes respectively, or in abvolts and

\* The application of these laws to the solution of complicated network problems is given in detail in Del Mar's *Electric Power Conductors*, New York, 1913.

s respectively, the power input is in ergs per second, if  $t$  is in seconds the gy input is in ergs. See *Units and Conversion Factors*.

Applying the above relations to the simple circuit shown in Fig. 6 containing generator and a motor (armature windings only are considered), the power  $P_t$  to the motor armature is

$$P_t = E_m I + R_m I^2, \quad (15a)$$

power output of the generator armature is

$$P_g = E_g I - R_g I^2 \quad (15b)$$

the power lost in the line is

$$P_l = R_l I^2.$$

The term  $R_g I^2$  represents the power lost in heating the armature winding of the generator due to its resistance, and the term  $R_m I^2$  represents the power dissipated as heat in the armature winding of the motor. The net electric input to the generator armature is  $E_g I$  and the gross mechanical output of the motor armature is  $E_m I$ . The gross mechanical input to the generator is greater than  $I$  and the net mechanical output of the motor is less than  $E_m I$  by an amount equal to the friction and "core-loss" in the respective machines; see *Generators and Motors*.

**Joule's Law.** — That portion of the power input to any device which is equal to the product of the resistance of the conductors forming the winding of the device by the square of the current through this winding is always converted into heat. That is, when a current  $I$  flows through a resistance  $r$  heat is always dissipated in this resistance, and the rate of dissipation is

$$P_h = r I^2. \quad (15c)$$

This experimental fact is known as "Joule's Law." This law applies directly to continuous or non-varying currents. The relation  $P_h = r I^2$  is, however, also the basis for defining the "effective" resistance of a conductor to an alternating current (q.v.).

### DIELECTRIC FLUX ( $\psi$ ) AND DIELECTRIC FLUX DENSITY

$D$ . — As noted above the displacement current through a dielectric at any point depends upon the rate of change of the electric field intensity and upon the permittivity of the dielectric, and the density of this displacement current at any point may be expressed by the relation

$$i_d = \frac{1}{4\pi} \frac{d}{dt} (kF), \quad (16)$$

where  $F$  is the field intensity and  $k$  a coefficient depending upon the nature of the dielectric. The coefficient  $k$  in this expression is the so-called dielectric coefficient or dielectric constant.

The quantity  $kF$ , whose rate of change is equal to  $4\pi$  times the density of the displacement current, is called the "dielectric flux density," and may be represented by the symbol  $D$ . Then

$$D = kF. \quad (17)$$

The direction of the dielectric flux density is arbitrarily chosen to be the same as that of the electric field intensity  $F$ . Through any surface of area  $A$  at each point of which the dielectric flux density has a constant value  $D$  and is perpendicular to that surface, there is said to exist a "dielectric flux" equal to  $DA$ . The total dielectric flux through a surface may be represented by the symbol  $\psi$ .

In general, the total dielectric flux through any surface perpendicular *at* point to the direction of the field intensity at that point (i.e., through an potential surface) is

$$\psi = \int D ds,$$

where  $ds$  represents any elementary area of this surface and  $D$  the flux *de* per unit area at  $ds$ , and  $\int$  represents the sum of all the products  $D ds$  for surface. The total displacement current through this surface is then

$$i = \frac{1}{4\pi} \frac{d\psi}{dt}.$$

**Lines of Dielectric Flux.** — The electrostatic flux through any surface be represented by lines drawn in the same direction as the lines of electric intensity, but of such a density that *their number per unit area perpendicular to* direction at any point *is equal to the dielectric flux density at this point.* number of these lines cutting any surface is then equal to the total dielectric flux through this surface. The ratio of the number of flux lines through surface to the number of lines of electric intensity through that surface is  $\epsilon$  to the dielectric coefficient of the substance in which the field exists.

**ELECTRIC CHARGE ( $Q$ ) AND DIELECTRIC FLUX ( $\psi$ ).** — *W* any substance of uniform structure throughout the dielectric flux lines are continuous lines, i.e., the number of these lines coming up to one side of a surface *within* such a substance is equal to the number of these lines leaving the *o* side of that surface. Experience shows that it is impossible to produce appreciable dielectric flux in those substances ordinarily classed as conductors; hence dielectric flux lines cannot pass through a good conductor, but terminate at its surface. Every dielectric is a conductor to at least a slight extent, on account of this fact the dielectric flux lines coming up through one dielectric to the surface of contact between this dielectric and another do not pass through the second dielectric, but some of them terminate at this surface.

Experience shows that to establish an electric field in the dielectric around a conductor, electricity must be conducted through the conductor to the surface of contact between the conductor and the dielectric. For example, consider a good conductor in contact with a perfect dielectric,

Fig. 9; a momentary conduction current must flow through the conductor along the stream lines of the conduction current, represented by the dotted lines. While the field is being established (and therefore varying) a displacement current is set up in the dielectric requiring an equal conduction current in

Fig. 9.

the conductor, and consequently  $\frac{1}{4\pi}$  times the rate of change of the dielectric flux ( $\psi$ ) established in the dielectric must be equal to the conduction current flowing up to this surface through the conductor, i.e.,

$$\frac{1}{4\pi} \frac{d\psi}{dt} = i,$$

or

$$\psi = 4\pi \int i dt = 4\pi Q.$$

$Q$  is the quantity of electricity (current multiplied by time) conducted through the conductor to this surface.

This relation is a general one, viz., the total dielectric flux from any area  $A$  of the surface of a conductor is equal to  $4\pi$  times the total charge on this area. Every flux line originates at a positively charged conducting surface and terminates at a negatively charged conducting surface,  $4\pi$  of these lines connecting each unit positive charge to each unit negative charge.

The quantity of electricity conducted through a conductor when a momentary current is established through it can be readily measured by means of a sensitive galvanometer (see *Galvanometers*) and consequently the dielectric flux through it ( $4\pi Q$ ) may be readily determined.

**Units of Dielectric Flux.** — Dielectric flux may be expressed in the same units as electric charge, viz., coulombs, statcoulombs or abcoulombs; see *Units Conversion Factors*.

**Surface Density of Charge ( $\sigma_c$ ) and Dielectric Flux Density ( $D$ ).** — When there is no current in a conductor there can be no electric field within it, see *Art. 7*, and therefore the surface of a conductor in which no current is flowing is an equipotential surface. Hence the lines of electrostatic intensity,  $E$ , in the surrounding dielectric, and therefore the dielectric flux lines also, must all enter this surface in a direction perpendicular to it. The dielectric flux density in the dielectric just outside a conducting surface in which there is no current is perpendicular to this surface and is

$$D = 4\pi\sigma_c \quad (20a)$$

$\sigma_c$  is the charge per unit area of the surface at this point, or the "surface density" of the charge.

**Dielectric Flux Density Due to a Number of Charged Conductors.** — It can be shown that when any number of charged conductors are surrounded by a uniform dielectric, the dielectric flux density at any point in the field may be ascertained by considering each elementary surface having a charge  $q$  as producing at any point  $P$  at a distance  $r$  from  $q$  a flux density equal to  $q/r^2$ , in the direction of the line from  $q$  to  $P$  when  $q$  is positive and in the direction of the line from  $P$  to  $q$  when  $q$  is negative. The total flux density at  $P$  due to the charges is then the vector summation

$$D = \sum \frac{q}{r^2} \quad (20b)$$

**Dielectric Flux Density at any Point due to a Uniformly Charged Wire of Circular Cross Section and Infinite Length.** — Let  $q$  be the charge per unit length,  $K$  the dielectric coefficient of the surrounding dielectric, assumed uniform, and  $r$  the perpendicular distance from the center of the wire to any point  $P$ , then the dielectric flux density at  $P$  due to this wire is

$$D = \frac{2q}{r} \quad (20c)$$

The resultant dielectric flux density at any point due to any number of uniformly charged wires is the vector sum of the flux densities due to each separately. However, when two or more wires are close together the distribution of charge on them is not uniform,\* but when the wires are more than 10

\* The distribution can be calculated readily in the case of two parallel wires; see *Miller and Osborne, Elec. World, 1910, Vol. 56, p. 607.*

diameters apart the error introduced by the assumption of uniform is practically negligible.

**ELECTROSTATIC CAPACITY (C) AND CONDENSERS.** — To establish a given dielectric flux  $\psi$  through a given dielectric a certain dielectric potential is always required. Consider any portion of an electric field (Fig. 10) between the two equipotential surfaces  $S$  and  $S_1$  bounded laterally by a surface tangent at each point to the flux line through that point. Let  $V$  be the drop of potential from  $S$  to  $S_1$ , and let  $\psi$  be the dielectric flux through this region. When there is no source of e.m.f. between  $S$  and  $S_1$  the quotient

$$C = \frac{\psi}{4\pi V} \quad (21)$$

Fig.

is defined as the "electrostatic capacity" of this portion of the field. Compare with the definition of conductance, equation (8).

When the equipotential surfaces  $S$  and  $S_1$  are the surfaces of two conductors and the dielectric between them are said to form a "dielectric condenser." Practical forms of condensers are described in the article *Condensers, Electric*. When all the flux lines from one conductor end on a second conductor (e.g., when they are given equal and opposite charges connecting them respectively to the two terminals of a source of e.m.f.), the flux from one to the other is equal to  $4\pi Q$  where  $Q$  is the numerical value of the total charge on either conductor. The capacity of the condenser may be written

$$C = \frac{Q}{V}$$

When there are several charged conductors in the field the total flux from one conductor does not in general all end on another single conductor. Some of the flux lines from No. 1, say, may run to No. 2, some to No. 3. Let  $\psi_{12}$  be that portion of the flux from any conductor 1 which ends on another conductor 2, and let  $V_{12}$  be the drop of potential from 1 to 2, the capacity between conductor No. 1 and conductor No. 2 is

$$C_{12} = \frac{\psi_{12}}{4\pi V_{12}}$$

Or, calling  $Q_{12}$  that portion of the charge on No. 1 which is balanced by an equal and opposite charge on No. 2, the capacity between 1 and 2 is

$$C_{12} = \frac{Q_{12}}{V_{12}}$$

**Units of Capacity.** — The unit of capacity in the practical system is the farad (see *Units, Practical Electric*), but as this is a very large unit equal to one-millionth of a farad, called the microfarad, is usually employed. The c.g.s. electrostatic unit may be called the statfarad or the c.g.s. electromagnetic unit the abfarad. See *Units and Conversion Factors*.

**Factors Upon Which Capacity Depends.** — The capacity of a given portion of a dielectric depends upon (a) the dielectric coefficient  $k$  of the dielectric, (b) the length of the dielectric flux lines through it, (c) the cross-section of the dielectric at right angles to the flux lines, and (d) upon the distribution of the flux lines over this cross-section. Compare with electric conductance

of a dielectric bounded laterally by flux lines surfaces (Fig. 10) can be expressed by the

$$C = \frac{k\psi}{4\pi \int D dl}, \quad (21d)$$

where  $\psi$  is the total dielectric flux through the given elementary length along one of the flux lines and  $D$  is the dielectric constant at any point, the integral being taken along the flux line. When the end surfaces are conductors respectively, then

$$C = \frac{KQ}{\int D dl}. \quad (21e)$$

As to the capacity of various practical forms of condensers, see the article on *Capacity and Charging Current*. It is noted that the capacity of a condenser depends on the dielectric flux ( $k$  being assumed constant), but not on the distance between the plates; i.e., for a given dielectric and given distance, the capacity is constant. In general, when any conductor is placed in the electric field of a condenser, the distribution of the flux, and hence the capacity, is altered.

**Resistance and Capacity.** — Comparing equations (21) and (22) it is seen that when the dielectric flux lines and the current lines are distributed in any given region, the ratio of the capacity of this region to its conductance is  $4\pi\gamma/k$  where  $\gamma$  is the conductivity of the material in this region. Hence the capacity and conductance of the dielectric between the plates of a condenser differ only by a constant coefficient. If the dielectric is a conductor, then

$$R = \frac{4\pi\gamma}{k} \cdot C \quad (22)$$

between its plates. Values of  $C$  for various practical forms of condensers are given in the article on *Capacity and Charging Current*.

**Charging a Condenser.** — To charge a condenser a difference of potential is established between its plates. This may be done by connecting the two plates of the condenser respectively to the positive and negative terminals of a source of e.m.f., see Fig. 11. If the dielectric is a conductor, the source of e.m.f.

is a battery set up in this circuit. The difference of potential is established across the plates of the condenser, and a charge equal to the capacity times the "negative" to

Fig. 11.

the condenser. The establishment of the electric flux lines in the condenser may be looked upon as setting up in the circuit an opposing force set up in a spring. When the opposing force just balances the impressed force, the spring ceases to compress, just as the compressing of a spring ceases

when the force producing the compression is just balanced by the force due to the elasticity of the spring.

When a condenser has thus been charged, the wires connecting it to the source of e.m.f. may be removed and the condenser remains charged for a length of time depending upon the resistance of the dielectric separating the plates; the longer this resistance the longer the time that the condenser remains charged. The plates may also be moved apart and they still retain their charges, one a positive charge and the other a negative charge, but the distribution of charges on the plates will in general become altered. Experience shows that a mechanical force is required to separate the charged plates irrespective of whether or not they are connected to the source of e.m.f.

When the two charged plates are "short-circuited" by a wire, as shown in Fig. 12, a momentary current is established through the wire and the electric field between the plates and the charges disappear. The quantity of electricity discharged through the wires is equal to the quantity of charge originally on either plate. A charged condenser, therefore, acts like a source of e.m.f., the direction of this e.m.f. around the circuit containing the condenser being in the direction through the condenser from its negative to its positive plate. A condenser when it is being charged may also be looked upon as producing a back e.m.f., that is, an e.m.f. opposing the e.m.f. which charges it. When a condenser is considered from this point of view the conducting portion of the circuit is to be considered in applying Kirchhoff's laws. When the condenser has an appreciable leakage its resistance must be considered to be in parallel with its e.m.f.

Fig.

**Charging or Capacity Current and Leakage Current.** — The current through the dielectric of a condenser is frequently called "charging" or "capacity" current. The conduction current through the dielectric is called the "leakage" current. Let  $C$  be the capacity of the condenser,  $g$  the conductance of the dielectric, and  $v$  the voltage across the condenser. The total current through the condenser is

$$i = gv + C \frac{dv}{dt}$$

where  $\frac{dv}{dt}$  represents the rate of change of  $v$  with time. The component

of this current is the leakage current and the component  $C \frac{dv}{dt}$  is the charging or capacity current.

**Capacities in Series.** — When several capacities\* are connected in series so that the same dielectric flux passes through each of them, they are said to be "in series." The total capacity of any number of individual capacities  $C_1, C_2, \dots$ , connected in series is  $C$  where

$$\frac{1}{C} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \dots$$

Compare with conductances in series, equation (11b).

**Capacities in Parallel.** — When several capacities\* are connected in parallel between the same pair of equipotential surfaces so that the same potential drop is established through each, they are said to be "in parallel." When there are  $n$

\* Either condensers, or dielectrics of different kinds, sizes or shapes in contact between equipotential surfaces.

two equipotential surfaces the total equivalent capacity is  $C_1, C_2, C_3$ , etc., connected in parallel is

$$C_1 + C_2 + C_3 \dots \quad (25)$$

parallel, equation (12a).

**CAPACITY ( $K$ ) AND DIELECTRIC COEFFICIENT**  
 From equation (21d) it is evident that when the capacity of a condenser is  $C$  when a dielectric  $A$  is between the plates and  $C'$  when  $B$  is between these plates, then the ratio of the capacities is the ratio of the dielectric coefficients of the dielectrics. The "dielectric" capacity of any dielectric is defined as the capacity of a condenser having this substance as its dielectric between two parallel plates. The dielectric coefficient of a dielectric is the ratio of the capacity of a condenser having this substance as its dielectric between two parallel plates to the capacity of a condenser having air as its dielectric between two parallel plates. The dielectric coefficient of air is not constant, but varies as the square of the velocity of light in air.

The dielectric coefficient of air is based on the arbitrary choice of unity for the dielectric coefficient, hence, in the c.g.s. electrostatic system of units the dielectric coefficient are numerically equal. In the m.k.s. system of units the dielectric coefficient of air is not unity.

The dielectric coefficient of air is not unity.

When the centimeter is taken as the unit of length, the dielectric coefficient of air is

$$k_{\text{air}} = \frac{1}{9 \times 10^{11}}.$$

Hence, calling  $K$  the specific dielectric capacity referred to air as unity, and  $k$  its dielectric coefficient, we have

$$\begin{aligned} \text{in the c.g.s. system} \quad k &= K, \\ \text{in the m.k.s. system} \quad k &= \frac{K}{9 \times 10^{20}}, \\ \text{in the S.I. system (meter as unit of length)} \quad k &= \frac{K}{9 \times 10^{11}}. \end{aligned}$$

The dielectric capacity of various insulating materials are given in the following table. *Materials, Properties of.*

**Dielectric Charge.** — The value of the dielectric coefficient is not strictly a constant unless the dielectric is homogeneous. In the case of such nonhomogeneous substances as wood, paper, etc., the dielectric coefficient is found to depend upon the length of time that the voltage is applied, and upon the time of electrification (see *Insulating Materials*). This phenomenon is sometimes described as "electric charge" and is due to the fact that the charge from the plates of the condenser does not remain on the plates but increases in the dielectric coefficient for a given quantity of electricity conducted to the plates. This is an experimental fact that when such a condenser is connected with a wire, Fig. 12, the wire then being connected to the plates after a lapse of a few seconds. This phenomenon is closely associated with electric leakage. The electric field in a heterogeneous dielectric is not uniform and a great deal of heat is dissipated in the dielectric greatly reducing its dielectric capacity. This is accounted for in terms of its leakage resistance as shown in the following table. This may be due in part to

an actual increase in the resistance of the dielectric with the speed of the field, or may be due to a phenomenon analogous to magnetic lag, i.e., to a lag of the dielectric flux density behind the electric field intensity (see *Magnetic Materials, Properties of*). Whatever may be the cause of loss of power for rapidly varying fields, it is generally described as the "dielectric hysteresis." The heat developed is in many cases quite appreciable. See also the article on *Condensers, Electric*.

**DIELECTRIC STRENGTH. — ELECTRIC SPARK AND ELECTRIC CORONA.** — Experience shows that when an electric field is established in a dielectric and the intensity of this field is increased, a point is reached at which the dielectric loses its insulating property and becomes a conductor. This condition of affairs is usually accompanied by a spark which burns a hole through the dielectric, i.e., the dielectric is "punctured." Under other conditions of breakdown may not be permanent, but may result in the acquisition of permanent conductivity by the dielectric only while the voltage gradient is maintained above the critical value, the dielectric regaining its insulating property when the field is reduced below this critical value. This latter condition is usually described as the formation of an electric "corona" in the dielectric; in the case of air the formation of corona manifests itself by a bluish light in the space between the conductors between which the field is established. Whether the breakdown produced by a given voltage is of the nature of a puncture or results in the formation of a corona depends chiefly upon the *distribution* of the dielectric flux density produced in the dielectric (see *Corona, Electric*).

The critical field intensity or voltage gradient at which breakdown occurs is called the "dielectric strength" of the dielectric. The dielectric strength depends upon the nature of the dielectric, its value for the various dielectrics ordinarily employed in practice depending decidedly upon their chemical and physical nature (see *Insulating Materials, Properties of*). It is also found that for a given dielectric the critical voltage gradient at which breakdown occurs depends in general upon (a) the distribution of the dielectric flux density in the dielectric at breakdown and (b) upon the thickness of the dielectric. It is naturally expected that the voltage (total potential difference) required to produce breakdown would depend upon the distribution of the dielectric flux density in the dielectric, for the voltage gradient at all voltages depends upon the geometry of the dielectric (see *above under Capacity*), but there is as yet no satisfactory explanation of the dependence of the *critical gradient* upon these factors.

In fact, but little is known regarding the nature of an electric breakdown, and even the values of the dielectric strength are known only approximately. In many instances, for in many of the tests made to determine its value the distribution of the electric flux was not known. The values of the dielectric strength given in the article on *Insulating Materials, Properties of*, must, therefore, be considered only as rough approximations except for conditions identical with those under which the tests were made.

**ELECTROSTATIC ENERGY.** — From the general relations derived in the preceding articles by equations (15) and (23) it is evident that when the potential difference between the plates of a condenser is increased from 0 to  $V$  the energy stored in the dielectric is

$$\int_0^t gv^2 dt + \int_0^V Cv dv.$$

The energy represented by the first term on the right-hand side of this equation is dissipated as heat in the dielectric, but the energy represented by the second term, which, when  $C$  is constant, may be written

$$W = \frac{1}{2} CV^2,$$

heat; this is a fact of experience. Moreover, by short-circuiting its plates with a wire,  $\frac{1}{2} CV^2$  is transferred to the wire. Hence, it is said to be stored in the condenser, or preferred, for the electric force  $F$  exists only in the dielectric, called the "electrostatic" energy. It is the energy of the spring when the latter is compressed or stretched. It may be written

$$\frac{1}{2} QV = \frac{1}{8\pi} \psi V. \quad (26a)$$

The energy of an electric field may be written

$$W = \frac{kF^2}{8\pi} = \frac{D^2}{8\pi k}, \quad (26b)$$

where  $F$  is the electric field intensity or potential drop per unit distance,  $D$  the electric flux density or flux per unit area perpendicular to the direction of the field.

Equations (26) to (26b) are based on the assumption that the value of  $F$  is constant throughout the field. When this condition does not obtain, the value of  $F$  is given by the line integral  $\int_0^V C v dv$ , the evaluation of which gives the relation between  $C$  and  $v$ .

**ENERGY OF AN ELECTROSTATIC FIELD.** — The forces upon the conductors (or insulators) in an electric field tend to produce a change in the energy of the field. Let  $f$  be the force exerted upon any body in the field in a given direction. The energy of the field due to displacing the body a distance  $x$  is then

$$W = - \frac{dW}{dx}, \quad (27)$$

where  $W$  is the energy of the field. Because of a change in the existing electric charges, a general relation it can be shown that every repulsion on every other surface charged with positive charge is balanced by a force of attraction on every surface charged with negative charge.

For two conductors forming a condenser the force of attraction on the other is

$$F = \frac{V^2 dC}{2 dx}, \quad (27a)$$

where  $V$  is the potential difference between the conductors,  $C$  the capacity of the condenser, and  $dC/dx$  the rate of change of the capacity of the condenser when one conductor is displaced a distance  $dx$  toward the other. This relation results from the substitution of  $C = Q/V$  in the above. For example, the capacity of a parallel plate condenser

$$C = \frac{kA}{4\pi x},$$

where  $k$  is the dielectric coefficient,  $A$  the area of the smaller plate, and  $x$  the distance between the plates. Hence the force of attraction is

$$f = \frac{V^2 k A}{8 \pi x^2}.$$

**Principle of the Electrometer.** — This relation suggests a method of finding potential difference, for, by transposing,

$$V = x \sqrt{\frac{8 \pi f}{k A}}.$$

If the force acting on the upper plate is measured by means of a balance, and  $x$  is also measured, and the dielectric between them is air ( $k = 1$ , electrostatic system, by definition), then all the data necessary for the calculation of  $V$  is at hand. The above formula for  $V$  is approximate only, since the capacity formula is approximate, due to the assumption of a uniform flux density in the dielectric between the plates. As a matter of fact the flux density near the edges of the plate is not uniform, but it is possible to correct for this non-uniformity; see article on *Electrometers*.

**MAGNETS AND MAGNETIC SUBSTANCES.** — A magnet is defined as any body which possesses the property of attracting pieces of iron and steel\* and which when freely suspended† takes up a definite position with respect to the geographical meridian. A magnetic substance is any body which acquires this property when it is placed near a magnet or near a conductor carrying an electric current. A body which is given this property is said to be "magnetized." A magnetic needle is a magnetized needle of iron or steel; the north-seeking end of such a needle is called its north pole and the south-seeking end its south pole. When such a needle is freely† suspended near a magnet or a conductor carrying an electric current a couple is bound to be exerted upon it which causes it to take up a definite direction. The needle is said to "point" in the direction of a line drawn through it from its south to its north pole.

**MAGNETIC FIELD OF FORCE.** — Any region in which a magnetic substance (e.g., a piece of soft iron), when placed therein, becomes magnetized is said to be a "magnetic field." A magnetic field exists in and around a magnetized substance and around every stream line of electric current. The direction of the magnetic field at any point  $P$  is arbitrarily chosen as the direction in which a small magnetic needle point would point when placed at  $P$  without disturbing appreciably the existing conditions.

**Magnetic Flux ( $\phi$ ).** — Consider a small closed turn of wire, Fig. 13, placed in a magnetic field with its plane perpendicular to the direction of the field. Experience shows that when such a turn of wire is removed from the field in any manner whatever (the coil remaining short-circuited on itself or forming part of a closed circuit), or when the magnetic field is caused to disappear in any manner whatever, a momentary electromotive force is set up or "induced" in this coil, which in turn causes a momentary electric current to flow through the coil. This e.m.f. exists only while the coil is moving across the field or while the field through the coil is varying.

Fig. 13.

\* With a force in excess of the gravitational force, which latter is extremely small.

† A needle is said to be freely suspended when there is no controlling force exerted on it through its suspension tending to make it take up any definite position.

time integral of the induced e.m.f. when the coil is removed entirely; the magnetic field is taken as the measure of the "magnetic flux" through the coil when in its original position. That is, calling  $\epsilon$  the induced e.m.f. in the coil at any instant due to its motion through the field,  $t$  the time during which the e.m.f. exists in the coil, then the magnetic flux through the coil when in its original position is

$$\phi = \int_0^t \epsilon dt. \quad (28)$$

Intensity is readily measured by means of a ballistic galvanometer; see *Testing*.

**Unit of Magnetic Flux.** — The unit of magnetic flux in the c.g.s. electro-magnetic system is frequently called a "maxwell" or simply a "line." The flux in the practical system of units is sometimes called a "weber"; see *Conversion Factors*.

**Magnetic Flux Density ( $B$ ).** — Experience shows that the magnetic flux through any closed loop, such as the turn of wire described above, depends upon the area enclosed by this loop. The magnetic flux per unit area through any surface perpendicular to the direction of the field is defined as the "magnetic flux density" at this surface, and is usually represented by the symbol  $B$ . By flux density at any point is meant the flux density at an infinitely small area drawn perpendicular to the field at this point. The direction of the flux density at any point is the same as that in which a magnetic pole would point if placed at this point; i.e., the direction of the flux density is the direction of the magnetic field are the same. When the flux density has the same value  $B$  at every point of a surface of area  $A$  and is perpendicular to the surface, then the total flux through this surface is

$$\phi = BA. \quad (29)$$

The total magnetic flux across any surface  $S$  may in general be expressed mathematically by the surface integral

$$\phi = \int (B \cos \alpha) ds, \quad (29a)$$

where  $ds$  represents any elementary area of this surface and  $(B \cos \alpha)$  the component of the flux density perpendicular to  $ds$ .

**Unit of Magnetic Flux Density.** — The unit of magnetic flux density in the electromagnetic system is called the "gauss"; no name has been given to the corresponding practical unit.

**Magnetic Flux Lines.** — **Continuity of Magnetic Flux.** — Magnetic flux is represented by lines drawn in the field in such a direction that their direction coincides at each point with the direction of the field at that point, and such a number that their density at each point (number per unit area perpendicular to their direction) is equal to the magnetic flux density at that point. Such lines are called "magnetic flux lines." Experience shows that lines drawn in a magnetic field always form *closed* loops, i.e., a magnetic flux line has no ends. As a consequence of this fact the total magnetic flux coming into any surface in a magnetic field is always equal to the total flux leaving the surface. (Compare with stream lines of electric current.) When the flux

leaving a surface is considered as equivalent to a negative flux crossing that surface, this relation may be expressed by the formula

$$\Sigma\phi = 0$$

at every surface, the summation being an algebraic one. This is an application of Kirchhoff's first law for electric circuits.

**Magnetic Fields Due to Electric Currents.**— Experience shows that every stream line of electric current is always accompanied by a magnetic field the flux lines of which *link* the stream line of current. That is, the flux lines thread the loops formed by the stream lines and the stream lines thread the loops formed by the flux lines; see Fig. 14.

Fig. 14.

**Right-handed Screw Law.**— The direction of the current around any electric circuit and the direction in which the flux lines of the current thread this circuit are related to each other in the same manner as the direction of motion of a point on the edge of the head of a right-handed screw and the direction of advance of the screw. Or, if one faces the electric circuit looking in the direction of the flux lines, the current producing these lines is in the clockwise direction around the circuit. The relative direction of the current and its magnetic flux is briefly described by saying that the current is in the right-handed screw sense with respect to the flux which it produces.

**MAGNETICALLY INDUCED ELECTROMOTIVE FORCE.**— The measure of magnetic flux is based on the experimental fact that when the magnetic field threading an electric circuit changes, an electromotive force is induced in that circuit. When the circuit is formed by a single turn, this induced e.m.f. is, from the definition above, equal to the rate of change of this flux with respect to time, i.e.,  $e = \frac{d\phi}{dt}$ . When the circuit is in the form of a coil each turn of which links the flux, the e.m.f. induced in each turn is  $\frac{d\phi}{dt}$  where  $\phi$  is the flux which links that particular turn. When the coil has  $N$  turns, each linking the same number of flux lines, then the total induced e.m.f. in the coil is

$$e = N \frac{d\phi}{dt}$$

When the change in flux is due to a motion of a circuit or part of it through a magnetic field the induced e.m.f. in any conductor is also equal to the number of flux lines which *cut across* this conductor.

**Magnetic Linkages ( $\lambda$ ).**— The condition that each turn be linked by the same flux  $\phi$  is seldom the case; some of the flux lines link only part of the turns, see Fig. 14. In general, the total e.m.f. is

$$e = \frac{d}{dt} (\phi_1 + \phi_2 + \dots + \phi_n),$$

where  $\phi_1, \phi_2, \dots$ , represent the fluxes linking the various turns. The sum  $(\phi_1 + \phi_2 + \dots + \phi_n)$  may be called the total number of "magnetic linkages" and may be conveniently represented by the symbol  $\lambda$ , viz.,

$$\lambda = \phi_1 + \phi_2 + \dots + \phi_n.$$

**NOTE.**— ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROSTATIC UNITS.

may then be written

$$e = \frac{d\lambda}{dt}. \quad (31a)$$

same flux,  $\phi$ , then  $\lambda = N\phi$ .

**E.M.F.** — The direction of this induced e.m.f. be in the *left-handed* screw direction with respect to one faces the circuit looking in the direction of induced e.m.f. is in the counter-clockwise direction. set up by this e.m.f., however, would produce a right-handed screw direction. Hence a change in an electric circuit always sets up an e.m.f. current around this circuit in such a direction as to fact may be expressed mathematically by writing

equation (31), i.e., by putting

$$e = -N \frac{d\phi}{dt}. \quad (31b)$$

then the e.m.f. induced in the circuit in the right-hand respect to the increase of flux. Or stated in other words, the rise of electric potential and  $N \frac{d\phi}{dt}$  represents the e.m.f. induced in the circuit in the right-handed screw direction with

**VARYING MAGNETIC FLUX.** — Consider a wire, and let each of these  $N$  turns be linked by a magnetic agent, e.g., another current is flowing.

Let the magnetic flux  $\phi$  to  $B$  be increasing in the *left-handed* screw direction to the current  $I$  in the direction of  $I$

Fig. 16.

Therefore, the electric power at any instant is  $eI = NI \frac{d\phi}{dt}$ . This power is transmitted through the varying flux through it; hence the power

$$p = NI \frac{d\phi}{dt} \quad (32)$$

is the magnetic power input, this power being converted into electric power.

**Current.** — The varying flux established by  $B$  upon  $A$  as the means whereby this energy is transmitted, just as an electric current may be looked upon as a means whereby energy is transferred from one point to another in an

ON THIS PAGE ARE IN C.G.S. ELECTROMAG-

electric circuit. Hence the varying flux may be looked upon as a "displacement current."

**Magnetomotive Force ( $\mathcal{F}$ ).** — The above expression for the rate of energy by a varying magnetic field may be compared with the rate of energy, or power input  $P = EI$ , corresponding to an electric current  $I$  in a circuit in which there is back electromotive force  $E$ . The strength "magnetic displacement current" may be chosen arbitrarily\* as

$$\text{Magnetic displacement current} = \frac{1}{4\pi} \frac{d\phi}{dt},$$

just as the strength of the electric displacement current is taken as  $\frac{1}{4\pi} \frac{d\psi}{dt}$ .  $\psi$  is the total electrostatic flux. Then the quantity corresponding to electromotive force must be chosen numerically equal to

$$\mathcal{F} = 4\pi NI$$

and may be called the "magnetomotive force," abbreviated "m.m.f." magnetic power input may then be written

$$P = \mathcal{F} \times (\text{Magnetic displacement current}).$$

where  $\mathcal{F}$  is the back magnetomotive force.

**Direction of the Magnetomotive Force.** — The closed path of magnetic flux lines through a magnetic field is called a "magnetic circuit," the path of the stream lines of an electric current is called an electric circuit. In general, a magnetomotive force is produced in every magnetic circuit if it is linked by an electric circuit, equal in numerical value to  $4\pi NI$ ,  $N$  is the number of times the current  $I$  links this circuit. The magnetomotive force is taken as positive when the current links the flux lines in the right-hand screw direction, for then an increase in the flux corresponds to a power output. When the current links the flux lines in the left-hand screw direction the magnetomotive force is taken as negative, i.e., a "back" magnetomotive force, for in this case an increase in flux corresponds to a magnetomotive input; see the special case considered above.

**Units of Magnetomotive Force.** — **Ampere-Turns.** — The unit in the expression for the magnetomotive force, equation (33), is called "current-turns"; when  $I$  is expressed in amperes it is called the "ampere-turn." The magnetomotive force as above defined differs from this product of current and turns by a constant numerical factor; hence the ampere-turns of a coil may be taken as a measure of the magnetomotive force produced by it. This unit of magnetomotive force, namely, one ampere-turn, is the unit commonly employed in the practical calculation of magnetic circuits. The c.g.s. electromagnetic unit is called the gilbert; 1 ampere-turn = 1.2566 gilberts. See *Units and Conversion Factors*.

#### MAGNETIZING FORCE OR MAGNETIC FIELD INTENSITY

— Experience shows that the magnetic flux density produced at any point by a given magnetomotive force depends (a) upon the position of the point with respect to the source of the m.m.f. and (b) upon the nature of the substance through which this m.m.f. produces the magnetic flux. Compare the magnetic flux density produced by an electric current density or dielectric flux density produced at a given point.

\* The factor  $4\pi$  arises from the manner in which the conceptions of the magnetic field were originally developed.

**NOTE.** — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

These facts lead to the conception of the magnetic field as being due to a "magnetizing force  $H$  depending solely upon the field and the distribution of the flux lines, an intensity  $B$  which depends not only upon these two of the medium at the point in question.

Relation between electromotive force and electric force (also called the "magnetic field intensity") along any closed path in a magnetic field may be expressed as follows: The line integral around such a path is equal to the current passing around this path, viz.,

$$\oint \mathbf{H} \cdot d\mathbf{l} = NI \quad (34)$$

where  $dl$  is the elementary length of this path, see Fig. 16, ( $H \cos \theta$ ) is the component of the magnetizing force at  $dl$  in the direction of the path. It is such a definition leads to a quantitative manner the experimental facts. Magnetizing force is defined as the force in dynes which would move a unit magnetic pole." see p. 412.

The direction with the magnetizing force  $H$  may be written

$$\oint \mathbf{H} \cdot d\mathbf{l} \quad (34a)$$

Fig. 16.

For a more complete formula see the articles on *Magnetic Properties of*

**Magnetizing Force.** — Experience shows that except for the direction of the magnetizing force  $H$  and the flux density, the direction of the magnetic field intensity  $H$ , due solely to the magnet itself, is the same as the direction of the flux lines, i.e., a permanent magnet produces a magnetic field of its own.

**Magnetic Force.** — The magnetizing force at any point in a magnetic field is represented by lines drawn in the field in such a direction that the number of lines per unit area perpendicular to their direction that pass through the point gives the value of the magnetizing force at that point. These lines are called "lines of magnetizing force" or "lines of magnetic force." The direction of the lines of magnetizing force and the magnetic field intensity are the same, except within the substance of permanent magnets, where they are different. Only in non-magnetic substances do the lines of magnetizing force coincide. The simple expression is used to designate either the flux lines or the lines of magnetizing force. It is evident that such a loose use of this term is not correct when speaking of the magnetic field within a magnet.

**Magnetizing force.** — Magnetizing force is of the nature of magnetic field intensity, just as electric field intensity is of the nature of electric field intensity.

ON THIS PAGE ARE IN C.G.S. ELECTROMAG-

of electric potential difference per unit length. Hence the c.g.s. electrostatic unit of magnetizing force may be called the "gilbert per centimeter"; with volts per centimeter. When the magnetomotive force is expressed in ampere-turns, the magnetizing force is expressed in ampere-turns per meter or per inch; see *Units and Conversion Factors*.

**Values of the Magnetizing Force in a Uniform Medium.** — A uniform medium surrounding the stream lines of an electric current is of a *uniform magnetic nature throughout*, the magnetizing force at any point may be calculated from the shape and distribution of the stream lines of the current, irrespective of whether the medium be non-magnetic or highly magnetic, e.g., iron. See *Units and Conversion Factors* for numerical multipliers to change to practical units.

**Magnetizing Force at any Point Due to an Element of a Stream Line (Fig. 17).** — Consider any closed stream line of electric current and let the surrounding *medium be uniform* in its magnetic properties throughout the region in which the magnetic field produced by this stream line exists. It can be shown that each elementary length  $dl$  of this stream line may be considered as contributing to the magnetizing force  $H$  at any point  $P$  in this region an amount

$$dH = \frac{(I \sin \theta) dl}{x^2}, \quad (35)$$

Fig.

where  $I$  is the current flowing along this stream line,  $x$  the distance from  $dl$  to  $P$ , and  $\theta$  the angle between  $x$  and  $dl$ . The direction of  $dH$  is perpendicular to the plane determined by  $x$  and  $dl$ . The total magnetizing force at  $P$  is the *vector sum* or *vector integral* of  $dH$  for all the elementary lengths into which the stream line is divided.

**Magnetizing Force Due to a Straight Wire (Fig. 18).** — Applying equation (35) to the case of a straight wire of circular cross-section carrying a current  $I$ , the magnetizing force at any point  $P$  due to a length  $l$  of this wire is

$$H = \frac{I}{x} (\sin \theta_1 + \sin \theta_2), \quad (35a)$$

where  $x$  is the perpendicular distance from  $P$  to the wire and  $\theta_1$  and  $\theta_2$  the angles designated in Fig. 18.

When the wire is very long compared with  $x$ , this becomes

$$H = \frac{2I}{x}.$$

This formula also holds approximately for any point outside a wire of circular cross-section, provided  $x$  is large compared with the maximum diameter of this section. For a point *inside* a long wire of circular cross-section of diameter  $a$  the magnetizing force is also given by (35b) when  $I$  is taken to represent the current inside the circle through  $P$  concentric with the axis of the wire. When the current density is uniform over the cross-section, as is usually the case (see, however, the article on *Skin Effect*), the magnetizing force inside the

$$H = \frac{2xI}{a^2}.$$

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROSTATIC AND ELECTROMAGNETIC UNITS.

**Magnetizing Force on the Axis of a Circular Coil of  $N$  Turns.** — Let  $I$  be the current,  $r$  the mean radius of the coil, and  $x$  the distance of the point from the center of the circle; then

$$H = \frac{2\pi N I r^2}{(r^2 + x^2)^{3/2}} \quad (35d)$$

**Magnetizing Force due to a Solenoid.** — A solenoid is a helical coil of wire, each turn having the same radius. Let  $N$  = total number of turns,  $I$  = current in amperes,  $r$  = mean radius of the helix in centimeters,  $l$  = length of helix in centimeters. Then at any point on the axis of the helix (inside or outside) at a distance of  $x$  centimeters from its center, the magnetizing force in gilberts per centimeter is

$$H = \frac{2\pi N I}{l} \left[ \frac{0.5l + x}{\sqrt{r^2 + (0.5l + x)^2}} + \frac{0.5l - x}{\sqrt{r^2 + (0.5l - x)^2}} \right] \quad (35e)$$

This formula holds only when the thickness of the winding is small compared with the mean radius  $r$ . When  $l$  is large compared with  $r$  this reduces to

$$H = \frac{4\pi N I}{l} \quad (35f)$$

At all points inside the solenoid (whether on the axis or not) at a distance from the axis large compared with  $r$ , that is, inside the central portion of a long solenoid, the field is uniform over the cross-section of the solenoid and its value is given by (35f). An exact formula for field intensity at any point inside a solenoid is given by O. Billieux in *Rev. Gen. d'El.* 6, p. 827, Dec. 13, 1919.

**Magnetizing Force Inside a Toroid (Fig. 19).** — A toroid is a cylinder bent into the form of a closed ring, making a shape like a doughnut. When such a ring is uniformly wound with an insulated wire so that the turns of the wire are close together and cover the entire surface of the toroid, the magnetic field is confined entirely within the space enclosed by these turns, and therefore, when the core on which the wire is wound is of uniform magnetic material throughout, both the lines of magnetizing force and the flux lines must be circles concentric with the hole in the "doughnut." The magnetizing force will have the same value at every point on the circumference of any one of these circles, and therefore, from equation (34a) the value of  $H$  at any point  $P$  within the core is

$$H = \frac{4\pi N I}{l} \quad (35g)$$

Here  $N$  is the total number of turns on the core,  $I$  the current in each turn and  $l$  the length of the circumference through  $P$ . Unless the hole in the "doughnut" has a large radius compared with the radius of the cross-section of the core,  $H$  will not be uniform over this section, since  $l$  for the various points in the cross-section will differ considerably.

It should be noted that the value of  $H$  is independent of the material of the core provided only that the core be of uniform material throughout. That is,

Fig. 19.

equation (35g) applies to an iron core as well as to an air or wood core, provided the iron is uniform throughout and there is no air gap across the path of the flux lines. Even a mechanically perfect contact between two pieces of iron of the same kind, however, is sufficient to vitiate the above formula.

**MAGNETIC PERMEABILITY ( $\mu$ ). — PARAMAGNETIC AND DIAMAGNETIC SUBSTANCES.** — The quotient of the magnetic flux density  $B$  at any point by the magnetizing force  $H$  at that point is defined as the "magnetic permeability"  $\mu$  of the substance as medium at that point, viz.,

$$\mu = \frac{B}{H} \quad (6)$$

Compare with the definition of dielectric coefficient, equation (17.) The c.g.s. electromagnetic system of units is based on the arbitrary assumption of unity as the value of the magnetic permeability of air. Any substance which has a magnetic permeability greater than that of air is called a "paramagnetic substance," and any substance which has a permeability less than that of air is called a "diamagnetic substance." The only substances which are strongly paramagnetic, i.e., which have a permeability considerably greater than that of air, are iron, steel, nickel and cobalt, and certain alloys of non-magnetic elements. The only substance which is appreciably diamagnetic is bismuth which has a permeability of about 0.9998. All other elements are practically non-magnetic, i.e., their permeabilities differ from unity by less than 1 per cent.

The permeability of a given sample of any highly magnetic substance is not a constant, but depends upon the value of the magnetizing force; see the curve in the article on *Magnetic Properties of Iron*. The permeability also depends very largely upon the previous heat treatment and the exact composition of the material, and also upon its previous magnetic history; these relations are also discussed in detail in that article. The methods of measuring permeability are described in the article on *Magnetic Testing*.

**North and South Poles.** — That portion of the surface of any magnetized body from which the flux lines pass out into the air (or into any substance of lower permeability) is said to be a north magnetic pole, and that portion of the surface at which the flux lines enter the body is said to be a south magnetic pole. A "unit north pole" is a pole from which  $4\pi$  flux lines emerge into the surrounding air. When a magnetic needle is placed near the surface of a magnetized body its north-seeking end points away from this surface when this surface is a north pole and toward the surface when this surface is a south pole.

**Difference of Magnetic Potential ( $U$ ).** — Consider any two points 1 and 2 in a magnetic field (Fig. 20) and let the path between them from 1 to 2 pass through an electric circuit producing a magnetomotive force in the direction from 1 to 2, then from analogy with the electric circuit, equation (2), the expression

$$U_{12} = \int_1^2 (H \cos \theta) dl - \mathcal{F}_{12} \quad (37)$$

Fig. 20.

is called the "drop of magnetic potential" from 1 to 2. From the definition of magnetizing force, equation (34), it follows that around any closed circuit the drop of magnetic potential is always zero. A magnetomotive force  $\mathcal{F}_{12}$  is therefore, equivalent to a rise of magnetic potential from 1 to 2.

**NOTE.** — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

When there is no source of m.m.f. between 1 and 2 and the path coincides with that of magnetizing force, the drop of magnetic potential is

$$U_{12} = \int_1^2 H dl. \quad (37a)$$

Magnetic potential difference is of the same nature as magnetomotive force and therefore, be expressed in the same units, viz., gilberts or ampere turns.

**Magnetic Equipotential Surfaces.** — A surface drawn in a magnetic field such a manner that this surface is perpendicular at each point to the magnetizing force at this point (i.e., to the line of magnetizing force through this point) is called a "magnetic equipotential surface," compare with *electric equipotential surface*.

**Magnetic Reluctance ( $R$ ).** — To establish a magnetic flux  $\phi$  through a given portion of a substance which is *not itself linked by a source of m.m.f.*, a difference of magnetic potential must always be established between the end surfaces of the substance. Let  $U$  be the magnetic potential drop established from one face to the other, then the quotient

$$R = \frac{U}{\phi} \quad (38)$$

is defined as the magnetic reluctance of the given portion of the substance. Compare with electric resistance. The c.g.s. electromagnetic unit of reluctance is called the oersted. It should be noted that the above definition is meaningless except when applied to a portion of a substance of which the end surfaces are magnetic equipotential surfaces and through every cross-section of which the same flux passes.

**Factors upon Which Reluctance Depends.** — The magnetic reluctance of a given portion of a substance included between two equipotential surfaces and bounded laterally by a surface through which no flux line passes depends upon 1. the magnetic permeability of the substance, 2. the dimensions of this portion of the substance and 3. upon the distribution of the flux lines over each cross-section perpendicular to them. The relations are identical with those which determine the electrical resistance of a conductor, the magnetic permeability taking the place of the electric conductivity. For example, for a straight wire of constant cross-section  $A$  and length  $l$ , through which the flux lines are straight, parallel and uniformly distributed, the reluctance is

$$R = \frac{l}{\mu A}. \quad (38a)$$

Note particularly that this formula for reluctance is applicable only under the special conditions just stated. Formulas for other cases are much more complex; see Douglas, J. F. H., *Reluctance of Irregular Magnetic Fields*, A.I.E.E., vol. 34, May, 1915.

Magnetic reluctance is not a constant quantity even for a given material and fixed flux distribution, unless this material is non-magnetic. For all highly magnetic materials  $\mu$  depends upon the magnetizing force and therefore also upon the flux density. It should also be noted that the magnetic reluctance does not represent a "resistance" in the sense of something which causes a dissipation of energy.

**Magnetic Permeance ( $\mathcal{P}$ ).** — The reciprocal of magnetic reluctance is called "magnetic permeance." The permeance of a straight bar under the conditions defined above is

$$\mathcal{P} = \frac{\mu A}{l} \quad (39)$$

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

The permeability of a substance is, therefore, equal to the permeance of a cube of this substance when the flux through the cube is parallel to one of the cube and is uniformly distributed over the section at right angles to the four edges.

Magnetic permeance is analogous to electric conductance, except that it is not a factor which affects the *dissipation* of energy in a substance. It, however, enters into the expression for the energy stored in a magnet in the same way that the electrostatic capacity of a dielectric is a factor in the expression for the energy stored in the electric field.

**Kirchhoff's Laws for the Magnetic Circuit.** — As already noted (30), the total magnetic flux coming up to any surface in a magnet is always zero, provided a flux leaving a surface is considered as a flux coming up to that surface. This fact may be represented by the formula

$$\Sigma \phi = 0$$

for every surface in the field. Similarly, from the definition of magnetic potential drop, it follows that the *total* magnetic potential drop around a circuit is zero, or that the total magnetomotive force acting around a circuit is equal to the sum of the reluctance drops around that circuit, which may be represented by the formula

$$\Sigma \mathcal{F} = \Sigma R \phi.$$

These two equations are identical in form with those representing Kirchhoff's laws for the electric circuit, equation (13). They are, however, not so easy to use for practical calculations, for the magnetic flux is not confined to approximately geometrical lines like the currents in a network of wires, but in general fills all space surrounding the coils which establish the magnetomotive forces; also, when there is iron or other magnetic material in the circuit, the permeability depends on the flux density and the history of the iron. (The distribution of magnetic flux in and around an iron circuit is analogous to the distribution of current in and around an unimpure mass of copper of the same shape as the iron circuit immersed in a liquid of a conductivity about equal to that of carbon.) Only in the special case of a uniformly wound circular ring or toroid are the lines of induction confined *entirely* to an iron circuit; in general a certain number also exist in the air, and in whatever other substances are in the vicinity of the iron circuit.

**SELF AND MUTUAL INDUCTION.** — When the current in an electric circuit varies with time the magnetic flux accompanying the current also varies with time, and, since this flux links the current which produces it, an e.m.f. is induced in each turn of the circuit equal to the rate at which the flux through this turn is varying, and in such a direction as to *oppose* the change of the current. That is, an *increasing* electric current is always accompanied by a *back* e.m.f. due to the increase in the magnetic flux which accompanies the increase of current. Or, viewed from another point of view, an increase in the velocity of a stream of electricity develops a back pressure, just as an increase in the velocity of a stream of water is increasing it develops a back pressure, or "velocity head" due to the inertia of the water. The magnetic field accompanying an electric current may, therefore, be looked upon as a result of its "magnetic inertia," or "electromagnetic mass"; see also the article on *Induction Theory*.

Again, when an electric current *decreases* its accompanying flux also decreases, and an e.m.f. is set up in the circuit tending to oppose this decrease, i.e.

**NOTE.** — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROSTATIC AND ELECTRODYNAMIC UNITS.

ing. This is again analogous to the effect of matter.

**Self Inductance ( $L$ ).**— In general, the change of the current  $\left(\frac{di}{dt}\right)$  in any circuit must induce an electromotive force  $e$  is called the "coefficient of self inductance" of the electric circuit. In e.m.f. in an electric circuit is

$$e = L \frac{di}{dt}, \quad (41)$$

where  $L$  is the self inductance of the electric circuit and  $\frac{di}{dt}$  represents the change in current. Since  $e = \frac{d\lambda}{dt}$ , see equation (31a), where  $\lambda$  is the flux linkage between the electric circuit and the flux established by the current,  $L$  may also be defined by the relation

$$L = \frac{d\lambda}{di}. \quad (42)$$

If the permeability of the magnetic circuit is constant and the number of linkages per unit current is constant, then  $L$  is constant and equal to the linkages per unit current. If every stream line of electric current, and the magnetic circuit is constant, then

$$L = \frac{4\pi N^2}{\mathcal{R}}, \quad (42a)$$

where  $N$  is the number of turns forming the electric circuit and  $\mathcal{R}$  is the reluctance of the magnetic circuit.

Examples of various electric circuits are given in the article on *Inductance*.

The practical unit of inductance is called the henry; the abhenry and the millihenry see *Units*.

**Mutual Inductance ( $M$ ).**— In

which the rate of change of the current  $\left(\frac{di_a}{dt}\right)$  in circuit  $A$  induces an electromotive force  $e_b$  in circuit  $B$ , is called the "coefficient of mutual inductance" between  $A$  and  $B$ ; see Fig. 15. In any circuit  $B$  by a varying current  $i_a$  in any

$$e_b = M_{ab} \frac{di_a}{dt}, \quad (43)$$

where  $M_{ab}$  is the mutual inductance between  $A$  and  $B$ .

The principle of the conservation of energy that the mutual inductance with respect to a second circuit  $B$  must be equal to that of circuit  $A$  with respect to circuit  $B$ .

to the mutual inductance of  $B$  with respect to  $A$ , that is,  $M_{ab} = M_{ba}$ —the e.m.f. induced in  $A$  when the current in  $B$  increases by an amount

$$e_a = M_{ab} \frac{di_b}{dt}.$$

Since  $e_b = \frac{d\lambda_{ab}}{dt}$ , where  $\lambda_{ab}$  is the number of linkages between the and the flux through  $B$  due to the current  $i_a$ , the mutual inductance be defined by the relation

$$M_{ab} = \frac{d\lambda_{ab}}{di_a}.$$

That is, the mutual inductance between two circuits  $A$  and  $B$  is equal to the increase in the number of magnetic linkages of the circuit  $B$  per unit increase in current in  $A$ , and vice versa. When the permeability of the magnetic circuit is constant, the mutual inductance is also a constant equal to the linkages per unit current in  $A$ , and vice versa. When every flux line linking both circuits is linked by every turn in  $A$  and every turn in  $B$ , then

$$M_{ab} = \frac{4\pi N_a N_b}{R_{ab}},$$

where  $N_a$  and  $N_b$  are the number of turns forming the circuits  $A$  and  $B$  respectively and  $R_{ab}$  is the reluctance of that part of the magnetic circuit through which the flux from  $A$  to  $B$  passes when there is current in one coil only.

The units of mutual inductance are the same as those of self-inductance; see *Units and Conversion Factors*.

Formulas for mutual inductance for a few special cases are given in *Tables on Inductance, and Inductive Reactance*.

**Instantaneous Potential Drop Through a Coil.**—Consider a coil which has a resistance  $r$  and an inductance  $L$ . Then when this coil is connected to another source of e.m.f. than its own self-induced e.m.f., the expression for the instantaneous potential drop through the coil is

$$v = ri + L \frac{di}{dt},$$

where  $i$  is the instantaneous value of the current and  $\frac{di}{dt}$  the increase in current per unit of time. Compare with the equation

$$i = gv + C \frac{dv}{dt},$$

for the instantaneous current through a condenser, where  $g$  is the conductance of the dielectric in the condenser,  $v$  the potential drop across it, and  $\frac{dv}{dt}$  the increase in the potential drop per unit of time.

When there is another coil near the first coil, and the two coils have resistances  $r_1$  and  $r_2$  and self-inductances  $L_1$  and  $L_2$  respectively, and a mutual inductance  $M$ , then the potential drops through them are respectively

$$\left. \begin{aligned} v_1 &= r_1 i_1 + L_1 \frac{di_1}{dt} + M \frac{di_2}{dt} \\ v_2 &= r_2 i_2 + L_2 \frac{di_2}{dt} + M \frac{di_1}{dt} \end{aligned} \right\}$$

where  $i_1$  and  $i_2$  are the currents in the two coils in the same direction.

**Effective or "Total" Inductance.** — In certain cases of symmetry, when the algebraic sum of all the currents in the field is zero, the voltage drop along any portion of a circuit may be represented by an expression of the form

$$v = r_i i + L \frac{di}{dt}$$

although there may be several electric circuits in the vicinity in which electric currents are flowing. An example of this is the case of the wires of a three-phase transmission line arranged so that they form the three edges of an equilateral prism; see *Inductance and Inductive Reactance*. The coefficient  $L$  in this case is called the "effective self-inductance" of this particular portion of the circuit; it really takes into account not only the self-induction of the particular part of the circuit under consideration but also the mutual induction of the rest of the circuit or circuits with respect to this particular portion. Similarly, when the voltage drop in any portion of a circuit involves not only the current  $i_1$  in this circuit but also a current  $i_2$  in some part of this circuit or in some other circuit, the coefficient  $M_{12}$  in the expression

$$v_1 = r_1 i_1 + L_1 \frac{di_1}{dt} + M_{12} \frac{di_2}{dt}$$

represents the effective mutual inductance of the part 2 with respect to 1 although this may also be due in part to circuit 2.

**Leakage Inductances.** — In discussing the action of a transformer (q.v.), which is merely two electric circuits linking the same iron core, it is more convenient to deal with the resultant flux due to the currents in both electric circuits and windings instead of considering the fluxes due to the two windings separately. Referring to Fig. 21, let  $\phi_r$  represent that portion of the resultant flux due to the currents  $i_1$  and  $i_2$  in the two windings 1 and 2, and let  $\phi_1$  represent that part of the total flux which links 1 only and  $\phi_2$  that part of the total flux which links 2 only. Let  $\lambda_1$  be the linkages between  $\phi_1$  and circuit 1 and  $\lambda_2$  be the linkages between  $\phi_2$  and circuit 2. Then

Fig. 21.

$$L_1' = \frac{\lambda_1}{i_1} \quad \text{and} \quad L_2' = \frac{\lambda_2}{i_2}$$

are called the "leakage inductances" of the two windings respectively; the distance of the paths of  $\phi_1$  and  $\phi_2$  are practically constant since the air portion of these paths forms a greater part of the reluctance in each case.

Let  $i_1$  be the current in winding 1 and  $i_2$  be the current in winding 2 in the opposite direction to  $i_1$  (this is the actual relation in a transformer during most of the time) and let  $e_1$  be the impressed e.m.f. across the terminals of the first or primary winding and  $e_2$  the terminal e.m.f. at the terminals of the second or secondary winding when the current  $i_2$  is flowing. Then

$$\left. \begin{aligned} e_1 &= r_1 i_1 + L_1' \frac{di_1}{dt} + N_1 \frac{d\phi_r}{dt} \\ e_2 &= N_2 \frac{d\phi_r}{dt} - r_2 i_2 - L_2' \frac{di_2}{dt} \end{aligned} \right\} \quad (47)$$

where  $r_1$  and  $r_2$  are the resistances of the two windings and  $N_1$  and  $N_2$  are the number of turns in the two windings respectively.

Comparing equation (47) with (45) and noting that  $e_1 = v_1$  and  $e_2 = -v_2$  in (47) is taken in the opposite direction from  $v_2$  in (45), it may be shown

$$L_1' = L_1 - \frac{N_1}{N_2} M,$$

$$L_2' = L_2 - \frac{N_2}{N_1} M.$$

Whence the leakage inductance of each winding is very much less than the total self-inductance of that winding.

**Fundamental Equations of the Transformer.** — Comparing equations (47) and (45) it may also be seen that\*

$$\phi_r = \frac{M}{N_2} \left( i_1 - \frac{N_2}{N_1} i_2 \right).$$

Put  $i_2' = \frac{N_2}{N_1} i_2$ , that is,  $i_2'$  is the current which would be produced in the secondary if it had the same number of turns as the primary. The difference

$$i_m = i_1 - i_2'$$

is called the "magnetizing current," and the quantity  $L_m = \frac{M}{N_2}$  may be called the magnetizing inductance. Then

$$\phi_r = L_m i_m.$$

In the above deduction no account is taken of the eddy-current and hysteresis loss in the iron core; these losses (the eddy-current loss in particular) may be looked upon as due to a third current  $i_3$  flowing in a single turn short-circuited on itself and having a resistance  $r_3$  and negligible inductance. The voltage drop for this tertiary circuit is then

$$0 = \frac{d\phi_r}{dt} - r_3 i_3.$$

Whence the corresponding current in the primary winding is  $i_3' = \frac{N_1}{r_3}$  and may also be written

$$i_3' = g N_1 \frac{d\phi_r}{dt},$$

where  $g = \frac{1}{r_3 N_1^2}$  is called the "leakage conductance" of the transformer. The total primary current is then

$$i_1 = i_2' + i_m + i_3'.$$

From equation (47) and the relations given in the last two paragraphs a complete theory of the transformer may be developed.

**ENERGY OF THE MAGNETIC FIELD.** — Energy is required to establish a flow of electricity just as energy is required to set a column of water in motion, this "energy of motion" of electricity being analogous to the energy of a moving body. This energy of motion is most conveniently

\* In this equation  $i_1$  and  $i_2$  are taken in the opposite direction.

**NOTE.** — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROSTATIC UNITS.

field which accompanies the flow of electricity  
 atical expression for it may be put into various

 adily shown that the total energy required to  
 several electric circuits linking one or more  
 ctance is

$$W = \frac{1}{2} L_1 I_1^2 + \frac{1}{2} L_2 I_2^2 + \dots + M_{12} I_1 I_2 + M_{23} I_2 I_3 + \dots \quad (49)$$

the self and mutual inductances respectively.

$$W = \frac{1}{2} \sum \phi I, \quad (49a)$$

one and includes every complete *turn* of the  
 ent in this turn and  $\phi$  the magnetic flux linking  
 w direction with respect to the current.

THIS PAGE ARE IN C.G.S. ELECTROMAG-

The energy per unit volume at any point in the magnetic field due to a number of electric circuits is represented by equation (48b), where  $H$  and  $B$  are taken as the resultant magnetizing force and flux density respectively at this point.

When the permeability is not constant the energy transferred to us by the magnetic field due to any number of currents is

$$w = \frac{1}{4\pi} \int_0^B H dB$$

provided the magnetizing force  $H$  and the flux density  $B$  are either in the same or directly opposite directions, as, for example, in the case of a uniformly magnetized iron toroid. To integrate this expression requires a knowledge of the relation between  $B$  and  $H$ . Note also that, due to the phenomenon of magnetic hysteresis, part of the energy required to establish a magnetic field in any other magnetic substance is dissipated as heat and is not recoverable when the field disappears; therefore, only part of the energy represented by equation (48b) is "stored" in the field in a recoverable form. See article on *Properties of Iron*.

#### MECHANICAL FORCES IN THE MAGNETIC FIELD.

(See article on *Electromagnets*.) — Experience shows that all bodies in which a current exists, and all bodies in which a magnetic flux exists, exert on each other mutual mechanical forces upon one another tending to produce such a motion of these bodies as will increase the energy of the magnetic field. Let  $f$  be the component of the force tending to move any body in the field in the direction  $dx$  and let  $dW$  be the increase in the energy of the field due to the displacement of the body a distance  $dx$  in this direction, then

$$f = \frac{dW}{dx},$$

provided this displacement does not alter the existing magnetomotive force of the field.

Similarly, calling  $T$  the component of the torque tending to turn any body in the field about a given axis, and  $dW$  the increase in the magnetic energy due to the turning of the body through an angle of  $d\alpha$  radians about this axis, then

$$T = \frac{dW}{d\alpha},$$

provided this displacement does not alter the existing magnetomotive force of the field.

Equations (51) and (51a) also give the actual force and torque respectively during a change in position which does cause a change in the magnetic field, provided  $dW$  is taken to represent the net increase in the energy of the field. This force and torque may differ greatly from the static state force and torque; see article on *Electromagnets*.

**Force Produced by a Magnetic Field on a Coil Carrying a Current.** From equation (32) the energy output of an electric circuit, when the magnetic flux threading it in the right-handed screw direction with respect to the axis of the circuit increases by an amount  $d\phi$ , is  $dW = NI d\phi$ , where  $N$  is the number of turns linked by this increase in flux and  $I$  is the current in each turn. Hence the energy input into the magnetic field. Whence if an increase in

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROSTATIC UNITS.

induced through the coil when it moves a distance  $dx$ , the force acting on the coil in the direction of  $dx$  is

$$f = NI \frac{d\phi}{dx}; \quad (5a)$$

$d\phi$  represents the increase in the flux linking the coil in the *right-handed* screw direction with respect to the current in it or the number of flux lines which cut the coil as the result of its motion. Similarly, when the coil is so mounted that it can move only about a fixed axis, then the value of the torque tending to turn it about this axis is

$$T = NI \frac{d\phi}{d\alpha}, \quad (5a')$$

where  $d\phi$  represents the increase in the flux linking the coil in the right-handed screw direction with respect to the current in it when the coil turns through an angle  $\alpha$  (in radians).

From these relations it follows that a coil carrying an electric current, when in a magnetic field due to any other agent (current or permanent magnet), always tends to take up that position in which it will embrace the maximum possible flux linking the coil in the right-handed screw direction with respect to the current in it. This accounts for the attraction of two parallel coils when they carry currents in the same direction, and the repulsion of two such coils when they carry currents in opposite directions. This principle is useful in determining the direction of motion of the moving element in such devices as the electric motor, galvanometer, current balance, electro-dynamometer (q.v.).

**Torque on the Coil When its Plane is Parallel to the Magnetic Field.** — When the coil is placed with its plane parallel to the flux lines due to some other agent (e.g., a permanent magnet or another coil carrying a current), the flux linking the coil due to this agent is zero; see Fig. 22. Let the two circles represent sections of the two sides of the coil its plane being perpendicular to the page, and let the dot in the left-hand circle indicate that the current is up through this side of the coil and the cross in the other circle that it is down through the other side. Let  $B$  be the flux density of the field constant for each point along the flux line since the flux lines are parallel, and let  $A$  be the area of the coil and let  $\phi = BA$ , that is,  $\phi$  represents the total flux which would be produced through the coil by a uniform field of flux density  $B$  at right angles to it. Then the torque on the coil when its plane is parallel to the field is

$$T = N\phi I. \quad (5b)$$

This relation is useful in calculating the torque on the moving element of a galvanometer, ammeter, electro-dynamometer, wattmeter, etc.

**Average Torque on a Coil Rotating in a Magnetic Field.** — Consider a coil which is rotating with an angular velocity  $\omega$  about a fixed axis in a magnetic field due to some other agent (e.g., an armature coil rotating in the magnetic field produced by the current in the field coils). Let the current in this coil be constant and in the same direction with respect to the coil while the coil turns from the position in which it embraces the maximum flux  $\phi$  in the left-handed screw direction to the position (a half revolution in a 2-pole machine) when it embraces this same maximum flux  $\phi$  in the right-handed

Fig. 22.

screw direction. The total change in the flux while the coil turns through an angle,  $\pi$  radians in the case of a 2-pole machine, is  $2\phi$ , whence the torque turning the coil through this half revolution is

$$T = \frac{2N}{\pi} I\phi.$$

That is, the average torque is proportional to the product of the current and total flux per pole. When a commutator is provided to change the direction of the current every half turn, then the torque is in the same direction for every complete turn. See *Motors*.

When the coil is mounted in a slotted iron core which rotates with it, as in an ordinary motor, this torque is exerted partly on the wire and partly on the teeth of the core.

**Force on a Wire in a Magnetic Field.** — Consider a wire of length  $l$  forming part of a closed circuit, Fig. 23. Let  $B$  be the value of the flux density at the wire,  $I$  be the current in the direction indicated, and let the lines representing the flux be perpendicular to the wire in the direction from the eye to the page. When this wire moves a distance  $dx$  to the left the flux threading the closed loop formed by the circuit is increased by an amount  $d\phi = Bldx$ , whence the force acting on the wire is, from equation (51),

$$f = BI l.$$

Fig. 23

**Left-hand Rule.** — The relative directions of this force, the flux density  $B$  and the current  $I$  may be conveniently determined by pointing the forefinger of the left hand in the direction of the flux and the middle finger in the direction of the current ( $I$ ), then if the thumb is held perpendicular to these two fingers it will point in the direction in which the force tends to move the wire. Compare with the right-handed rule for e.m.f.

**Force between Two Current-Carrying Conductors.** — The force between any two electric circuits carrying currents  $i_1$  and  $i_2$ , due to the magnetic field of these currents, may be readily found by combining equation (49) and (51). This gives for the component of this force in any direction  $dx$  the value

$$f_x = i_1 i_2 \frac{dM}{dx}$$

where  $dM$  is the increase in the mutual inductance between the two circuits when one circuit is displaced a distance  $dx$  with respect to the other,  $dx$  being measured in the direction in which it is wished to find the component of the force. In this formula  $i_1$  and  $i_2$  are both to be considered positive when they link the mutual flux in the same direction. From this relation follows the well known fact that two coils, or conductors, carrying currents which are in the same direction attract each other, since when one is moved toward the other their mutual inductance increases.

The mutual inductance of two long parallel wires when these are separated by a distance  $D$  relative to their diameters is

$$M = 2l \log_e \frac{2l}{D},$$

**NOTE.** — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROSTATIC UNITS.

and  $l$  their length, both in centimeters (see *Reactance*). Hence, from equation (56) the force between two parallel wires on the other is

$$\text{dynes per centimeter} \quad (56a)$$

and in the plane formed by two. This formula applies to parallel conductors of any cross-section, provided the greatest dimension of their cross-section is small compared with the distance between them, e.g., in the case of parallel bus-bars close together. The force is much more complex (see *Dwight, H. B., Trans. A. I. E. E., Elec. World, 70, p. 522, Sept. 15, 1917*).

**Force in a Magnetic Field.** — In general the reluctance is due to the flux set up by a given magnetomotive force. The reluctance of the various magnetic bodies in the field with respect to the electric circuit producing the field (the body in the field) is displaced the total reluctance is due chiefly to the change in the dimensions of the magnetic body in the field. From equations (48a) and (51) it can be shown that the force on a magnetic body in the field is in the direction of the field and is equal to the value

$$-\frac{1}{8\pi} \phi^2 \frac{dR}{dx} \quad (57)$$

where  $\phi$  remains constant; where  $\phi$  represents the magnetic flux,  $dR$  represents the increase in the reluctance of the circuit due to a displacement  $dx$  of the body in the field. The minus sign in this formula indicates that the force is in the direction which a motion of the body would decrease the reluctance. In deducing this expression it is assumed that the field is constant. It can also be shown that the same formula holds for actual magnetic circuits where the permeability is not a constant.

The force of attraction of one magnet for another is greater for unlike poles than for like poles, and the force of repulsion is greater when their like poles are nearer than their unlike poles. The force of attraction of a magnetic substance by the "face" of an electric circuit, and the repulsion of a magnetic substance by either pole of a magnet, can be calculated; see article on *Electro-*

In equation (56) consider the case of a magnetic circuit which is one form of "permeability" of iron the flat end  $P$  of a magnetic yoke  $Y$ . This rod passes through the yoke.  $C$  is a magnetizing coil wound around the yoke. The flux density is uniformly distributed over the area of the yoke at the joint  $P$ . Let

Fig. 24.

Let  $B$  be the flux density at this area. Let  $dx$  be the length of an air gap formed at the joint  $P$ . The reluctance of the magnetic circuit is produced due to the air gap.

THIS PAGE ARE IN C.G.S. ELECTROMAG-

the formation of an air gap at  $P$ , and a decrease in reluctance is produced by the shortening of the iron part of the circuit, i.e., by the reluctance of length  $dx$  of the rod. Due to the high permeability of the iron compared with that of the air, the decrease in the reluctance of the iron part of the circuit is neglected in comparison with the increase in reluctance due to the formation of the air gap. The net increase in reluctance may then be taken as the reluctance of this air gap of length  $dx$ , that is  $dR = dx/A$ , since the permeability of air is unity. Whence, from equation (56), the force required to raise the rod

$$f = \frac{1}{8\pi} \frac{\phi^2}{A} = \frac{B^2 A}{8\pi}$$

That is, the tractive force per unit area between the rod and the pole is proportional to the square of the flux density in the rod.

#### HYPOTHESIS REGARDING THE NATURE OF MAGNETISM

The peculiar properties possessed by a magnetic needle or other magnetic substance are accounted for by assuming that at least some of the molecular currents in a magnetic substance have an orbital motion without friction, forming a "molecular solar system." The magnetization of such a substance is due to the setting of the molecular currents in planes more or less parallel to the plane of the magnetizing current. In the case of a permanent magnet the molecular currents retain their parallel or "polarized" condition even when the magnetizing current is removed. For example, when a needle is magnetized by a current in a coil placed around it, the molecular currents are set at right angles to the axis of the needle. A magnetic needle placed in a magnetic field therefore tends to set itself so that each molecular current embraces the flux and hence "points" in the direction of this flux.

**ELECTROCHEMICAL PROCESSES, INDUSTRIAL.** — (See also *Electrochemistry, Principles of; Furnaces, Electric.*) The principal industrial electrochemical processes are the following :

- Electroplating,
- Galvanoplasty, including electrotyping,
- Electrolytic refining of metals,
- Electrolytic winning of metals,
- Electrolytic oxidation and reduction,
- Electrolysis of sodium and potassium in chloride solutions,
- Electrolysis of water,
- Electric-furnace processes (see *Furnaces, Electric*),
- Production of ozone.

Some of the more important of these various processes are briefly described below.

**ELECTROPLATING.** — Electroplating consists in covering a conducting surface (usually metallic) with a thin, smooth, compact, well-adhering layer of metal by depositing this metal electrolytically from an aqueous solution of one of its salts. The anode of the electroplating vat consists of rods or plates of the same metal as that of the salt in solution and is connected to the positive terminal of the source of electricity. The object to be plated forms the cathode, and is connected to the negative terminal. The anode dissolves approximately to the same extent that the cathode gains, so that the amount of the metal ions in the bath remains nearly constant.

**Suspension of Objects to be Plated.** — The cathodes are always suspended in the bath between two rows of anodes, so that they will be plated uniformly on both sides. When the cathode is of irregular shape, or very large, it must be turned frequently during the plating in order to get a uniform deposit. The cathodes and anodes are suspended by copper wires from horizontal metallic tubes, the ends of which rest on the edge of the plating vat. The metallic tubes are permanently connected to the source of the electricity, so that as soon as the cathodes are suspended in the bath, electrolysis begins. Small objects, such as tacks, pins and screws, are suspended in the vat in a wire basket, which is, of course, plated simultaneously. To get a uniform plated surface the objects should be well shaken during electrolysis. The objects are removed from the bath only when they are nearly used up and have to be replaced.

**Construction of Vats.** — Large plating vats are made of wood lined with some specially prepared substance resembling pitch, or with lead. Small tanks for silver or gold plating are usually porcelain lined.

**Voltage and Current Density.** — Electroplating tanks are always connected in parallel, so that they will be electrically independent of each other.

Low-voltage generators of from 5 to 6 volts are, therefore, used in plating, and each tank must be connected directly to the generator through a regulating resistor in order to regulate the voltage.

The proper current density in any plating process is that density at which a good deposit is formed. This may vary within certain limits for a given solution and temperature; it is a function of the temperature and the nature of the solution.

**Washing and Pickling.** — In order to make the metal adhere well to the surface to be plated, the surface must be smooth and perfectly clean. It is first washed, and the grease is then removed by dipping it into a hot alkaline bath containing 20 per cent, by weight, of sodium carbonate or sodium hydrate.

After washing off the alkali, the object is dipped into a bath called a "pickling bath," the purpose of which is to remove any oxide that may have been produced by the alkali, and to give a bright surface. The pickle is then washed off with water and the object is suspended immediately in the electroplating vat.

**Pickling Solutions.** — The pickle varies with the nature of the metal to be treated. Cast iron and wrought iron are pickled in a solution consisting of 15 parts, by weight, of water to 1 part of concentrated sulphuric acid. A suitable pickle for zinc is dilute sulphuric or hydrochloric acid. Copper, bronze and German silver are pickled first in a bath consisting of 200 parts, by weight, of nitric acid of specific gravity 1.33, 1 part of common salt and 1 part of lampblack. The lampblack is intended to form some nitrous acid with the nitric acid. The object is then washed in boiling water and is immersed in a "bright dipping bath," to give a bright surface. This bath consists of 100 parts, by weight, of nitric acid of specific gravity 1.38, 100 parts of concentrated sulphuric acid and 1 part of common salt.

After the plating is finished, the object is removed from the plating bath, washed in hot water and placed in warm sawdust to dry.

**Plating by Dipping.** — A thin film of metal may be deposited on a metal by dipping it into a solution of a salt of a metal which is electronegative (see *Electrochemistry, Principles of*) with respect to the metal to be plated, e.g. dipping iron into a copper-sulphate solution. A small amount of iron and an equivalent amount of copper is deposited on the remaining surface. In this course, only a thin film can be produced in this way, for, as soon as the surface is covered with copper, the action ceases. No external electric current is needed in this process.

**Plating by Contact.** — When the metal to be plated is electronegative with respect to the metal to be deposited on it, the electro-deposition can be obtained by connecting the former to a zinc rod. In this case, the solution should be of a complex salt, in order to reduce the deposition of the metal on the zinc itself. For example, silver may be deposited on copper by connecting a zinc rod or plate to the copper object by a wire and dipping both into a potassium-silver-cyanide solution; the zinc dissolves and silver is deposited on the copper, while some silver is also deposited on the zinc. No external electric current is needed in this process.

**Nickel Plating.** — The solution ordinarily used consists of 50 parts, by weight, of the double nickel-ammonium sulphate,  $\text{NiSO}_4 \cdot (\text{NH}_4)_2\text{SO}_4 \cdot 6 \text{H}_2\text{O}$  with 25 to 50 parts of ammonium sulphate to 1000 parts of water. The solution is made acid enough to redden litmus slightly, and the addition of a small amount of sulphuric acid or one-half per cent of citric acid is desirable. The proper current density on the cathode is about 0.6 ampere per square meter (5.5 amperes per square foot) of exposed surface, which requires 1.5 to 2 volts. The surface should be perceptibly coated with nickel in two minutes, and a few bubbles of hydrogen are liberated continuously. If the current is too weak, the surface becomes discolored, and if too strong, hydrogen is evolved more rapidly and the surface turns dark.

Iron is sometimes copper plated before it is nickel plated, but this is not necessary, for nickel adheres to iron perfectly well if the surface has been properly cleaned.

A nickel-chloride solution gives good results in plating any metal except iron. Iron always eventually rusts if plated in a chloride bath.

**Copper Plating.** — The metals on which copper is usually plated, zinc, iron and tin, are more electropositive than copper. On dipping these metals into an acid copper-sulphate bath, they would become covered with a layer of copper, which in some cases is spongy and does not

velocity with which this reaction takes place a solution of copper and potassium,  $KCu(CN)_2$ , is used. Cuprous cyanide in potassium cyanide to form an excess of 0.2 per cent of potassium cyanide. The proper current density at 50° to 60° C. The proper current density at 100 per square decimeter (4.6 amperes per square foot) at room temperature. For further details, see *Trans. Am. Electrochem. Soc.*, No. 52.

Received a thin coating of copper in a cyanide bath and a sulphate bath. The cyanide must be used in the sulphate bath. A sulphate bath may be made of copper sulphate  $CuSO_4 \cdot 5 H_2O$  and 50 grams per liter of water. The proper current density is 100 per square decimeter (6.5 amperes per square foot) which

is weakened by copper plating in a cyanide bath. While suspended, slightly stretched, in the bath due to absorbed hydrogen. See *Met. and Chem. Eng. Progress*, Vol. 32, p. 247, 1917;

ly deposited zinc is of a dull color and is not as bright as that obtained by dipping in melted zinc, but it is better to protect iron better for a given thickness of zinc than melted zinc. (*Burgess, Electrochem. and Met. Eng. Progress*, Vol. 32, p. 247, 1917.) A suitable solution consists of 200 grams of zinc sulphate and 10 grams of sodium sulphate,  $Na_2SO_4 \cdot 10H_2O$  and 10 grams of sulphuric acid. The proper current density is from 0.5 to 2 amperes per square decimeter (0.5 to 2 amperes per square foot) which requires from about 1 to 2.5 volts. More zinc is dissolved than is deposited, due to the fact that the zinc is replaced as it is used up. The resistance may be from 40° or 45° C.

A solution of zinc and of copper sulphates were used. Zinc and copper were deposited. In a cyanide solution of zinc and copper were deposited simultaneously in the form of an alloy. (*Chem. Abstr.*, Vol. 11, p. 367, 1905.) The copper is deposited, so that at a low current density, 0.1 ampere per square foot, only a small amount of zinc is deposited. At 2.8 amperes per square foot, 80 per cent of copper. Increasing the current density the deposit only slightly.

Plating is made by substituting zinc cyanide for half of the potassium cyanide given above for plating. Brass anodes are used. The following are found to give good deposits are the following:

- 1. Zinc, dried,
- 2. Zinc, dried,
- 3. Potassium and copper,
- 4. Potassium cyanide,
- 5. Potassium and zinc,

The solution contains  $n$  parts, by weight, of that substance per 100 parts of solution.

With the electrodes 15 centimeters apart, current density 0.3 ampere per square decimeter (2.78 amperes per square foot) about 3 volts are required.

- 1 liter water,
- 15 grams double cyanide of potassium and copper, crystallized,
- 16.5 grams double cyanide of potassium and zinc,
- 25.0 grams sodium sulphite,
- 2.0 grams potassium cyanide, 98 per cent.

Current density 0.3 ampere per square decimeter (2.78 amperes per square foot) requiring 3 volts when the electrodes are 10 centimeters apart. (*Galvanostegie, 1. Teil, p. 238, 1910.*)

**Silver Plating.** — The double cyanide of potassium and silver is used for silver plating on account of the smooth deposit obtained in solution. The deposit from a nitrate comes down in the form of isolated particles which do not cover the surface completely. The solution contains 65 per cent silver as potassium-silver cyanide,  $\text{KAg}(\text{CN})_2$ , with 0.5 per cent potassium cyanide. Too much or too little free cyanide gives a bad deposit. A good silver plating bath may be made up as follows:

- 20 grams potassium silver cyanide,
- 10-12 grams potassium cyanide, 99 per cent,
- 1 liter water.

The current density is 0.3 ampere per square decimeter, at about 3 volts. (*Schlötter, Galvanostegie, 1. Teil, p. 140, 1910.*) The anodes are silver.

Silver is deposited only on a surface of copper or copper alloy. Other metals must be copper plated before silvering. In order to make the silver adhere to the copper surface must be amalgamated by dipping the cleaned surface in a "quicking bath," consisting of a solution of 30 grams of potassium cyanide,  $\text{KCN}$ , and 30 grams of potassium cyanide in 1 liter of water. On removal from the quicking bath, articles are washed and placed immediately in the silvering bath.

**Gold Plating.** — The solution used in gold plating contains from 1 to 2 per cent of gold as the double cyanide of gold and potassium,  $\text{KAu}(\text{CN})_2$ , twice as much free potassium cyanide. The current density on the cathode is about 0.2 ampere per square decimeter (1.9 amperes per square foot) requires about 1.5 volts. The anodes are pure gold. The solution may be used hot or cold. The deposit from a hot solution is more dense, more uniform, and of a richer color. The color of the gold deposit may be influenced by the cathode simultaneously depositing some other metal. Green gilding may be obtained by adding a little silver cyanide to the bath, until the desired tint is obtained. The solution should be cold. To give the deposit a red tint, a little copper cyanide is added to the solution.

**Other Plating Processes.** — Plating with the following metals is also carried out: platinum, tin, lead, iron, antimony, and arsenic.

**Plating on Aluminum** frequently does not wear well, on account of the difficulty in getting a perfectly clean aluminum surface on which to plate. This is due to the rapidity with which a thin invisible film of oxide or hydroxide forms on aluminum when exposed to the air or to any solution. One method for overcoming this difficulty is to immerse the aluminum in a solution of potassium hydroxide until hydrogen is evolved, and then dip without previous washing in a potassium-silver-cyanide solution. The aluminum is immediately covered with a layer of silver. It is still better to amalgamate by dipping into a 0.5 per cent solution of mercuric chloride immediately after treating with hydroxide. The mercuric chloride is rinsed off, and the object again treated with potassium hydroxide.

be immediately suspended in the silvering bath. (*Langbein, Electrodeposition of Metals, 5th ed., p. 409, 1902.*)

Burgess (*Electrochem. Ind., Vol. 2, p. 85, 1904*) recommends cleaning first with dilute hydrofluoric acid, then with a mixture of 100 parts of sulphuric acid and 5 parts of nitric acid, both concentrated. After rinsing with water the surface is immediately plated with zinc, as this metal is found to adhere better than any others. Starting with the zinc surface, other metals are readily deposited.

**GALVANOPLASTY.** — Galvanoplasty is the art of reproducing by electrolysis articles of various kinds, or of making finished products, such as set-type, copper tubes, etc.

**Electrotyping.** — The object is to make a copper plate which shall be an exact duplicate of type which has been set up ready for printing. First an impression of the type is made in wax, which is then covered with a thin layer of graphite, by dusting the fine powder over the wax surface with soft brushes. A thin layer of copper is then formed by sprinkling the surface with iron filings and pouring over the surface a solution of copper sulphate. The iron goes into solution, depositing copper on itself and on the graphite. The wax plate is then washed in water and suspended in an acid bath of copper sulphate, where copper is deposited electrolytically until a thin sheet that can be stripped from the wax has been formed. After removing the copper sheet from the wax plate a melted lead-antimony alloy is poured on its reverse side, making a plate approximately 0.5 inch thick. This is then used for printing in place of the original type. The economy of this procedure comes in the saving of wear on the type, and the relatively small amount of type which has to be kept in stock.

The current density ranges from 1 to 2 amperes per square decimeter (0.9 to 1.5 amperes per square foot) and the volts per cell from 0.75 to 1.5.

Copper tubes are made by the Elmore process by depositing copper on a conducting cylinder which rotates in an acid copper-sulphate bath. The surface must be conducting, but the copper must not stick so firmly that the cylinder cannot be slipped out of the tube when finished. In order to keep the outer surface of the tube smooth, it is frequently polished during the deposition of copper. Copper sheets may be made by making tubes of large diameter and cutting them open.

Metallic foil may be made by the electrolytic deposition of a thin metallic layer on a surface from which it can be removed.

Parabolic mirrors are made by depositing copper electrolytically on a parabolic glass surface that has been silvered, and separating the metal from the glass by warming. (*Cowper-Coles, Electrolytisches Verfahren zur Herstellung parabolischer Spiegel, 1904.*)

**ELECTROLYTIC REFINING.** — The method of refining metals electrolytically is as follows. The impure metal is made the anode of an electrolytic bath, the electrolyte of which is, at the start, a solution of a pure salt of the metal to be refined, and the cathode is a sheet of the refined metal. On passing the current, metal dissolves, along with certain of the impurities. The impurities which are electronegative with respect to the principal metal dissolve; those electropositive with respect to the principal metal remain adhering to the anode. When the latter finally drop from the anode they may be dissolved by the free acid, in which case they would be precipitated again on coming in contact with the anode or the cathode. Some metals are precipitated as an insoluble salt as soon as they dissolve, and are thus removed from the further action of the current.

When it goes into solution, the principal metal is, therefore, separated from those metals which are electronegative with respect to it. When it is deposited

on the cathode, it is separated from those metals which are electropositive respect to it. The bath thus becomes contaminated with certain of the ties in the anode, and these would eventually be deposited on the cathode bath is not purified from time to time.

**Anode Mud.** — The metals which do not dissolve drop to the bottom of the tank forming the "anode mud." It is from this mud that the platinum, gold and silver are recovered in copper refining. For methods of working anode mud, see Kern, *Met. and Chem. Eng.*, Vol. 9, p. 417, 1911.

**Copper Refining.** — The object in refining copper electrolytically is to obtain as pure copper as possible for electric conductors and to obtain the precious metals contained in the crude copper. A representative composition of crude copper anodes for American refineries is the following:

Copper	98-99.5 per cent.
Silver	0-300 oz. per ton.
Gold	0-40 oz. per ton.
Arsenic	0-2 per cent.

The refined copper is about 99.95 per cent copper. The electrolyte is a solution of  $\text{CuSO}_4$  and  $\text{H}_2\text{SO}_4$  containing from 4 to 10 per cent of free acid and 12 to 20 per cent of  $\text{CuSO}_4$ . The current density ranges from 0.43 to 4.8 amperes per square decimeter (4 to 45 amperes per square foot) of cathode surface. The volts per cell range from 0.1 to 0.3. (*Ulke, Die Elektrolytische Raffinierung des Kupfers*, p. 42, 1904.) The electrolyte circulates slowly from tank to tank. The cathodes, called *starting sheets*, are thin sheets of refined copper.

**Multiple and Series Systems of Arranging the Electrodes.** Tanks for holding the solution and electrodes are made of wood and are frequently lined with lead. There are two methods of arranging the electrodes. In the "multiple system" all the cathodes of one tank are connected to one bus bar, likewise the anodes, the cathodes having an anode on each side, as shown in Fig. 1.

Fig. 1. Multiple System

Fig. 2. Walker Multiple System

Fig. 3. Series

The most economical method as regards the use of copper of construction tanks in the multiple system with each other is that devised by Walker (*Pat. 687, 800, 1901*). In this system the current flows from tank to tank out being collected in a single bus bar in this passage. The cathodes of the first tank rest on a conducting bar *G* (Fig. 2) on which the anodes of the second tank also rest. The figure shows two series of tanks with a leading in bus bar *B'* connecting the two series, and leading out bus bar *B''*. A more economical improvement is to have the cathodes of a tank make direct contact with the anodes of the adjacent tank.

In the Hayden or "series system," the electrodes are arranged as shown in Fig. 3. The impure copper plates are suspended in the solution at equal distances apart, only the end ones being connected to the dynamo. The current flows at the electrode *A*, which dissolves, and on flowing through the tank through the intermediate plates. Pure copper is deposited on the sides of the plates facing *A*, and dissolved from the opposite surfaces facing *B*.

dorting preparation is painted over the sides of the intermediate electrodes as *A*, so that the copper deposited can be separated from the impure copper. As a certain amount of the impure copper has been dissolved, the electrodes removed, the pure copper is separated from the impure, and the latter is melted and cast into new electrodes. This method is in use at the large plant of the Nichols Copper Company, Laurel Hill, New York, and at the Baltimore Copper Smelting & Rolling Co., Canton, Md. All others use the multiple system.

**Comparison of the Two Systems.** — The energy required in the series system is about 70 per cent of that required in the multiple system. Contacts cause more trouble in the multiple than in the series system. The electrodes in the series system cost more to prepare than in the multiple system. The investment in a series plant of given capacity is less than in a multiple plant. Lead-lined tanks cannot be used in the series system, the maintenance price of a series plant is greater than that of a multiple plant.

**Nickel Refining.** — Nickel may be refined by using a weakly acid solution of nickel chloride or nickel sulphate. To get thick deposits the solution must be heated from 50° to 90° C. Nickel and copper may be separated by the David Brown process, in which nickel is separated from an alloy of nickel and copper depositing the nickel electrolytically. Very pure nickel required for special uses is refined electrolytically by the Orford Copper Company, by a secret process. Foerster obtained good results with a current density of 0.5 to 2.5 amperes per square decimeter (4.5 to 23 amperes per square foot) between 50° C. and 70° C. The neutral nickel-sulphate solution contained 30 grams of nickel per liter. Günther obtained good deposits at 60° to 65° C., with 4 to 5 amperes per square decimeter (37 to 45 amperes per square foot) at 3.5 to 4 volts, with nickel sulphate baths.

**Silver Refining.** — Two cases arise, (1) the separation of silver from copper alloy consisting mainly of these two metals, and (2) the separation of silver from relatively small amounts of gold and platinum.

**Dietzel Process.** — One method of separating silver and copper is the Dietzel process. This consists in dissolving both of the metals as anode in a weakly acid solution of copper nitrate. The solution is then transferred to another vessel and the silver is precipitated by metallic copper, following which copper is deposited electrolytically.

The current density is about 1.5 amperes per square decimeter (14 amperes per square foot) of cathode surface, and the voltage per cell from 2.5 to 3.5 volts.

**Moebius Process.** — Silver is separated from small amounts of other metals by the Moebius process. In this process the anodes consist of the impure metal, the cathodes of thin sheet silver, and the electrolyte is a slightly acid silver-nitrate solution. In the earlier type of apparatus the cathodes are stationary; in the later type the cathode is a rotating sheet of silver. In this way the pure silver is scraped off as crystals.

The current density is about 3 amperes per square decimeter (28 amperes per square foot) of cathode surface, and the voltage per cell from 1.4 to 1.5 volts. Another type is the Balbach-Thum cell (*Met. and Chem. Eng.*, Vol. 9, p. 444, 1911).

**Gold refining** is carried out in a slightly acid solution of gold chloride. Gold does not dissolve in a solution of gold chloride  $AuCl_3$ , or of chloroauric acid,  $HAuCl_4$ , but the chlorine liberated comes off in the gaseous form. If some alkali chloride or hydrochloric acid is present, the gold dissolves. The resulting gold is never less than 999.8 fine, and frequently is 1000 fine.

The baths contain about 3 per cent of free hydrochloric acid with 30 to 40 grams of gold as chloroauric acid per liter. The bath is heated to 60° or 70° C.,

and the current density is about 10 amperes per square decimeter (93 amp per square foot) at about 1 volt.

Lead refining is carried out by the Betts process. The electrolyte solution of lead fluosilicate ( $\text{PbSiF}_6$ ) containing 60 to 70 grams of lead 120 to 130 grams of  $\text{SiF}_4$  per liter, and 0.1 per cent of glue. The object of refining lead is to recover the copper, antimony, bismuth, gold and silver. These cannot be separated from the lead electrolytically, on account of its proximity to lead in the electrolytic series.

The current density ranges from 1.3 to 1.7 amperes per square decimeter (16 amperes per square foot) of cathode surface, and the voltage per cell is 0.30 to 0.38 volt.

According to Duisberg (*Journ. of Ind. and Eng. Chem. for 1912, p. 752*) it is now refined electrolytically by the firm Langbein-Planhauser & Co., Leipzig. It has valuable magnetic properties, and is used in electromotors. The electrolysis is carried out at  $100^\circ$  to  $120^\circ\text{C}$ . See also Guillet, *J. Iron and Steel Inst.* Vol. 90, pp. 66-80, 1914, and Story, *Tr. Am. Electrochem. Soc.*, Vol. 29, pp. 3367, 1916.

**Refining of Other Metals.** — A number of other metals may be refined electrolytically, such as mercury, tin, bismuth, and antimony, but these are relatively unimportant.

**ELECTROLYTIC WINNING OF METALS.** — The attempts that have been made to win metals directly from their ores or from matter are based on the same principle as that underlying metal refining. These attempts have not been successful until recently, however, on account of the large amount of impurity that gets into the bath and on account of mechanical difficulties. The best known of such attempts, are the following.

**Marchese Process.** — In the Marchese process it was attempted to obtain pure copper from a matte containing principally copper, lead, iron and sulphur, by electrolyzing this matte as an anode in a sulphate bath. This process seemed a success at first, but finally failed.

**Siemens and Halske Process.** — The Siemens and Halske process for extracting copper consists in electrolyzing a solution of iron sulphate and copper sulphate in a cell in which the anode and cathode are separated by a linen diaphragm. The anode was carbon; the cathode pure copper. In the cathode compartment the solution loses copper by deposition on the cathode. The solution then circulates to the anode compartment, where the ferrous sulphate is oxidized to ferric sulphate. See below, under *Electrolytic Oxidation*. From here the solution circulates to another vat where fresh ore, consisting of copper pyrites ( $\text{Cu}_2\text{SFe}_2\text{S}_4$ ) that has been roasted so as to change the iron sulphide to oxide, is treated. The ferric sulphate dissolves the cuprous sulphide as follows:

This solution, enriched in copper, is then conveyed to the cathode compartment and the cycle is completed. This process also failed when tried on a commercial scale.

**Hoepfner Process.** — In the Hoepfner process the copper ore, consisting of copper sulphide, is dissolved in a cupric chloride solution containing a relatively large amount of sodium chloride. The reaction is as follows:

The cuprous chloride, insoluble in water, is held in solution by the sodium chloride. The anode and cathode of the electrolytic cell are separated by a diaphragm. The solution first circulates to the cathode compartment, where pure

the copper is deposited, and then to the anode, where the cuprous chloride is oxidized to cupric chloride. The solution from the anode then circulates to the cathode.

**Copper Hydrometallurgy at Chuquicamata.** — A process is now being tried by the Chile Exploration Company for winning copper directly from the ore of the Chuquicamata copper mine, in Chile. The ore is dissolved in dilute sulphuric acid in leaching tanks. The solution is then conducted to the electrolytic tanks where the copper is deposited, using insoluble anodes and copper cathode starting sheets. Originally fused magnetite anodes were used, but these were later replaced by *duriron* (ferro-silicon containing 12 per cent silicon). The electrolytic refinery will have a capacity of 335,000 pounds of copper per year. (*E. A. Coppel Smith, Met. and Chem. Eng., 1914, Vol. 12, pp. 291-294.*)

**Lead Process.** — Lead was at one time extracted from galena (PbS) by the *duriron* process, consisting in electrolyzing the powdered galena as cathode in sulphuric acid. The hydrogen deposited on the galena combines with the lead, forming hydrogen sulphide and leaving the lead as lead sponge. This process was given up, partly at least, on account of the poisonous action of the lead sulphide. (*Trans. Am. Electrochem. Soc. Vol. 1, p. 87, 1902; Vol. 4, pp. 190-193.*)

**Electrolytic Zinc.** — Within recent years a large quantity of high grade electrolytic zinc has been produced in the United States and Canada, by a process similar to that used for copper at Chuquicamata. Sulphate solutions are used, with lead anodes and aluminum cathodes, from which the zinc is stripped in sheets. The solution must be free from impurities in order to get good metal. See Hansen, *Bull. Am. Inst. Mining Eng., Vol. 135, p. 615, 1919*; French, *Trans. Am. Electrochem. Soc., Vol. 31, pp. 321-328, 1917*; *Met. and Chem. Eng., Vol. 18, pp. 549-550, 1918.*

**Recovering Tin Scrap and Old Cans.** — The two principal methods of recovering tin from tin scrap and old tin cans are due to Goldschmidt. The first consists in electrolytically dissolving the tin and depositing it in the metallic form; the second method, which however is not electrolytic, converts the tin into stannic tetrachloride by treating with dry chlorine.

In the electrolytic method the solution consists of a sodium hydrate solution, containing a certain amount of carbonate, absorbed from the air, and sodium stannate. The best concentrations are: 10 to 12 per cent alkalinity, not over 2 per cent free alkali; carbonate not over 3 per cent; stannate not over 5 per cent. Temperature, 60° to 70° C. About one-tenth of the solution must be changed every week.

The tin scrap is suspended in the solution in baskets (39 by 35 by 18 inches) of perforated sheet iron, containing 100 to 130 pounds of scrap. Old cans are used, compressed and then cut up. The cathodes are sheet iron 39 by 35 inches. The tin dissolves from the anode and is deposited as spongy tin on the cathode. The scrap is left in the bath for three hours. The spongy tin is compressed by a hydraulic press into cylinders weighing six pounds; these are subsequently melted in a furnace with sealed tubes. This sponge contains 50 per cent tin and 50 per cent ash. The ash is subsequently reduced with carbon in open-hearth furnace, yielding 70 per cent of the tin.

Very careful working is necessary to remove the tin so completely that the iron can be sold to open-hearth plants. Even then the iron contains 0.1 to 0.5 per cent tin.

The cathode current density is never over 0.75 ampere per square decimeter (ampere per square foot), at 2 to 3 volts per cell. (*Electrochem. and Met. Ind., Vol. 7, p. 79, 1909; Met. and Chem. Eng., Vol. 10, p. 202, 1912.*)

**ELECTROLYTIC OXIDATION AND REDUCTION** is frequently carried out on substances in solution. One of the advantages of the method is that no other substance has to be added to the solution. In carrying out an electrolytic oxidation or reduction a porous diaphragm is used to separate the anode and cathode compartments. The substance to be reduced is placed in the cathode compartment, where the whole or a part of the hydrogen which would be evolved by the current while in the nascent state, acts on the substance in question. The intensity of the reduction may be varied by changing the potential difference between the solution and the cathode. This may be accomplished either by increasing the current density on the cathode, or by using the cathode of different metals on which the overvoltage (*see Electrochemical Principles of*) is different. It frequently happens that the metal compound on the cathode has a marked accelerating effect on the velocity of the reduction. Thus the reduction may be much more complete on one metal than on another, although the potential difference between the metals and the solution is the same in both cases. The same considerations apply to oxidation at the anode.

**Typical Reduction and Oxidation Processes.**— Examples of electrolytic reduction has been found useful are: in the manufacture of vanadium by corroding a lead anode in a suitable solvent, e.g., the Luckow process; in the preparation of the lower salts of vanadium, molybdenum and titanium. Examples where electrolytic oxidation has been employed are: in the oxidation of cerium lower cerium sulphate,  $\text{Ce}(\text{SO}_4)_2$ , to  $\text{Ce}(\text{SO}_4)_3$ , the latter being useful as a bleaching agent; in oxidizing potassium manganate,  $\text{K}_2\text{MnO}_4$ , to permanganate,  $\text{KMnO}_4$ ; in the oxidation of potassium ferrocyanide,  $\text{K}_4\text{Fe}(\text{CN})_6$ , to potassium ferricyanide,  $\text{K}_3\text{Fe}(\text{CN})_6$ ; and of chromium sulphate to a chromate.

Sodium permanganate has been made on a semi-commercial scale by electrolyzing ferro-manganese anodes in sodium carbonate or hydrate solution (*Am. Electrochem. Soc., Vol. 35, pp. 371-383, 1919*). Potassium permanganate has been made in the same way (*Chem. and Met. Eng., Vol. 21, pp. 680-681*).

### **ELECTROLYSIS OF SODIUM OR POTASSIUM CHLORIDE**

The electrolysis of sodium or potassium chloride may yield several products, depending on the kind of cell employed. In the following section the reactions for sodium chloride are given; these reactions also apply to potassium chloride when K is substituted for Na.

**Production of Electrolytic Bleach.**— If there is no diaphragm between the compartments, the solution is kept cool, the chlorine and hydrate react on each other to form principally sodium hypochlorite or "electrolytic bleach," according to the following equation

As soon as hypochlorite is formed, it begins to change to chlorate, but not as rapidly as it is formed. As the concentration of the hypochlorite increases, a larger and larger proportion changes to chlorate, until finally the concentration of the hypochlorite reaches a limit, which depends on temperature, original salt concentration, current density, and other factors. After this limit is reached, hypochlorite then changes to chlorate as rapidly as it is formed.

The reactions by which hypochlorite changes to chlorate are two; (1) the action of the discharged  $\text{ClO}$  ion on water:

and (2) in a slightly acid solution:

the solution is warmed to about 50° C. the conditions are so changed that the maximum concentration of hypochlorite is much lower than when cold. Sodium and potassium hypochlorites are used only in solution, but the chlorates are solidified out.

By further electrolysis of a cooled sodium (or potassium) chlorate solution, perchlorate,  $\text{NaClO}_4$ , is produced by the action of the liberated  $\text{ClO}_2$  ion on  $\text{ClO}_3^-$ :

In most of the cells used for producing hypochlorite, a vessel is divided into a number of narrow compartments by bipolar or intermediate electrodes, consisting of carbon plates (Hass and Oetzel) or platinum-iridium wire wound on carbon plates (the Kellner cell). The solution is cooled by circulation. There is no essential difference between a hypochlorite and a chlorate cell, except that the latter is used at a higher temperature. (See numerous volumes in the *Engelhardt Monographs*.)

**Production of Chlorine and Caustic.** — If the anode and cathode are separated by a diaphragm of some kind, sodium hydrate is produced at the cathode by the action of the alkali metal on water:

while at the anode chlorine is set free, which may be used to make bleaching powder.

Various devices are used to separate the hydrate and chlorine in cells intended to produce these products. In the McDonald cell (*Electrochem. Ind.*, Vol. 1, page 387, 1907) and others a porous diaphragm is used. In the Hargreaves-Bird cell (*S. Pat.* 655,343, 1900; 506,157, 1897), the porous diaphragm is supported by a heavy copper gauze cathode, which is wetted only by the solution percolating through the diaphragm. In the Townsend cell (*Electrochem. and Met. Ind.*, Vol. 1, page 209, 1907) the cathode compartment is filled with kerosene oil. During electrolysis the solution in the anode compartment percolates through the porous diaphragm and the perforated cathode, and on coming in contact with the oil forms drops and sinks to the bottom of the cathode compartment where it is collected. In the "bell process" the anode is inside an inverted non-porous, nonporous bell, and the cathode is a conducting ring outside. Two important diaphragm cells are the Allen-Moore cell and the Nelson cell (*Trans. Electrochem. Soc.*, Vol. 35, pp. 239-249, 1919).

In the Castner cell the compartments are separated by a mercury diaphragm, acting as an intermediate electrode; and in the Solvay and the Whiting cells a mercury cathode is used, which, when charged with sodium in the electrolytic cell, is decomposed by water in a different compartment. The sodium amalgam reacts with water like metallic sodium. (See the *Engelhardt Monographs*.)

**ELECTROLYSIS OF WATER.** — The electrolysis of water is carried out on a commercial scale for the production of hydrogen and oxygen. The electrolyte is usually a 15-per cent sodium hydrate solution. A diaphragm of asbestos is used to separate the hydrogen and oxygen in the Flamand cell, now used by the International Oxygen Company at Newark, N. J. The vessel containing the electrolyte is cast iron and acts as the cathode; the anode is platinum. In the Siemens and Halske apparatus the gases are separated by a metallic gauze while bubbling to the surface of the solution; the Garuti and

Pompeili apparatus is based on a similar principle. (See *Vierteljahrsschrift für Naturgeschichte*, 1902.)

**ELECTROTHERMAL PROCESSES.** — Some of the more important industrial electrothermal processes and products and the various types of furnaces are described in the article on *Furnaces, Electric*.

**OZONE (O<sub>3</sub>)** is made by the silent discharge of electricity through oxygen. The electrodes are water cooled, and protected to prevent the passage of oxygen. From 8000 to 50,000 volts alternating are applied, this voltage being obtained from a small step-up transformer. For the Siemens and Halske process the concentration of the ozone is about 2 or 3 grams per cubic meter of the gas that passes through it, and the yield is from 18 to 37 grams per kilowatt hour. (*Ind. Chem. Ind., Vol. 2, p. 67, 1904.*) Milk has been sterilized by high voltage discharges; one process being the Shelmerdine process (*Electrical Times*, 1914, pp. 502-505, 1914).

**BIBLIOGRAPHY.** — In addition to the references given above, the following books should be consulted for further information regarding industrial electrochemical processes:

**ELECTROCHEMISTRY, PRINCIPLES OF.**—(See also *Electricity Magnetism, Principles of; Elements, Chemical; Electrochemical Processes, Physical; Furnaces, Electric.*) Electrochemistry is the science which deals with the phenomena resulting from the direct transformation of electrical into chemical energy or the converse transformation of chemical into electrical energy. By general usage the term, especially as applied to industrial processes, is made to include also those thermochemical phenomena which occur at temperatures produced in electric furnaces, although in such processes electrical energy frequently plays no other rôle than that of generating heat.

**DEFINITIONS.**—The following terms are commonly used:

**Element.**—An element is a substance which cannot be decomposed into other substances by any known means of chemical analysis. (See *Table of Chemical Equivalents below, and article on Elements, Chemical.*)

**Atoms and Atomic Weights.**—An atom is the smallest mass of an element which can enter into chemical combination with another element or itself. The atomic weight of an element is a number which is proportional to the smallest combining mass of the element, that of oxygen being chosen as the standard taken as 16. The relative proportions, by mass, of the elements forming any substance are simple multiples of these numbers. For table of the atomic weights of the more common elements see below, and for a complete treatment see article on *Elements, Chemical*. On the atomic theory the atomic weight is proportional to the mass of the atom.

**Molecules and Molecular Weight.**—A molecule is the smallest mass of a substance which can exist and preserve its chemical properties. The molecular weight of an element or of a chemical compound is equal to the sum of the atomic weights of the atoms contained in the molecule, and may readily be calculated from the atomic weights when the molecular symbol of the compound is known. Thus the molecular weight of oxygen,  $O_2$ , is  $2 \times 16.00 = 32.00$  there are two atoms in the molecule. The molecular weight of silver nitrate,  $AgNO_3$ , is  $107.88 + 14.01 + 3 \times 16.00 = 169.89$ .

**Radical.**—A radical is a combination of two or more elements which persists as a group in chemical reactions, e.g., the  $SO_4$  in  $H_2SO_4$  is a radical, as is implied by the reaction  $H_2SO_4 + Zn = ZnSO_4 + H_2$ .

**Formula Weight.**—The formula weight of an atom, radical or molecule is the sum of the atomic weights of the elements of which it is formed. For example, the formula weight of an oxygen atom,  $O$ , is 16; the formula weight

of an oxygen molecule,  $O_2$ , is 32; the formula weight of the radical  $14.01 + 3 \times 16.00 = 62.01$ .

**Valency.** — An adequate consideration of valency would involve a *disquisition* beyond the limits of this article. As a simple definition, the valency of an acid or acid radical may be taken as the number of replaceable hydrogen atoms which the acid molecule contains, the valency of the hydrogen atom always equal to unity. Thus hydrochloric acid, HCl, and nitric acid,  $HNO_3$ , are univalent acids and the elements H and Cl and the radical  $NO_3$  are univalent; sulphuric acid,  $H_2(SO_4)$ , is a bivalent acid and  $SO_4$  a bivalent radical;  $H_3(PO_4)$  is a trivalent acid and  $PO_4$  a trivalent radical, etc. Similarly, in sodium chloride, NaCl, sodium is a univalent metal, since one atom of sodium replaces one atom of hydrogen in the corresponding acid. In barium chloride,  $BaCl_2$ , barium is a bivalent metal, as it replaces the hydrogen of two molecules of hydrochloric acid to form the salt. To completely define the valency of a salt it is therefore necessary to stipulate the valency of its basic and acid constituents; thus sodium chloride, NaCl, is a uni-univalent salt; sodium sulphate,  $Na_2SO_4$ , is a uni-bivalent salt, the basic constituent being univalent and the acid constituent bivalent. Barium sulphate,  $BaSO_4$ , on the other hand, is a bi-bivalent salt. The valency of a number of elements according to the compound of which the element forms a part, e.g., copper is bivalent in cupric salts like  $CuSO_4$  but univalent in cuprous salts as  $CuCl$  is bivalent or trivalent according as it is a constituent of a ferrous or ferric respectively.

**Bonds or Affinities.** — An atom or radical is sometimes said to possess a number of "bonds" or "affinities" equal to its valency in the compound which it forms a part.

**Equivalent Weight—Chemical Equivalent.** — The equivalent weight of an atom, ion or radical is defined as its formula weight divided by its valency. The equivalent weight of an element or compound is also referred to as "chemical equivalent." The equivalent weight of an acid, base or salt is its molecular formula weight divided by the highest valency of either of its constituents. As hydrogen exhibits no other valency than unity its equivalent weight and atomic weight are identical. Similarly, the equivalent weight and molecular weight of hydrochloric acid, HCl, are each 36.47. Copper in copper sulphate,  $Cu(SO_4)$ , and in cupric chloride,  $CuCl_2$ , has a valency of 2, hence equivalent weights of these salts are one half their molecular weights respectively.

In computations of electrochemical reactions it is frequently convenient to take as the unit of mass (or weight) of a substance, a mass in grams equal to the number expressing the atomic weight, ionic weight, molecular weight or equivalent weight of the substance. The following names have been given to these units.

**Gram-Atom or Gram-atomic Weight.** — A number of grams of an element equal to its atomic weight, e.g., one gram-atom of oxygen is 16 grams.

**Gram-Molecule or Mol.** — A number of grams of a substance equal to its molecular weight, e.g., one mol of silver nitrate,  $AgNO_3$ , is 169.89 grams.

**Gram-Equivalent.** — A number of grams of an atom, radical or molecule equal to its equivalent weight,  $\frac{1}{n}$  of its formula weight divided by its valency. For example, a gram-equivalent of sulphuric acid is  $98.09/2 = 49.04$  gr. A gram-equivalent is usually represented by the chemical formula divided by the valency, e.g., a gram-equivalent of sulphuric acid is denoted by  $\frac{1}{2} H_2SO_4$ .

**Electrolyte—Electrolysis.** — When an electric current is passed through certain substances a chemical reaction takes place at the places where the current enters or leaves the substance. Such substances are called "electrolytes."

is," if the current effects a decomposition or chemical change in the electrolyte the process is called "electrolysis."

**Electrodes — Anode and Cathode.** — Electrodes are the conductors by which the current enters and leaves the electrolyte. The electrode at which the current enters the electrolyte is called the "anode," and that by which the current leaves the electrolyte is called the "cathode." The anode is therefore that electrode which is connected to the positive terminal of the generator; the electrode that is connected to the negative terminal.

**Ions — Anions and Cations.** — The constituents of an electrolyte which are either liberated or deposited from an electrolyte at the electrodes are called ions. The term also applies to the constituents of an electrolyte which conduct the current. (See sections below on *Dissociation Theory and Theory of Electric Conduction.*) The ions liberated at the anode are called "anions," while those liberated at the cathode are called "cations." For example, when a current enters and leaves an aqueous solution of copper sulphate,  $\text{CuSO}_4$ , at platinum electrodes, the  $\text{CuSO}_4$  is decomposed, the copper  $\text{Cu}$  being liberated in the solution and deposited on the cathode, and the  $\text{SO}_4$  being liberated at the anode where it reacts with the water to form oxygen gas and sulphuric acid. The copper in the sulphate solution is therefore a cation and the  $\text{SO}_4$  an anion. In general the metal atoms in salts and bases and the replaceable hydrogen atoms in acids are cations, while the acid radicals (e.g.,  $\text{SO}_4$ ) and the hydroxyl radicals (e.g.  $\text{OH}$  in  $\text{KOH}$ ) are anions.

The terms anion and cation are also used to designate specifically the negative and positive constituents of an electrolyte. For example, in dilute aqueous solution a molecule of hydrochloric acid,  $\text{HCl}$ , is looked upon as consisting of one hydrogen cation and one chlorine anion; sulphuric acid,  $\text{H}_2\text{SO}_4$ , of two hydrogen cations and one  $\text{SO}_4$  anion. There is much evidence to indicate that a negative charge of fixed amount is associated with each anion and a positive charge (deficit of negative electricity) of equal amount is associated with each cation, irrespective of the chemical nature of the ion, except that the charges carried by ions are directly proportional to its valency. The charge carried by each univalent ion as determined by Millikan, is  $4.774 \pm 0.005 \times 10^{-10}$  electrostatic units, the charge carried by every bivalent ion is twice this amount,  $9.548 \pm 0.005 \times 10^{-10}$  electrostatic units of negative electricity, being the charge of an electron. Hence on the basis of the electron theory, a univalent anion as  $\text{Cl}$  has associated with it one free electron, a divalent anion as  $\text{SO}_4$  two electrons, while a univalent cation as  $\text{H}$  has a deficit of one electron, a divalent cation as  $\text{Cu}$  has a deficit of two electrons, etc. See *Electron Theory*.

To distinguish cations and anions from neutral atoms or molecules, small plus or minus signs are often written over the symbol, the number of such signs being equal to the valance of the ion. Thus

$\overset{+}{\text{Na}}, \overset{++}{\text{Cu}}, \overset{+++}{\text{Fe}}$  (ferric iron) represent cations;  $\overset{-}{\text{Cl}}, \overset{-}{\text{NO}_3}, \overset{-}{\text{SO}_4}, \overset{-}{\text{PO}_4}$  anions, etc.

**Ionic Weight.** — The formula weight of an ion is called its ionic weight.

**Gram-Ion.** — A number of grams of an ion equal to its ionic weight, e.g., one gram-ion of hydrogen is 1.008 grams, and one gram-ion of  $\text{SO}_4$  is 96.07 grams.

**Electrochemical Equivalent.** — The electrochemical equivalent of an ion is the mass in grams of the ion liberated or deposited by one coulomb of electricity.

**Electrochemical Constant or "Faraday."** — The electrochemical constant, denoted by  $F$ , and called the "Faraday," is the number of coulombs required to liberate one gram-equivalent of any ion. It is a constant for all ions, and its value, as adopted by the International Congress of Applied Chemistry in 1903, is  $F = 96,540$  coulombs. (See also page 452.)

**Solvent, Solute and Solution.**—When a substance *A* “dissolves” substance *B*, the substance *A* which dissolves is called the “solute” substance *B* is called the “solvent.” The two substances together “solution.”

**Osmotic Pressure.**—The osmotic pressure of a solution may be defined as the force in virtue of which a solute tends to diffuse from regions of higher concentration to regions of lower concentration. It can be measured by separating the solute and solvent by means of a diaphragm which is permeable to the solvent but not to the solute. (See section below on *Theory of Solutions*.)

**Specific Conductance ( $\kappa$ ).**—The specific conductance of a solution is the reciprocal of its specific resistance, i.e., it is the conductance of a liquid one centimeter long and one square centimeter cross section. It is expressed in reciprocal ohms, or mhos, and is denoted by  $\kappa$ .

**Concentration ( $c$ ).**—The concentration ( $c$ ) of a solution is the quantity of the solute contained in unit volume of the solution. Thus it may be expressed as grams per cubic centimeter or grams per liter, etc.

**Equivalent Concentration ( $\eta$ ).**—The equivalent concentration of a solution is the number of gram-equivalents of solute contained in one cubic centimeter of the solution; it is denoted by  $\eta$ . Calling  $w$  the equivalent weight of the solute,  $\eta = c/w$ .

**Dilution ( $\phi$ ).**—The dilution of a solution is the reciprocal of its concentration, i.e., it is the number of cubic centimeters of solution in which one gram-equivalent of solute is dissolved. It is denoted by  $\phi$ . Hence,  $\phi = 1/\eta$ .

**Normal Solution.**—A normal solution is a solution containing one gram-equivalent of solute per liter. For such a solution  $\eta = 10^{-3}$  or  $\phi = 10^3$ .

**Equivalent Conductance ( $\Lambda$ ).**—The equivalent conductance of a solution at the dilution  $\phi$  is the conductance which a volume (in cu. cm.) of the solution containing one gram-equivalent of the solute would have, if placed between parallel plate electrodes one centimeter apart. It is denoted by  $\Lambda_\phi$  or  $\Lambda_c$  as the dilution or concentration of the solution is given. Hence,  $\Lambda_\phi = \kappa/\eta$ .

The dilution or concentration of a solution should always be stated in connection with its equivalent conductance, otherwise the expression is incomplete.

**Heat of Reaction.**—The heat of reaction is the heat energy given out or absorbed in a chemical reaction. It is usually expressed in calories, and *Heat Effects*. Ostwald recommends the use of a calorie equal to the mean gram-calorie for expressing thermochemical data and this has been adopted in the present discussion. It will be denoted in this article by  $Q$ .

**Exothermic Reactions.**—Reactions in which heat is given out to the surrounding bodies.

**Endothermic Reactions.**—Reactions in which heat is absorbed from the surrounding bodies.

**NOTATION.**—The notation used in this article is, in most instances, as proposed by the Bunsen Gesellschaft and adopted by the Fifth International Congress of Applied Chemistry in Berlin, 1903. For convenience of reference the symbols most frequently used are tabulated below.

- $\kappa$  = specific conductance in reciprocal ohms;
- $\eta$  = concentration, expressed as gram-equivalents of solute per cubic centimeter solution;
- $\phi$  = dilution, expressed as cubic centimeters of solution per gram-equivalent of solute;

at infinite dilution;

reference;

[by International Congress]

is taken positive in direction of rise of potential;\*

measured against a normal hydrogen electrode;

and Symbols.

the voltage and intensity of the current, size of electrodes and concentration of electrolyte, so long as the total quantity of electricity flowing through the circuit remains constant. (These factors, however, do affect the *rate* of an electrolysis.)

**Second Law.** — A given quantity of electricity always decomposes weights of different electrolytes irrespective of their nature. For example, three electrolytic cells containing aqueous solutions of silver nitrate, copper sulphate  $\text{CuSO}_4$ , and cuprous chloride  $\text{CuCl}$  (dissolved in hydrochloric acid), respectively, be connected in series and the same quantity of electricity passed through each, it will be found if  $a$  grams of silver are deposited in the first cell,  $b$  grams of copper in the second and  $c$  grams of copper in the third, that the following proportion holds between these weights:

$\frac{107.88}{1} : \frac{63.57}{2} : \frac{63.57}{1}$ , where 107.88 and 63.57 are the atomic weights

of silver and copper respectively. In copper sulphate the valency of copper is 2; in cuprous chloride its valency is 1; silver is always univalent and its atomic weight is 107.88. The weights  $a, b, c$  are proportional not to the atomic weights but to the *equivalent weights* of the metals in the compounds from which they are electrolytically deposited. It follows from this that a given current will deposit in a given time a weight of metal from a salt in which it is combined with a valency of 2, twice the weight of metal from a salt in which it exists with a valency of 1. Thus, the same current will deposit in a given time twice the weight of copper from a cuprous as from a cupric salt solution. In general, if the ion in a compound has a valency of  $n$ , the quantity of electricity required to liberate it will be  $n$  times as great as that required to liberate the same ion from a compound in which it is univalent.

It is to be noted, since the numbers expressing the atomic weights and hence their equivalent weights, are purely relative, that the weights of substances decomposed by a given quantity of electricity expressed in grams, kilograms, pounds or any other unit of weight.

In the above illustration the quantity of electricity which will deposit  $\frac{63.57}{2}$  pounds of copper from a copper sulphate solution will deposit 107.88 pounds of silver.

Faraday's Laws are the expression of the results of direct experiments which have been tested to the limit of precision with which physical and chemical measurements are capable of being carried out at the present time. Experience indicates that they hold rigidly, i.e., that they are exact laws. In cases where exceptions have seemed to exist these have been shown to be due to secondary causes. See Kraus, *Trans. Am. Elec. Chem. Soc.*, 21, for special cases of electronic and ionic conduction.

**Value of the Electrochemical Constant or Faraday.** — The determination of the number of coulombs required to deposit one gram-equivalent of a substance, i.e., the constant connecting the quantity of electricity and the mass of substance liberated, involves two distinct investigations; first, the measurement of the number of coulombs which pass through a given electrolytic cell in a given time, second, the determination of the amount of the chemical decomposition. The importance of the constant has enlisted the skill of a number of physicists, and its value is still being investigated at the present time.

The various methods which have been employed vary primarily in the method adopted for measuring the current. A primary instrument the construction of which can be computed from its dimensions, is essential. Tangent galvanometers and various forms of current balances or dynamometers have been constructed for this purpose. The ultimate precision of the measurements made with these instruments is thus referred back to instrumental constants and

accuracy with which the horizontal component of the earth's field, or the value of the acceleration due to gravity, is known at the place where the research is carried out, respectively.

The amount of silver deposited from a silver nitrate solution has been adopted almost universally for the chemical part of the research. The amount of silver deposited depends to a slight extent upon whether or not the solution at the cathode is allowed to diffuse to the cathode. The following résumé of the determinations of the mass of silver in milligrams deposited by one coulomb is given in *Bulletin of the Bureau of Standards*, 1905, Vol. 1, p. 363).

TABLE I.—ELECTROCHEMICAL EQUIVALENT OF SILVER IN MILLIGRAMS PER COULOMB

Observer	Year	Found	Electrochemical equivalent corrected by		
			Richards and Heinrod	Van Dijk	Guthe
		mg.	mg.	mg.	mg.
Lehmann	1884	1.1156	.....	1.1155	1.1153
Ernst W. Kohlrausch	1884	1.1183	1.1173	1.1184	1.1177
Wright and Sidgwick	1884	1.1179	1.1175	1.1178	1.1176
Ray	1886	1.1183	.....	.....	1.1178
Wright	1887	1.1174	.....	.....	1.1169
Blat and Potier	1890	1.1192	.....	1.1191	1.1189
Sturman and Guthe	1898	1.1192	1.1175	1.1180	1.1177
Blat and Ledwicz	1903	1.1195	.....	1.1192	1.1190
Van Dijk and Kunst	1904	1.1182	.....	1.1180	1.1178
			Mean 1.1176		

If the atomic weight of silver be taken as 107.88 (latest corrected value) the value of the Faraday from the average of Guthe's corrected values is

$\frac{107.88}{0.0011176} = 96,530$  coulombs. This value agrees very closely with the

value  $F = 96,540$  adopted by the International Congress of Applied Chemistry in 1903 and based on the atomic weight of silver = 107.93, and on the definition of the legal ampere as that current which in one second deposits 0.001118 gram silver. (See *Report of International Electrical Congress, 1893; Definition legalized by the U. S. Government in 1894.*) In view of the above agreement it seems advisable to adhere to the value 96,540 until by international agreement another value shall be adopted. For a complete résumé of recent work on the value of the Faraday the *Bull. Bureau of Standards*, 13, 479, 1916, should be consulted. The Bureau of standards gives 96,503 as the most probable value, and recommends 96,500 as the best round value.

**ELECTROCHEMICAL EQUIVALENTS OF THE ELEMENTS.**—From the definitions of the electrochemical equivalent and the Faraday, it follows that the electrochemical equivalent of any ion, expressed in grams per coulomb (one ampere per second) is equal to

$$\frac{\text{gram-equivalent of the ion}}{96,540}$$

Table II contains the values of the electrochemical equivalents of common elements which may be found useful in certain calculations.

Soc.*, 21, 105, 1912;

**ELECTROLYTIC CELLS.** — When a cell formed by two electrolytes gives out electric energy the cell is called by chemical batteries are voltaic cells. If across

the terminals of a cell an external electromotive force, greater than the electromotive force developed within the cell, is impressed, then a current flows through the cell in the opposite direction, and the cell will absorb energy. A cell which absorbs electric energy is usually referred to as an "electrolytic cell." The cells used in electrolytic refining and similar processes are electrolytic cells. An electrolytic cell may or may not have an electromotive force on open circuit, but may develop an electromotive force of its own from the chemical changes or changes in concentration which take place. The current is forced through it by some external source. A voltaic cell acts as an electrolytic cell when the electromotive force impressed across its terminals exceeds (and opposes) its own electromotive force.

**POLARIZATION.** — When an electric current passes through a voltaic or an electrolytic cell there is, in general, developed at the electrodes of the cell as a result of the chemical actions and changes in concentration which take place, a *back* or *counter-electromotive* force, in addition to its own electromotive force (if any), and an *increase in the resistance* of the cell. In addition to the change in resistance due to the heating effect of the current. Both of these effects cause a decrease in the strength of the current flowing through the cell. These two phenomena are said to be due to "polarization," the former being "transition resistance" respectively.

Even in the case where the electrolyte, as a whole, suffers no change in concentration, as in the electrolysis of copper sulphate between copper electrodes, a counter e.m.f. of polarization is produced in consequence of the increase in concentration of the copper ions in the neighborhood of the anode and the resulting polarization, but, except for very low current densities, vigorous stirring of the electrolyte tends to reduce this concentration and the resulting polarization, but, except for very low current densities, cannot be completely eliminated. It is for this reason, in refining processes, that energy is required to transfer the metal from anode to cathode in addition to that necessary to overcome the internal resistance of the cell.

A transition resistance results from the formation of a film of polarizing material over the electrode and may or may not be present, depending on the character of the electrolysis.

#### Measurement of E.M.F. of Polarization and Transition Resistance

As both transition resistance and polarization tend to cut down the current flowing through the cell, they cannot be distinguished by this effect. The transition resistance may be determined by measuring the ohmic resistance of the cell before and after the passage of the current by the usual alternating current method. The existence of an e.m.f. of polarization in a cell which normally has no open-circuit e.m.f. may be qualitatively demonstrated by short-circuiting the cell through a galvanometer immediately after the current has been broken in the primary circuit; if the cell be polarized, a current which diminishes with time will flow through it in the reverse direction. A voltmeter, or, better, a potentiometer connected across the electrolytic cell, will indicate the potential difference voltage the instant after the current is broken. This voltage will diminish as the polarization disappears, the rate depending upon the current through the cell, the voltmeter and the rate of diffusion of the electrolytic products causing the polarization. Owing to the rapidity with which the e.m.f. of polarization disappears after the exciting cause is removed, special precautions must be taken in its measurement. One of the best methods is to connect up the circuit containing the applied e.m.f., and electrolytic cell with a tuning-fork in series with an electrometer so that at the instant the battery current is broken the vibration of the fork, the circuit containing the cell and electrometer being closed, and vice versa. By this arrangement, the e.m.f. of polarization is measured during the fraction of a second that the battery circuit

it before it has had time to sensibly diminish. The polarizing current may be regarded as practically constant.

It is frequently of importance to know, not the polarization of the cell as a whole, but the polarization at each electrode. This is obtained by measuring the drop in potential at each electrode against a normal hydrogen or calomel anode while the impressed e.m.f. is acting on the electrolytic cell, or immediately after the current through the cell is interrupted.

**REVERSIBLE ELECTRODES — DEPOLARIZERS.** — If the chemical and thermal actions which take place at a given electrode when a given quantity of electricity passes in one direction through a cell are exactly the reverse of the actions which take place when the same quantity of electricity goes through it in the opposite direction, the electrode and the solution with which it is in contact are said to form a "reversible electrode." Such an electrode does not polarize provided the concentration of the solution is kept constant.

There are two types of reversible metal-liquid electrodes, namely:

**Electrodes of the First Type**, consisting of a metal in contact with a solution of one of its own salts, e.g., copper in copper sulphate, zinc in zinc sulphate, etc. The two electrodes of a Daniell cell are of this type.

**Electrodes of the Second Type**, consisting of a metal in contact with a solution containing one of its difficultly soluble salts and a second soluble salt of some other metal, having the same anion. The difficultly soluble salt, called the "depolarizer," must be present in excess as solid. Such an electrode is mercury in contact with a solution of zinc sulphate containing mercurous sulphate in excess as solid; this is one of the electrodes of the Clark cell.

**Reversible Gas Electrode.** — An electrode consisting of "platinum black" saturated with an atmosphere of hydrogen gas and dipping partially into a solution containing hydrogen ions is also a reversible electrode. This is a special form of electrode of the first type in which a gas by being occluded in platinum is made to play the rôle of a metal.

Other "gas electrodes" e.g., chlorine, may be similarly prepared.

**CONTACT POTENTIALS; ELECTROMOTIVE FORCE.** — The electromotive force of a voltaic cell, the back-electromotive force of an electrolytic cell, and the electromotive force of a thermocouple, are all due to differences of potential which always exist at the junction of dissimilar substances. These single potential differences are called "contact potentials," the word "difference" being understood. For a general discussion of this subject see Langmuir, *Trans. Am. Elec. Chem. Soc.*, 29, 125, 1916.

**Metal-metal Potentials.** — The potential at the junction of two dissimilar metals may be measured either by the Peltier effect, i.e., by the heat developed or absorbed at the junction when a known quantity of electricity is forced across it, or by the thermoelectric force set up in a circuit formed by the two metals in question when the two junctions are kept at different temperatures. In the former case the potential may be calculated from the expression  $\epsilon = H/nF$  when  $H$  is the Peltier heat developed or absorbed at the junction by the passage of  $nF$  coulombs. In the latter case  $\epsilon = T \frac{d\epsilon}{dT}$  where  $\frac{d\epsilon}{dT}$  is the thermoelectric

coefficient of the junction at the absolute temperature  $T$ . Both methods give results which prove that the potential difference thus arising is of the order of magnitude of a few millivolts, except in the unusual combination of antimony and bismuth where it amounts to about 0.03 volt. Table III taken from an article by Caswell, *Physical Review*, 33, 401, 1911, contains the values of the metal-metal potentials for the more common metals against copper at ordinary

temperatures. The columns headed *A* give the values as determined first method, columns headed *B* give the values as determined by the second method. The plus sign (+) indicates that at a junction formed by the metal and copper the given metal is at the higher potential, the minus sign (-) indicates that it is at a lower potential than the copper.

TABLE III. — CONTACT POTENTIALS BETWEEN COPPER AND OTHER METALS, IN MILLIVOLTS

(Temperature 15–25° C.)

Metal	LeRoux		Jahn		Edlund		Caswell		Other Observations
	Against Copper	A	A	B	A	B	A	B	
Antimony	- 5.64								-3.06
Iron	- 2.93	-3.68	-3.07	- 2.96	- 3.08				
Cadmium	- 0.53	-0.72	-0.72	+ 0.16	+ 0.21				
Zinc	- 0.45	-0.68	-0.41	- 0.01	- 0.02				
Copper	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00
Silver		-0.48	-0.58	+ 0.03	+ 0.04	+ 0.03	+ 0.06		
Gold				+ 0.33	+ 0.50				
Lead				+ 0.50	+ 0.57				
Tin				+ 0.56	+ 0.82				
Aluminium				+ 0.70	+ 0.89	+ 0.70	+ 0.89		
Platinum		+0.37	+0.38	+ 1.02	+ 1.23	+ 0.85	+ 0.66		
Palladium				+ 2.17	+ 2.43				
Nickel		+5.07	+5.44			+ 6.0	+ 6.35		{ +6.75 +8.03
Bismuth	+22.3			+17.7	+17.6	+16.1	+16.0		

The contact potential difference between any two of these metals is the algebraic difference between the potentials of the two metals against copper. e.g., the contact potential difference between iron and platinum according to Jahn's measurements (*A*) is  $+0.37 - (-3.68) = 4.05$  millivolts.

The contact potential difference between any two metals is a function of temperature, the sign of the potential for a given pair of metals so reversing as the temperature rises. Although of importance in thermopyrometry and radiometry, metal-metal potentials are of little significance in the considerations of the voltaic cell.

**Metal-gas Potentials.** — The contact potential differences between two metals should be carefully distinguished from potential differences having their origin in the so-called "Volta effect," i.e., potential differences which are manifested when two dissimilar metals in metallic contact are separated by an air or other gaseous gap. The two phenomena are quite distinct, there being no known relation between them.

Zinc — air — lead	.....
Lead — air — tin	.....
Tin — air — iron	.....
Iron — air — copper	.....
Copper — air — platinum	.....
Platinum — air — carbon	.....

difference across the air gap between combinations of metals are given in the table at the bottom of this page. There is a fall of potential from the zinc to the lead and the reverse is taken from data by Ayrton and Perry, *Phil.*

— When two dissimilar electrolytic solutions are in contact, a phenomenon of diffusion takes place between them and the results are as follows. At the same time a difference of potential is set up between the solutions, the magnitude of which depends on the velocity of migration and the relative concentration of the ions. The gas constant: Liquid junction potentials are, in general, of small magnitude. Thus the potential between two solutions of potassium chloride, one solution of the other, is only 0.0004 volt, and diminishes as the concentration approaches unity, being, in fact, proportional to the logarithm of the concentration ratio. Potassium chloride is often used as an intermediate solution desired to reduce the liquid-liquid potentials of a cell to a minimum because of the small potential to which it is subjected. Details of eliminating liquid-liquid contact potentials, see *Chemische Messungen*, pages 448-449.

— The potential difference between acid or between alkali solutions of different concentrations whose concentrations are in the ratio of 18° C., there is a potential difference of 0.034 volt, these voltages also varying with the concentration ratio. For formulas, see page 482.

— From what has been said regarding the magnitude of liquid-liquid potentials, it follows by the process of elimination that the electromotive force of a voltaic cell must be determined between metals and liquids. The absolute value of the e.m.f. of a metal and the solution with which it is in contact is determined under certain assumptions regarding the nature of surface phenomena and is referred to below. For practical purposes the value of the e.m.f. of a cell constructed with two half-cells of a given metal and solution, and the other some form of electrode. Two normal electrodes are in common use, the calomel and the hydrogen electrode.

**Calomel electrode.** — The normal calomel electrode consists of a normal solution of potassium chloride saturated with calomel, the latter being present in excess as a solid.

**Hydrogen electrode.** — The normal hydrogen electrode consists of a platinum electrode coated with a thin deposit of platinum black and immersed in a solution at atmospheric pressure. The electrode is mounted in a glass tube through which hydrogen gas and partially dipping into an acid solution that it contains 1 gram-equivalent of hydrogen ion. The acid solution containing 2 gram-equivalents per liter of acid solution. Hydrogen gas is allowed to bubble through the solution.

— The results of the International Congress of Applied Chemistry, 1913, should hereafter be given as directly comparable to the normal calomel or the hydrogen electrode, unless otherwise stated.

— When a cell is constructed with a normal calomel electrode to a normal calomel electrode, there is

a rise of potential through the electrolyte of 0.283 volt, hence, if from a normal hydrogen electrode to any metal electrode the rise of potential is  $e_h$ , and from a calomel electrode to any metal electrode the rise of potential is  $e_c$ , then

$$e_h = e_c + 0.283 \text{ volt.}$$

The difference between any two metal-liquid potentials remains the same irrespective of the normal electrode to which they are referred.

**Specific Electrode Potentials.** — On the assumption that the conductivity ratio is a true measure of the degree of ionization of an electrolyte and that the gas laws hold for solutions up to normal concentration, it is possible to calculate from electrode potential measurements against a normal hydrogen electrode what the potential difference would be between an element and a solution containing ions of that element at a concentration of one gram formula weight per liter. Such potential differences (measured directly or calculated) are called specific electrode potentials. Much experimental work remains to be done before these fundamental constants are known with precision. For most metals these are known at present better than  $\pm 0.01$  volt. The following table contains values for some of the more typical electrochemical reactions. These values are all referred to the hydrogen electrode as standard. The symbol  $\theta$  signifies one electronic change which is subtracted from or added to the atom or ion. For a more complete table see the Monograph of Abernethy and Luther, *Abhandlungen Deutsch. Bunsen Gesellschaft*, Vol. 1 (1911) and No. 8 (1915), or Washburn's *Principle of Physical Chemistry*.

TABLE IV. — SPECIFIC ELECTRODE POTENTIALS

Elements (electrodes) in equilibrium with aqueous solutions containing one gram formula weight of the indicated ions per liter. The electrode potential is given with charge against the solution of the sign and magnitude indicated.

Fe $\theta(-) = \text{Fe}^{+++}$ ....	-0.04	
$\text{H}_2 - 2(-) = 2\text{H}^+$ .....	$\mp 0.0$	

**Variation of Electrode Potentials with Concentration.** — According to Nernst's theory of electrode potentials (see below) the change in the potential of these potentials with concentration may be calculated by the following

$$e_1 - e_2 = \frac{0.000198 T}{n} \log_{10} \frac{c_1}{c_2}$$

where  $e_1$  is the potential at concentration  $c_1$ , and  $e_2$  the potential at concentration  $c_2$ ,  $T$  is the absolute temperature, and  $n$  the valence of the metal in the

its formula is also justified by experiment. For example, the electrode potential of silver in a normal silver-nitrate solution at 25° C. is 0.80 referred to the normal hydrogen electrode. If the concentration of the silver ions be held to 1/1,000,000 its value in a normal solution, the electrode potential of it will become

$$e_2 = 0.80 - \frac{0.000198 \times 298}{1} \log_{10} \left( \frac{1}{10^{-6}} \right) \\ = 0.80 - 0.0590 \times 6 \times 0.45 \text{ volt.}$$

**Electrochemical Series — Nobility of the Elements.** — The elements, as arranged in Table IV, constitute the "Electrochemical Series." Those elements which  $e_2$  is negative are said to be less "noble" than hydrogen, while those which  $e_2$  is positive are said to be more "noble" than hydrogen. The alkali metals having the greatest tendency to form ions in water stand at one end, like the "noble" metals, such as gold, platinum, palladium, having but a very slight tendency to form ions, are at the other end. The halogens which go into solution as negative instead of positive ions stand at the lower end of the series. The series have been given which differ from the above in that the elements are not compared under similar conditions in regard to the concentration of the solution with which they are in contact. Changing the electrolyte, e.g., to potassium cyanide, alters not only the numerical values of the potentials, but may completely change the order in which certain elements occur in the series. A metal if placed in a solution of a salt of a metal standing below it in the series will tend to replace it; thus, zinc precipitates iron, copper, silver, etc., from their solutions but will not displace the alkali metals from solutions of their salts. Any metal standing above hydrogen will tend to displace it from an acid solution with evolution of hydrogen. Metals below hydrogen in the series will not dissolve in acid by a simple replacement of hydrogen. From a chemical standpoint the adoption of the hydrogen electrode as a standard is the advantage over the calomel standard that it divides the metals into two groups according to their behavior towards acids.

The approximate electromotive force of a battery consisting of two metals dipping into normal solutions of their respective salts may also be computed once from the table by taking the difference of the two corresponding electrode potentials. Thus a zinc-copper cell should have an electromotive force equal approximately to  $E_{Cu-Cu} - (e_2)_{Zn} - (e_2)_{Cu} = -0.76 - 0.34 = 1.10$ , the direction of potential being from the zinc to the copper in the cell. As a matter of fact, this combination, the Daniell cell, has an electromotive force of approximately 1.10 volts. Other conclusions to be drawn from the table will be pointed out below.

**ELECTROMOTIVE FORCE AND HEAT OF REACTION.** — The electromotive force of a reversible cell maintained at constant temperature may be readily calculated from the first and second law of thermodynamics (see Thermodynamics). By a "reversible" cell is meant a cell which does not polarize and which operates under conditions such that changes which take place within the cell constitute a thermodynamically reversible process. (See Thermodynamics, Principles of.) The discussion given below also applies, with a rough degree of approximation, to most commercial cells, which, as a rule, are not strictly reversible.

**Gibbs-Helmholtz Equation.** — In the case of a reversible cell, such, for example, as the Daniell cell,\* shown in Fig. 1, the relation between the heat of reaction ( $H$ ) and the electromotive force ( $E$ ) of the cell is calculated as follows.

\* The special construction of this cell renders it reversible.

From Faraday's Laws, the quantity of electricity which must flow the cell in order to deposit or liberate one gram-ion at either electrode is  $nF$  coulombs, where  $n$  is the valency of the ion of highest valency involved in the chemical reaction and  $F$  is the electrochemical constant (see above). Hence, the external work done by the cell (when there is no other external work than electrical work) is  $nFE$  joules, where  $E$  is the e.m.f. of the cell. If the cell is kept at the same temperature ( $T$  degrees, absolute scale) as the surrounding bodies, then the external work  $nFE$  done by the cell is the maximum external work it can do at this temperature  $T$  (see *Thermodynamics, Principles of*). Hence, from equation (8) of the article on thermodynamics,

$$nFE = H' + nFT \frac{dE}{dT},$$

or

$$E = \frac{H'}{nF} + T \frac{dE}{dT},$$

where  $H'$  = the heat of reaction, in joules per gram-ion, corresponding to the chemical change which takes place.\*  $H'$  gives the change in intrinsic energy corresponding to the chemical changes which take place within the cell.  $H'$  can be found by an independent calorimetric measurement, by causing the reaction to take place under such conditions (*constant volume*) that heat is the only form of energy produced.

**Temperature Coefficient of Electromotive Force.** — From the above equation it follows that the energy developed by the cell is equal to the heat energy of the chemical reaction taking place within it plus a certain quantity of energy equal to  $nFT dE/dT$ . This may be either positive or negative, according as the temperature coefficient of electromotive force  $dE/dT$  is plus or minus, i.e., according as the electromotive force of the cell increases or decreases with the temperature. If the electromotive force on an open circuit increases with the temperature of the cell, then on closed circuit the cell tends to cool, i.e., its temperature will fall, and its electromotive force will likewise decrease, the energy  $nFT dE/dT$  being derived from the heat developed within the cell (or surroundings). If the electromotive force on an open circuit decreases with increasing temperature of the cell, then on closed circuit the cell will tend to heat up, i.e., its temperature will rise and its electromotive force will decrease. A cell for which  $dE/dT$  is other than zero can work at constant temperature only by absorbing heat from or giving out heat to some surrounding body.

Only for the unique conditions that  $dE/dT = 0$ , or that  $T = 0$ , i.e., at absolute zero, the electromotive force is independent of the temperature or the cell works at constant temperatures approaching absolute zero, is  $E = H'/nF$ . By a curious coincidence it happens that the first of these conditions practically obtains in the case of the Daniell cell considered above. The electromotive force of the cell is independent of the temperature. Its observed value is  $E = 1.10$  volts, its value computed by the above equation, putting  $dE/dT = 0$ , is 1.09 volts.

**Thomson's Rule.** — In computing the electromotive force of a cell from heats of reaction it is usually necessary to content oneself with

\* Since 1 large mean calorie (Ostwald calorie) = 418.6 joules and  $F = 96,500$  coulombs may be written, putting  $H$  = heat of reaction in large mean calories,

$$E = \frac{H}{2.035 n} + T \frac{dE}{dT}.$$

Fig. 1

**ELECTROLYTIC DECOMPOSITION.** — Faraday's laws enable us to determine the amount of the substances primarily liberated or deposited at the electrodes of any electrolytic cell, but they do not enable one to predict the nature of the secondary chemical actions which may take place. (See *Section on Secondary Reactions.*) The factors which determine what products are formed in any given case are numerous. The chemical process occurring at the cathode is always of the nature of a reduction; at the anode, of an oxidation, these terms being used in their most general sense. It may be that the electrolyte, taken as a whole, undergoes no change, as is the case, for example, with a copper-sulphate solution when electrolyzed between copper electrodes; in this case the chemical reaction at the cathode is the exact reverse of that at the anode. Generally, however, this is not the case; different chemical products are usually formed at the two electrodes, and appear either in the form of a gas, or as a solid precipitate, or remain dissolved in the electrolyte.

**Decomposition Voltage of Electrolytes.** — When a gradually increasing difference of potential is applied to the electrodes of an electrolytic cell, electrolysis does not in general begin at once but only after a certain critical electromotive force is reached, even though the cell has no open-circuit voltage. It should be noted that this condition does not apply to the case of electrolytes whose electrodes are such that the electrolyte as a whole undergoes no change as a result of electrolysis. Thus, in the electrolysis of a zinc-sulphate solution between zinc electrodes an exceedingly small electromotive force is sufficient to maintain a steady current through it indefinitely (assuming that the concentration changes at the electrodes are completely eliminated by stirring). Although, in this case, electrolysis starts at once, the electrolyte as a whole is not decomposed, for as much zinc dissolves at the anode as is deposited at the cathode. If a platinum anode be substituted for the zinc anode so that the result of electrolysis zinc is separated at the cathode and oxygen gas is evolved at the anode, an e.m.f. of 2.35 volts is required to start the electrolysis. If the electrolyte is an aqueous solution of sulphuric acid it requires a minimum voltage of 1.67 volts to liberate oxygen and hydrogen gas against smooth platinum electrodes. The minimum voltage necessary to decompose a substance electrolytically is called its "decomposition voltage." It is influenced by a variety of factors and conditions which will now be considered.

**Measurement of Decomposition Voltage.** — Decomposition voltage has been experimentally determined in several ways. Certain investigators have taken the value necessary to produce visible electrolysis as the criterion; others have followed the polarization at the electrodes until it became constant and assumed this value as that at which electrolysis begins. Results obtained by the so-called ammeter-voltmeter method must be accepted with caution. In this method the value of the electromotive force applied to the cell is gradually increased from zero and plotted as abscissas and the corresponding currents through the cell plotted as ordinates. The resulting curves have the general form shown in Fig. 2.

The slope of these current-voltage curves depends upon the internal resistance of the cell, the size and the distance apart of the electrodes. The critical voltage at which the current suddenly increases in value is, however, quite

Fig. 2.

s, e.g., silver nitrate between platinum electrodes, which a metal is deposited. Below the critical voltage no current passes through the cell and no visible decomposition is apparent. When the point *A* is reached, visible decomposition begins and its course depends upon the sensitiveness of the galvanometer used, the size of electrodes and the tendency of the metal to go back into solution.

With a sensitive reflecting galvanometer, a steady current flows without any apparent electrolysis when an electrode (far below the "decomposition voltage") is dipped into acidulated water. It might seem that Faraday's law is here violated. These slight currents are to be ascribed to the formation of the products liberated slowly and in minute quantities which diffuse back into the solution. Currents produced in this way are called "leakage currents" and play an important rôle in the study of electrolysis, probably also in conduction in solid electrolytes. The decomposition of salts is less sharply marked; the decomposition of weak electrolytes and salts the current-voltage curve is of the form shown in Fig. 1. It is difficult to say from this curve at what voltage

the decomposition voltage is experimentally determined decomposition voltages of acids, bases and salts.

#### DECOMPOSITION VOLTAGES OF NORMAL SOLUTIONS

	ZnBr <sub>2</sub> .....	1.80
	ZnSO <sub>4</sub> .....	2.35

**Decomposition Voltage from Heat of Reaction.** — If the decomposition is possible in the thermodynamic sense, then Gibbs' free energy (Δ*G*) is directly applicable. Since however the maximum work (or free energy) is known in but

a few instances, one usually employs Thomson's rule, which gives a fair approximation in the case of most commercial processes, even though these processes are not strictly reversible. That is, calling  $H$  the heat of formation of a compound which is decomposed from the substances which are liberated at the electrodes (i.e.,  $H$  is the heat of the reverse reaction corresponding to the complete chemical actions which take place in the cell), the decomposition voltage is

$$E = \frac{H}{230.5n}$$

where  $n$  = the valency of the ion of highest valency involved in the reaction and  $H$  is expressed in large mean calories per gram-molecule.

Tables giving the voltages required to liberate a number of elements and radicals from various electrolytes computed by Thomson's rule from their heats of formation in dilute solutions are given by J. W. Richards in *Journal of the Franklin Institute*, 1906.

**Example.** — In the formation of one mol of solid lead chloride from metallic lead and chlorine gas 828 large mean calories are liberated. The valency of lead is 2; of chlorine, 1. As solid lead chloride does not decompose by electricity appreciably at ordinary temperatures, to decompose it electrolytically, it must be either dissolved or fused. If a saturated solution contains an excess of solid lead chloride be electrolyzed, metallic lead will be deposited at the cathode, chlorine gas liberated at the anode, and an equivalent amount of solid lead chloride will pass into solution, the net result then being the decomposition of solid lead chloride into its elements lead and chlorine. Under these conditions the decomposition voltage by Thomson's rule is

$$E = \frac{828}{230.5 \times 2} = 1.79 \text{ volts,}$$

as against 1.612 volts by actual measurement.

It should be pointed out that Nernst has recently applied his new heat law (see above) to the calculation of the e.m.f. of cells similar to the above, with very satisfactory results. Thus the computed value of the e.m.f. in the above case from thermal data by the formula developed by Nernst is  $E = 1.55$  volts, in excellent agreement with the observed value. See Nernst's *Treatise on Physical Chemistry*.

**Calculation of Decomposition Voltage from Electrode Potentials.** Le Blanc was the first to measure by means of a normal electrode the potential drop at the cathode when various salts were electrolyzed and found that the cathodic drop in potential necessary to discharge a given amount of metal numerically equal to the electrode potential which would be established if the separated metal were substituted for the actual cathode. For example, to deposit metallic zinc from a normal zinc-sulphate solution it is necessary to impress a potential from solution to electrode as measured against a hydrogen electrode of at least 0.76 volt, to overcome the natural rise of potential from the zinc electrode to the solution (as measured by the normal hydrogen electrode) of this amount. See table page 460.

Before continuous electrolysis can begin, however, not only must the e.m.f. be sufficient to establish the necessary cathodic drop  $e_c$ , but in addition it must also raise the anode potential to a value  $e_a$ , corresponding to the electrode potential of the anion which is liberated. If, as is usually the case, different anions are present in the electrolyte that one will be liberated which can part with its negative charge with the least expenditure of energy, i.e., at the lowest voltage. It frequently happens that  $e_c$  is established

the  $e_a$  is reached, in which case Le Blanc found that  $e_0$  remains constant till the impressed voltage  $E$  (and hence  $e_a$ ) is increased up to the decomposition point. The minimum e.m.f. at which decomposition of a given electrolyte begins may therefore be written  $E = e_c + e_a$  where  $e_c$  and  $e_a$  are the cathodic and anodic polarization values produced by that cation and anion respectively which gives up its charge most readily. In an electrolyte containing several different anions and cations all take part in the conduction of current through the solution, but only specific ions are effective in electrolysis, i.e., in giving up their charges to the electrodes.

**Overvoltage.**—When a gas is evolved at either electrode the above relations are usually more complicated owing to the phenomenon known as overvoltage. Thus in the electrolysis of an acid between polished platinum or inert metal electrodes, hydrogen gas is evolved, to liberate which the cathode potential must be raised to a value in excess of that required to liberate hydrogen at a reversible (platinum black) electrode.

This excess of voltage which is necessary to liberate a gas at any electrode other than that required to liberate the same gas against a reversible gas electrode is called "overvoltage." Its value depends upon the character of the material of the electrode against which the gas is set free and upon the nature of the gas. It is particularly large in the case of hydrogen. In Table VI are given values of the overvoltage for hydrogen as determined by Caspari when this gas is visibly free. The magnitude of the effect is closely related to the power of the electrode surface to occlude the gas in question. Thus, platinum and (to a less extent) iron absorb hydrogen readily and hence these metals exhibit slight overvoltage phenomena. Zinc and mercury, on the other hand, have little or no tendency to absorb hydrogen and hence this gas is liberated with great difficulty against cathodes of these metals, with correspondingly high overvoltages. For discussion of overvoltage phenomenon, see Möller, *Ann. d. Physik*, 27, 566, 1908; Crabtree, *Trans. Faraday Soc.*, Vol. 9, 125, 1913; Bennett and Thompson, *Trans. Am. Elec. Chem. Soc.*, 29, 269, 1916; MacInnes, *Am. Chem. J.* XLI, 194, 1919.

**Electrolytic Separation of Metals.**—The reason that two or more metals can be electrolytically separated from each other by a regulation of voltage follows from the preceding discussion. Consider a solution containing two salts, say silver and copper nitrates, each of normal concentration. As a gradually increasing e.m.f. be applied to inert electrodes dipping into this solution, electrolysis will begin when a voltage is reached sufficient to set free

*simultaneously* any anions and cations present in the solution. Referring to Table IV, it will be seen that copper stands  $0.80 - 0.34 = 0.46$  volt above silver in the electrochemical series, and hence, the latter metal can be separated from the solution with e.m.f. nearly half a volt less than copper. No ions can separate until the applied e.m.f. has been increased  $0.46$  volt that necessary to first separate the silver. The decomposition e.m.f. will, of course, depend on the nature and concentration of the anion. As electrolysis proceeds, the solution becomes weaker and weaker with respect to silver ions and the voltage necessary to separate them from the solution increases. If the electrolysis is continued until the silver remaining in the solution has a concentration only  $1/1,000,000$  that at the start (the limit of determination), the change in voltage will be approximately  $0.35$  volt (see section above on Variation of Electrode Potentials with Concentration), still insufficient to bring the applied e.m.f. up to a value sufficient to separate the copper to deposit, and hence, silver and copper may be completely separated for practical purposes, separated from each other.

It is to be noted that as the electrolysis proceeds and the silver is separated from the solution a greater and greater percentage of the current is carried by the copper. The solution in the neighborhood of the cathode becomes continually weaker with respect to silver ions. In a quiet electrolysis the silver ions at the cathode are replenished by diffusion from the interior of the electrolyte. This process may be greatly accelerated by violently stirring the solution, as, for example, by the use of a rapidly rotating electrode. Excellent deposits being obtained with higher current density and less time reduces the time required for the separation.

**Secondary Reactions.** — In the preceding sections the principles of primary electrolysis have been explained. The ultimate products are produced at the anode and cathode are often quite different from the ions or ionic complexes liberated by the action of the current. In general the primary process of discharge of ions at cathode and anode is followed by a secondary reaction of one of the following types:

1. The discharged ions form molecules, e.g.:

This may occur at both anode and cathode.

2. The discharged ions react with each other or break up, e.g.:

This is very characteristic at the anode, particularly of organic anions.

3. The discharged ions react with the solvent, e.g.:

4. The discharged ions react with the solute, e.g.:

5. Discharged ions react with the electrode, e.g.:

Which of the above reactions is most likely to occur in any given case depends more or less upon, (a) current density; (b) temperature; (c) concentration of the solution.

In general, it may be said that at the cathode a reduction takes place, while at the anode oxidation (in its general sense) occurs. The intensity of these reactions depends upon the electrode potential at which the reaction takes place. This can be varied by the use of different electrode materials (thereby changing the overvoltage). The efficiency of certain secondary reactions has been found to depend upon the nature of the electrode (catalytic action). The efficacy of electrolytic reduction and oxidation in organic chemistry where the intensity of the reaction must be carefully regulated likewise rests on the above factors.

**Passivity.** — A metal is said to assume the "passive" state when it comports itself towards acids like a noble metal, i.e., becomes insoluble. Iron affords a very striking example of this phenomenon, although it is exhibited by other metals as well. Thus, if dipped in strong nitric acid, or if anodically polarized, it becomes passive. Several explanations have been advanced to account for the phenomenon, one being that it is due to an invisible film of oxide on the surface, and another that the surface assumes a condition in virtue of which the velocity of reaction between it and the surrounding solution is infinitely slow. For some of the theories see *Trans. Am. Elec. Chem. Soc.*, 29, 217, 1916.

**Alternating-current Electrolysis.** — The decomposition of an electrolyte, and the solution of metal electrodes by electrolysis, can be effected under certain conditions by an alternating current as well as by a direct current. The chief determining factors are the velocity with which the chemical reaction takes place and the periodicity of the alternating current.

**THEORY OF SOLUTIONS.** — To understand the theory of the various phenomena described above, a knowledge of the theory of solutions is necessary.

**Osmotic Pressure.** — The present theory is based upon Van't Hoff's thermodynamic and experimental investigations published in 1887. When a substance is brought into contact with a second substance in which it is more or less soluble, it dissolves in virtue of a force (the nature of which is imperfectly understood), which is called its "solution tension" or "solution pressure." If the solute is present in excess, the process of solution continues until the solution becomes saturated, i.e., until equilibrium is established between the solid and solution, such that the solution pressure of the former is just balanced by an opposing pressure created within the solution which tends to cause the dissolved substance to separate out. This pressure is called the osmotic pressure of the solution. Under these conditions there are just as many molecules of solute passing into solution as separate out of the solution during any interval of time. A clearer conception of the osmotic pressure of a solution, as above defined, may be obtained from the following considerations.

**Semi-permeable Membranes.** — If a solution be placed at the bottom of a cylinder and carefully covered with a layer of pure solvent, the process of diffusion will begin at once and continue until a homogeneous dilute solution is formed. If the experiment be repeated with the single modification, that the pure solvent is separated from the solution by a piston consisting of a semi-permeable diaphragm which will permit the solvent to pass freely through it in either direction, but which will not allow the solute to pass through, the process of diffusion will take place as before, provided the piston is movable. Thus the piston will be forced back by the osmotic pressure of the solution while the solvent passes freely through it thereby diluting the solution. Membranes possessing the property of semi-permeability are not only theoretically con-

ceivable but may actually be prepared. Such a membrane is formed as a precipitate of copper ferrocyanide deposited within the walls of an porous cell when copper sulphate and potassium ferrocyanide solution is allowed to diffuse into the cell from within and without respectively. The membrane is permeable to water, but impermeable to sugar and many organic and inorganic substances, such as the copper and potassium salts from which it is formed. Most membranes, in fact, possess the property of being permeable to a limited degree.

**Measurement of Osmotic Pressure.**—To prevent the piston from being forced up by the diffusing solution, a downward pressure  $P$  must be applied to it equal to that exerted upon it from below by the solution. The magnitude of  $P$  is, therefore, a measure of the osmotic pressure of the solution. On account of experimental difficulties, it is impracticable to measure osmotic pressure in precisely the manner just described, but by slightly modifying the arrangement of the apparatus it may readily be done. Thus, if the solution is contained in a closed vessel,  $A$ , Fig. 3, the walls of which are made semi-permeable by depositing a membrane of copper ferrocyanide within the pores of the cell, and this be immersed in the solvent  $B$ , the osmotic pressure will be exerted as before against the membrane from within. If the latter could stretch like a rubber balloon, it would do so as the solution became diluted; being, however, restrained by the material of the walls of the cell on and in which it is deposited from doing this, dilution of the solution can take place only by the solvent passing through the fixed membrane into the solution cell. Thus it will do unless the cell  $A$  is hermetically sealed. If an open manometer  $M$  of small bore be inserted in the top of  $A$ , the solvent as it passes into the cell will cause the solution to rise gradually in  $M$  until the hydrostatic pressure thus produced prevents further entrance of solvent. When equilibrium is established, the hydrostatic pressure gives a measure of the osmotic pressure of the solution then existing in the cell. As the entrance of an appreciable amount of solvent into the cell reduces the concentration of the solution, the pressure thus measured is less than that of the original solution; hence for quantitative work an open manometer should be replaced by a closed mercury manometer.

**Laws of Osmotic Pressure in Non-electrolytic Solutions.**—By means of an apparatus similar in principle to that just described the following laws have been verified. They hold for dilute aqueous solutions of many organic substances such as sugar, and for many solutions in organic solvents, all of which possess the common property of being non-electrolytes.

1. The osmotic pressure of a solution is directly proportional to its concentration (and therefore inversely proportional to the volume in which a given mass of the solute is dissolved).
2. It is directly proportional to the absolute temperature.
3. It is independent of the nature of the solute, being a function only of the number of mols of substance dissolved in unit volume of solution.
4. The numerical magnitude of the osmotic pressure  $p$  of one mole of substance dissolved in a volume  $v$  of solution at the absolute temperature  $T$  is identical with the gaseous pressure exerted by one mol of a perfect gas at the same temperature  $T$  and occupying the same volume  $v$ .

The gas laws are therefore not only directly applicable to solutions, but the numerical value of the gas constant  $R$  is the same for each. Thus the laws of Boyle and Gay-Lussac for gases have the same form for solutions,

$$pv = RT,$$

re  $p$  = the osmotic pressure,  $v$  = the volume of the solution containing one l of solute, and  $T$  = the absolute temperature.

The accompanying table gives the numerical value of  $R$  when the above quantities are expressed in the units desired. In heat units

$$R = 1.985 \frac{\text{calories}}{\text{deg. cent.}}$$

Abs. pressure $p$	Volume $v$	Abs. temp. $T$	Gas constant $R$
Atmospheres	Liters	Deg. cent.	0.0821
Grams per sq. cm.	Cu. cm.	Deg. cent.	84,800
Dynes per sq. cm.	Cu. cm.	Deg. cent.	$0.83161 \times 10^6$

When applied to concentrated solutions of non-electrolytes the above laws suffer deviations analogous to those which they exhibit when applied to highly compressed gases.

**Osmotic Pressure in Electrolytic Solutions.** — The first of the above laws for non-electrolytic solutions applies to electrolytic solutions only within narrow limits, while the third and fourth laws fail absolutely. The osmotic pressure of this class of solutions is much greater than the equation  $p = RT$  would lead one to expect. Thus, a 0.1 normal sodium chloride solution has an osmotic pressure 1.9 times as great as that which it should have on the basis of the above formula. A potassium sulphate solution containing 0.1 gram-equivalent per liter has an osmotic pressure 2.3 times as great as that calculated. To bring these results within the scope of the gas-law formula, Van't Hoff proposed the empirical equation  $p = iRT$ , where  $i$  is a constant having the value unity for non-electrolytes and a value greater than unity for electrolytes.

**THE DISSOCIATION THEORY.** — Arrhenius, in 1887, gave the first satisfactory explanation of the anomalous behavior of electrolytes, which show not only abnormally high osmotic pressures, but also abnormally high boiling points and abnormally low vapor pressures and freezing points. On thermodynamic principles these phenomena can all be shown to be proportional to the total number of molecular complexes per unit volume and entirely independent of their chemical constitution. Abnormally high osmotic pressures may therefore be explained on the assumption that each molecule, when dissolved, exists in a more or less dissociated condition, i.e., at any given instant there are in the solution more discrete particles or complexes than there would be if each molecule remained continuously intact. The ions are not supposed to be permanently separated, but a continuous process of dissociation and combination is assumed to be going on all the time. If the further assumption be made that the dissolved substance is electrolytically active only during that fraction of time while it exists in a dissociated or ionized state, in other words, that dissociated molecules are alone capable of being acted upon by electric forces, the connection between electrolytes and solutions showing deviations from the gas laws is explained.

On the assumptions of this theory, sodium chloride, NaCl, in aqueous solution is partially dissociated or ionized according to the equation,  $\text{NaCl} \rightleftharpoons \text{Na}^+ + \text{Cl}^-$ , and therefore at any instant there are present in the solution not only sodium-chloride molecules, but also positively charged sodium ions and an equal number of negatively charged chlorine ions, the number of which at any instant depends upon the average fraction of a second during which the molecules are dissociated or "ionized." If the salt were "completely, i.e., 100 per cent ionized" there would be no molecules, as such, present in the solution, but instead twice the number of ions as there were molecules originally dissolved. Hence the osmotic pressure of such a solution would be twice as great as that calculated

from the equation  $p = RT$ ; in equation  $p = iRT$ ,  $i$  would be equal to 1. Again, if a given volume of solution contains one mol of potassium sulphate,  $K_2SO_4$ , which is 75 per cent ionized according to the equation  $K_2SO_4 \rightleftharpoons 2K^+ + SO_4^{2-}$ , then at any instant there will be  $1 - 0.75 = 0.25$  mol of  $K_2SO_4$  molecules,  $0.75$  mol of  $SO_4^{2-}$  ions, and  $2 \times 0.75 = 1.50$  mol of  $K^+$  ions present in the solution, or  $0.25 + 0.75 + 1.50 = 2.5$  molecular complexes for every sulphate dissolved; hence  $i = 2.5$ .

Although the nature of the ions resulting from the ionization of acids and salts is now known to be more complicated in many cases than assumed in such simple ionization reactions as the above, owing to their hydration and association with molecules of the solvent, still the above hypothesis of Arrhenius proved the most fruitful conception which has been introduced into chemistry during the last thirty-five years and it remains to-day, modified in the light of the recent research, the best working hypothesis with which to interpret electrochemical phenomena in aqueous solutions. It is a natural sequel to the free ion theory of Clausius which in turn displaced the old chain theory of Grotthuss.

**THEORY OF ELECTROLYTIC CONDUCTION.** — The external effect of a current flowing through an electrolyte cannot be distinguished from that produced by a current of the same strength conducted by a metal. The magnetic effect of a current flowing through a helical glass tube filled with an electrolyte is the same as that produced by the same current flowing through an equivalent circuit of an equal number of turns of copper wire. A current may be induced in a closed ring of electrolyte just as in a ring of metal. Ohm's Law and Joule's Law hold for conduction in electrolytes as well as in metals. The mechanism of the conduction in the two cases, however, is very different, as shown by the phenomena produced at the junction of two conductors, one of which the conduction is metallic or "electronic" and in the other of which it is electrolytic or "ionic."

**Migration of Ions.** — Electrical conduction, both metallic and electrolytic, is believed to be a convection phenomenon. In the case of electrolytic conduction there is much evidence to indicate that the convection consists in the transport of electrically charged ions through the electrolyte, both with and against the direction in which the current is assumed to flow. Simultaneous convection of anions and cations in opposite directions may not only be visible to the eye but their velocities may also be directly measured. On the assumption that the ions are the carriers of charges, the motion of which constitutes the current, the "velocity of migration" can also be calculated from conductivity measurements and the experimentally determined "transport ratios" (see below).

**Velocity of Migration.** — In Table VII are given the results of measurements of the migration velocity of various ions and also the conductivity velocities, both expressed in centimeters per second and for a potential gradient of one volt per centimeter.

The velocities are directly proportional to the potential gradient. They increase rapidly with the temperature. They vary but slightly with the concentration of the solution if the concentration is not too great, and for dilute solutions may be regarded as practically constant.

From the table it is seen that hydrogen migrates with the maximum velocity. Hydroxyl  $OH^-$  has the next greatest velocity. The high velocity of the hydrogen ion explains the fact that aqueous solutions of the mineral acids are among the best electrolytic conductors, and the high velocity of the hydroxyl ion accounts for the relatively good conductivity of the inorganic bases.

an ion migrates under the action of a given force which it has to overcome in moving through the solution (the force would be expected between it and the rate of diffusion of viscosity) of the solution. The viscosity of the solution increases rapidly with an increase in temperature (cent per degree) and experiment shows that the rate is approximately the same rate. The increased conductivity with rising temperature is the cause of the migration of electrolytes.

## VELOCITIES OF MIGRATION OF IONS

Velocities in cm. per sec. per volt per cm.

Gram-equivalent per liter, 18° C.		Infinite dilution, 18° C.

When a solution is subjected to electrolysis a change takes place in the immediate vicinity of the anode and another change takes place in the middle portion of the solution employed to prevent convection and diffusion from the solution about the anode and cathode respectively. A current has passed for a known time.

Gram-equivalents of the *solute* which disappear from the anode.

Gram-equivalents of the *solute* which disappear from the cathode.

Gram-equivalents of the *solute* which is decom-

The ratio  $n_a = c/(a+c)$  is called the transport ratio for the anion and  $n_c = 1 - n_a = a/(a+c)$  is called the transport ratio for the cation. They are also frequently referred to as "Hittorf's transference numbers." In a given electrolyte  $n_a$  is proportional to the number of gram-equivalents of anions which migrate through the solution from the cathode towards the anode and  $n_c$  to the number of gram-equivalents of the cations transported towards the cathode.

On the assumption that the ions are the sole carriers of the charges of which constitutes the electric current, the ratio of the current carried by anions or cations to the total current is the same as the above transport ratios for these ions, since the charge carried by one gram-equivalent of electrolyte is constant = 96,540 coulombs.

Note. — The  $\frac{1}{2}$  before the various bivalent electrolytes indicates that the equivalent =  $\frac{1}{2}$  mol.

Table VIII contains the generally accepted values of the transport ratios for more common ions. These numbers vary but slightly with the temperature. They tend to approach the value 0.5 with increasing temperature, as the temperature rises both ions of a given electrolyte tend to conduct equal per cents of the current. With increasing dilution the transport ratios of electrolytes approach constant limiting values; these are practically found in solutions whose concentration is 0.01 gram-equivalent per liter.

**Relation between Velocity of Migration and Transport Ratios.** — On the assumption that the ions are the carriers of the charges the motion of which constitutes the electric current, and on the further assumption that the moving ions do not carry along with them different quantities of the solvent, the ratio of the velocity  $u_a$  of the anions to the velocity  $u_c$  of the cations in any solution must be equal to the ratio of the transport ratios  $u_a = c/(a+c)$  and  $u_c = a/(a+c)$  of the anions and cations respectively, i.e.,

$$\frac{u_a}{u_c} = \frac{n_a}{n_c} = \frac{c}{a}$$

The transport ratios  $n_a$  and  $n_c$  may be determined experimentally as described above and by the use of this relation the relative velocities of migration may be compared with the ratio calculated from the direct determination of the velocities  $u_a$  and  $u_c$ . See Washburn's *Principles of Physical Chemistry*.

**Hydration or Solvation of Ions.** — The above relation between the velocities of migration and the transport ratios has been found to hold only approximately in a number of instances. The probable explanation of this lack of agreement between theory and experiment is that the changes in concentration at the two electrodes are due not only to the migration velocities of the ions, but also to the fact that the ions carry along with them molecules of the solvent, the amount of solvent carried by the anions and cations being different. This "hydration" or "solvation" of the ions has

recently been proved by direct experiment (Washburn, *Zeit. für Phys. Chem.*, Vol. 66, p. 513, 1910) by adding to the solution an indifferent substance upon which the electric current produces no migratory effect (e.g., sugar or glucose). See also Lewis, *J. Am. Chem. Soc.*, Vol. 32, p. 862, 1910.

**Conductances of Electrolytes.** — (See also article on Resistance and Conductance.) While no simple relations have been found to hold between the specific conductances of different electrolytic solutions, very important results follow at once from a comparison of their equivalent conductances.

Table IX shows the relation between the equivalent conductance  $\Lambda$  and the concentration  $w$  in gram-equivalents per liter for some typical aqueous solutions. In Fig. 4 certain of these data are shown graphically. From a study of these results the following important conclusions may be drawn.

Fig. 4.

Note. — The  $\frac{1}{2}$  before CuSO<sub>4</sub> and H<sub>2</sub>SO<sub>4</sub> indicates 1 gram-equivalent =  $\frac{1}{2}$  mole.

For complete tables consult *Landolt and Börnstein*, *Kohlrausch* and *Tables Annuelles Internationales de Constantes*.

1. **The Equivalent Conductance of a Solution Increases with Dilution of the Solution Increases and Approaches a Limiting Value.** — The maximum equivalent conductance, usually denoted by  $\Lambda_{\infty}$ , is different for different solutions. It may be found graphically for strong electrolytes (giving curves of the form A, Fig. 4), by extrapolating the curve representing the observed data until it cuts the ordinate of zero concentration. This method fails however for weak electrolytes such as acetic acid, see C.

2. **Independent Migration of Ions. Ionic Mobilities.** — The product of the equivalent conductance of any solution at infinite dilution by the transport ratio of either of the ions forming the electrolyte is a constant for that ion and independent of the nature of the electrolyte. That is  $\kappa_a$  and  $\kappa_c$  the transport ratios of the anions and cations respectively, the  $l_a = \kappa_a \Lambda_{\infty}$  is a constant irrespective of the nature of the electrolyte of which this anion forms a part; similarly  $l_c = \kappa_c \Lambda_{\infty}$  is a constant for the cation irrespective of the nature of the electrolyte of which it forms a part. For example the product  $\kappa_c \Lambda_{\infty}$  for the potassium ion is a constant whether the solution is one of potassium chloride, potassium bromide, potassium sulphate, etc. The constants  $l_a$  and  $l_c$  are called the "mobilities" or "ionic conductivities" of the ions. This relation was discovered by F. Kohlrausch in 1876 and states the law of the independent migration of ions.

r, it follows that

$$\Lambda_{\infty} = l_a + l_c.$$

Equivalent conductivity of a solution (at infinite dilution) is the sum of the mobilities of the anions and cations which form the solution. The mobility of an ion depends solely upon the nature of the substance of which it originally formed.

The mobility of any ion may be determined directly from the equivalent conductivity of the solution and the mobility of the ion with which it is associated.

The following table gives the equivalent conductances of the more common ions at 18° C. and at infinite dilution. From this table the equivalent conductance of any electrolyte at infinite dilution may be readily calculated by the formula  $\Lambda_{\infty} = l_{a\infty} + l_{c\infty}$ .

TYPICAL IONS AT INFINITE DILUTION AND 18° C.

The equivalent conductivity  $\Lambda_{\phi}$  may also be determined in the same way as  $\Lambda_{\infty}$  at this dilution and the corresponding  $n_c$ , but the product  $n_a \Lambda_{\phi}$  or  $n_c \Lambda_{\phi}$  for any electrolyte is not independent of the nature of the ions.

Examples of Electrolytic Conduction on the Disintegration of the above experimental facts in the

light of the dissociation theory is simple. On this theory, the value of  $\Lambda_\phi$  determined by three factors, any one of which, if zero, will make  $\Lambda_\phi = 0$ . are:

1. The fraction of the total number of molecules in one gram-equivalent of the solute which are dissociated at any instant. This fraction, called the "degree of ionization" or "ionization coefficient," is usually denoted by the subscript  $\phi$  indicating the dilution to which it refers.

2. The average velocities with which the ions migrate while free. Let  $u_a$  be these velocities, in centimeters per second, for the cations and  $u_c$  respectively, for a potential gradient of one volt per centimeter.

3. The charge carried by the ions. This is fixed, since one equivalent of every ion carries with it  $F = 96,540$  coulombs.

If a volume  $\phi$  of the solution containing one gram-equiv. of the solute is imagined placed between two parallel plate electrodes 1 cm. apart, an e.m.f. of one volt be applied, the quantity of electricity conducted across the electrolyte in one second, i.e., the current, will be equal to the equivalent conductance  $\Lambda_\phi$  (definition of  $\Lambda_\phi$ ). The current is also equal to the total quantity of electricity conducted by the cations plus that conducted by the anions:

$$\Lambda_\phi = \gamma_\phi F u_a + \gamma_\phi F u_c = \gamma_\phi F (u_a + u_c).$$

The experimental fact that for many electrolytes at infinite dilution  $\Lambda_\infty$  is equal to the sum of two constants  $\Lambda_a$  and  $\Lambda_c$  (the mobilities of the ions) indicates that the velocity of migration  $u_a$  or  $u_c$  of any given ion depends only upon the nature of the ion and not upon the electrolyte of which it forms a part, and that the degree of ionization at infinite dilution is the same for all such solutions; there is much evidence to indicate that this is practically 100 per cent (see below).

**Degree of Ionization.** — The fact that  $\Lambda_\phi$  increases with the dilution  $\phi$  may be due either to the velocities  $u_a$  and  $u_c$  or to  $\gamma_\phi$  increasing with dilution, or to both causes combined;  $F$  is a constant. In concentrated solutions both the velocities and the degree of ionization undoubtedly decrease as the concentration increases. For dilute solutions, however, there is considerable evidence to show that the frictional resistance opposed to the motion of the ions changes but slightly with increasing dilution, and hence the values of the limiting velocities in such solutions may be regarded as nearly constant. It may be assumed, and also that the nature of the ions remains unchanged, i.e., that  $u_c$  and  $u_a$  at the dilution  $\phi$  are practically the same as at infinite dilution  $\phi = \infty$ , then the observed increase in  $\Lambda_\phi$  with the dilution must be due to the increase in  $\gamma_\phi$ . On these assumptions, the solute becomes more and more completely ionized as the dilution increases, and at infinitely great dilution all the molecules of the solute are continuously dissociated or ionized, i.e., as  $\phi$  approaches infinity  $\gamma_\phi$  approaches unity.

Hence for  $\phi = \infty$ ,  $\Lambda_\infty = F(u_c + u_a)$ , and therefore

$$\frac{\Lambda_\phi}{\Lambda_\infty} = \frac{\gamma_\phi F(u_c + u_a)}{F(u_c + u_a)} = \gamma_\phi.$$

This relation affords the simplest way of determining the coefficient of ionization  $\gamma_\phi$  of an electrolyte, namely, finding the ratio of its equivalent conductance at dilution  $\phi$  to its maximum conductance at infinite dilution. The assumptions mentioned above should not be lost sight of when applying this formula. In general, the viscosity of the solution must be corrected for at great dilutions. See Washburn and Clark, *Jour. Am. Chem. Soc.*, 38

the above simple formula for a number of typical  
I.

COEFFICIENTS OF TYPICAL ELECTRO-  
IONS COMPUTED FROM RATIO  $\frac{\Lambda_{\phi}}{\Lambda_{\infty}} = \gamma_{\phi}$

(from Kohlrausch and Holborn's data)

HCl	KOH	$\frac{1}{2}\text{CuSO}_4$	$\text{NH}_4\text{OH}$	$\text{C}_2\text{H}_3\text{O}_2$
0.784	0.770	0.217	0.0037	0.0036
0.914	0.891	0.379	0.0139	0.0131
0.964	0.954	0.608	0.0403	0.0406
0.982	0.979	0.856	0.118	0.117

indicates that 1 gram-equivalent of  $\text{H}_2\text{SO}_4 = \frac{1}{2}$  mol.

**of Migration of Ions.** — From a knowledge of  
velocity of migration may be easily computed  
migration theory. Thus for aqueous solutions at  
ionization may be assumed complete,  $I_c = Fz_c$   
 $u_a = \frac{I_a}{F}$ . From Table X we have for the

chlorine ion  $I_a = 65.5$ ; therefore the velocity  
per centimeter with which these ions migrate  
 $\frac{\text{cm.}}{\text{sec.}}$  and  $\frac{65.5}{96,510} = 0.000677 \frac{\text{cm.}}{\text{sec.}}$  respectively.

ionization must be taken into account. The  
obtained in this way. For the relation of veloc-  
phenomena see Nernst's *Theoretical Chemistry*.

**on Degree of Ionization.** — It has been  
shown that the degree of ionization of a solution has relatively little effect on  
velocity of migration, except at high concentrations. Hence  
conductance with the dilution  $\phi$ , see Fig. 4,  
change in the degree of ionization. It can be  
shown that the ionization coefficient  $\gamma$  of a binary elec-  
trolyte varies with dilution  $\phi$  or concentration  $\eta$  according to the

$$K = \frac{\eta\gamma^2}{1-\gamma}$$

“the equilibrium constant of the ionization  
reaction at a given temperature and pressure. This formula, known as  
Ostwald's law, is applicable exactly only for weak electrolytes, i.e., those  
which are not organic acids, and which give rise to dilution  
curves of the type shown in Fig. 4. For good electrolytes, giving curves of the type  
shown in Fig. 5, a wholly satisfactory explanation for this  
phenomenon is not given. (See discussion in address by James

Walker, *British Association Meeting, 1911*. Also G. N. Lewis, *Zeit. f. Chem.*, 70, 216, 1910.) Instead of obeying the above law, curves of the form satisfy an exponential equation of the form

$$\frac{(\eta\gamma)^n}{\eta(1-\gamma)} = \text{constant},$$

in which  $n$  is a constant depending upon the electrolyte and having between 1.40 and 1.56. Other "dilution laws" have also been proposed by Kohlrausch, Van't Hoff, Rudolphi, Kraus, Bray, and Bates.

**Effect of Temperature on Ionization.** — The per cent to which a substance is ionized in solution may increase or decrease with the temperature. The sign and magnitude of the effect depend upon whether the ionization reaction is accompanied by an absorption or evolution of heat. Substances which dissociate with evolution of heat become less ionized with increasing temperature; substances which dissociate with absorption of heat become more ionized with rising temperature. Highly dissociated substances like sodium chloride, hydrochloric acid, etc., belong to the former class. Water is very slightly ionized and belongs to the latter class. In general a variation of temperature from 0° to 100° C. produces a change in ionization of only a few per cent. Recent investigations by Noyes carried out at temperatures up to 100° C. have confirmed these predictions of theory. The effect of temperature on the equilibrium constant  $K$  may be computed through its effect on  $K$  by means of Van't Hoff's dynamic relation

$$\frac{d \log K}{dT} = \frac{Q}{RT^2},$$

where  $K$  is the above equilibrium constant of the ionization reaction,  $Q$  the heat of the corresponding reaction,  $R$  the gas constant and  $T$  the absolute temperature to which the values of  $K$  and  $Q$  refer. For derivation of this equation see Nernst's *Theoretical Chemistry*.

**Negative Temperature Coefficients of Electrical Conductivity.** — The fact that certain electrolytes, e.g., a phosphoric-acid solution, may exhibit a negative temperature coefficient is readily explained in terms of the above relations. If the increase in the velocity of migration of the ions with increasing temperature is more than offset by a diminution in the average number of ions, resulting from a decrease in ionization, the conductivity of the solution will diminish. By combining solutions having positive and negative temperature coefficients in suitable proportions, electrolytes have been prepared which exhibit nearly a zero temperature coefficient over quite a range of temperature. The following mixture, proposed by Manganini, has this property: 121 grams potassium nitrate, 41 grams boracic acid, 0.06 gram potassium chloride dissolved in 1000 cc. water to make one liter. Its specific conductance at 18° C. is  $\kappa = 0.0001$ . Such a solution is well adapted for a liquid resistance just as manganin is adapted for resistance coils.

**Conductivity of Fused Electrolytes.** — In Table XII are given the specific conductance ( $\kappa$ ) and the equivalent conductance ( $\Lambda$ ) of several typical salts at their respective melting points; also for comparison the equivalent conductance of these salts in infinitely dilute aqueous solutions at 18° C. It will be seen that the values of the specific conductance ( $\kappa$ ) of the salts at their respective melting points are much greater than the values of the equivalent conductance of the same salts in normal aqueous solutions. On the other hand, if the volume  $\phi$  occupied by one gram-equivalent of the salts in the fused state is determined by specific gravity measurements and the equivalent conductance  $\Lambda$  computed ( $\Lambda = \phi\kappa$ ), it will be seen that these values

the maximum equivalent conductance  $\Lambda_{\infty}$  of the same salt in aqueous solutions. Thus the conducting power of one equivalent of fused sodium nitrate at 305° C. is less than when the same weight of salt is dissolved in one liter of water.

TABLE XII — SPECIFIC AND EQUIVALENT CONDUCTANCE OF TYPICAL FUSED SALTS AT THEIR MELTING POINTS

Salt	Temperature, melting point, °C.	Specific conductance, $\kappa$	Equivalent conductance, $\Lambda$	$\Lambda_{\infty}$ at 18° C. in aqueous solution

Electrical conduction in fusions is wholly electrolytic it is probable that it is determined by the same three factors which determine the conductance of solutions, and that the equivalent conductance may be expressed by an equation of the general form

$$\Lambda = \gamma F (\mu_e + \mu_a).$$

But, however, all attempts to measure the velocity with which ions migrate in fused salts have led to no satisfactory or conclusive results. Hittorf's transference ratios cannot be determined as in solutions, since in a pure fused salt concentration differences do not occur at the electrodes. Only indirect estimates of the value of  $\gamma$  have been possible. The evidence thus far obtained, however, points to a high rather than to a low state of ionization in molten salts. For a summary of the present status of this question see Goodwin, *Trans. Am. Electrochem. Soc.*, 1912.

The equivalent conductance of fused salts increases in general from 1 to 1½ percent per degree centigrade. As the increase has been found in a number of cases to be almost identical with the increase in the fluidity of one equivalent weight of the fused mass, it is probable that the velocity of migration of the ions increases in this proportion. The ionization of fused salts is certainly not a function of temperature, as in the case of gases; there is evidence, in fact, that the ionization of some fused salts may decrease with increasing temperature as does in their aqueous solutions.

**THEORY OF CONTACT POTENTIALS.** — In the case of liquid-liquid junctions and metal-liquid junctions a satisfactory theory, based on the dissociation theory and the theory of solutions, has been worked out.

**Theory of Liquid-liquid Potentials.** — Nernst (*Zeit. für Phys. Chem.*, 4, p. 120, 1889) was the first to show that in the case of electrolytes a difference in potential necessarily arises between two solutions in contact which gradually mix, until the solutions are completely mixed. The general theory, worked out by Planck (*Ann. der Physik*, Vol. 40, page 561, 1890) is complicated, but leads, however, to simple formulae in the following special cases.

Case 1. — The junction is between two dilute solutions of the same solute at different concentrations  $c_1$  and  $c_2$ , both ions of the solute having the valency  $n$ :

for example,  $c_1\text{-HCl} - c_2\text{-HCl}$  or  $c_1\text{-ZnSO}_4 - c_2\text{-ZnSO}_4$ . The potential between solutions 1 and 2 is given by the equation

$$e = \frac{RTl_c - l_a}{nFl_c + l_a} \log_e \frac{c_1}{c_2}$$

$$= \frac{0.000198}{n} T \frac{l_c - l_a}{l_c + l_a} \log_{10} \frac{c_1}{c_2} \text{ volts,}$$

where  $R$  = the gas constant;  $T$  = absolute temperature;  $F$  = the Faraday, 96,540 coulombs;  $n$  = valence of ions;  $l_c$  and  $l_a$  the mobilities of the cations and anions, respectively; and  $c_1$  and  $c_2$  the concentrations (or, more correctly, the corresponding osmotic pressures) of the ions in the two solutions respectively.

It follows from this formula that the potential at a liquid junction approaches zero if the electrolyte is composed of two ions which migrate with nearly equal velocities, and increases as the difference in their velocities increases.

$K$  and  $Cl$  ions have nearly identical mobilities, and hence between any two solutions of potassium chloride there exists only a very small potential difference. For a concentration ratio of 10 to 1 the potential difference at 18° C. is 0.0004 volt. This theory also explains why liquid-liquid potentials are greatest between acids or between alkali solutions, for hydrogen and hydroxyl possess relatively great mobilities.

**Case II.** — The liquid junction is between solutions of two different electrolytes, each containing two ions of the same valence  $n$  and at the same concentration. Here again the process of diffusion gives rise to potential difference. If solution 1 and solution 2, the value of which may be computed by the

$$e = \frac{RT}{nF} \log_e \frac{l_{c_2} + l_{a_2}}{l_{c_1} + l_{a_1}}$$

$$= \frac{0.000198}{n} T \log_{10} \frac{l_{c_2} + l_{a_2}}{l_{c_1} + l_{a_1}} \text{ volts,}$$

where  $l_{c_1}$ ,  $l_{a_1}$  and  $l_{c_2}$ ,  $l_{a_2}$  are the mobilities or migration velocities of the cations and anions in the two solutions respectively. The above formulae are the general formula for mixed electrolytes have been satisfactorily verified by experiment.

For most recent work see *Trans. Faraday Soc.* Vol. 8, p. 86, 1912.

**Theory of Metal-liquid Potentials.** — By extending the concept of the process of solution of solids in liquids to the case of metals, which pass into solution only as positively charged ions, Nernst (*Zeit. f. Phys. Chem.*, 1889) developed an osmotic theory of metal-liquid potentials. This theory applies to all kinds of electrodes which are reversible in the thermodynamic sense, which from an experimental standpoint are non-polarizable. For all such reversible electrodes Nernst has shown that the potential from metal to solution may be expressed by the relation

$$e = \frac{RT}{nF} \log_e \frac{P_M}{\phi}$$

$$= \frac{0.000198}{n} T \log_{10} \frac{P_M}{\phi} \text{ volts,}$$

where again  $R$  is the gas constant,  $T$  the absolute temperature,  $n$  the valence of the metal ions,  $F$  the Faraday,  $\phi$  the partial osmotic pressure of the metal ions present in the solution and  $P_M$  an integration constant characteristic for the metal, which depends upon the temperature and solvent, but is independent of the nature of the solute.

**Electrolytic Solution Pressure.** — The constant  $P_M$  in the above formula is called the "electrolytic solution pressure of the metal  $M$ ." Since  $e = 0$  and  $P_M = p$ , the electrolytic solution pressure  $P_M$  is sometimes regarded as equal to the osmotic pressure of the metal ions which would be just sufficient to prevent the metal electrode from dissolving or passing into the ionic form, in which case there would be no development of a potential difference at the metal-salt junction due to this cause. Hence the numerical value of  $P_M$  for a given metal and solvent may be considered as a measure of the tendency for the metal to dissolve in the solvent, i.e., to pass from the metallic to the ionic form. Thus alkali and alkali-earth metals, which pass readily into the form of ions, have a very high electrolytic solution pressure, while the noble metals like gold, silver and platinum have a very low solution pressure. From this point of view the electrolytic solution pressure of a metal may be taken as a measure of its position in the electrochemical series. The only method thus far proposed for determining the value of  $P_M$  is by computation from Nernst's formula for electrode potentials given above. The value to be assigned to  $e$  depends upon the experimental determination of the "absolute" difference in potential (see next paragraph) between the electrode and the solution with which it is in contact. At present there is some question as to whether the actual difference of potential between the electrode and solution may not be partially due to the phenomenon of selective absorption of the ions, which is not taken into account in the Nernst formula. For this reason the values of  $P_M$  frequently computed from measured electrode potentials are open to question. See Le Blanc's *Lehrbuch der Elektrochemie*, pages 230-235; Lehfeld, *Phi. Mag.* 48, 430, 1899.

**Absolute Electrode Potentials.** — On the assumption that the potential difference between a metal and a solution is zero when the surface tension of the metal is a maximum and that this condition is fulfilled in "dropping electrodes," or may be obtained in a properly adjusted Lippmann capillary electrometer, the absolute potential rise from the solution to the mercury in the normal calomel electrode has been found to be  $e = 0.5600 + 0.0006(t - 18^\circ \text{C.})$ . It is in terms of this value for the normal calomel electrode that "absolute" electrode potentials have been expressed. On account of the uncertainty attending the interpretation of this value it is better for the present to adopt an arbitrary value zero as the potential drop at the calomel electrode.

**ELECTRODYNAMOMETERS.** — (See also *Ammeters; Balancers; Wattmeters.*) One of the most reliable and accurate laboratory instruments for current and power measurements, particularly a-c. measurements is the electro-dynamometer.

This instrument depends upon the action of one circuit carrying upon another carrying the same current (see *Electricity and Magnetism, Principles of*). The working parts of the instrument consist of two coils, and the other movable.

**SIEMENS ELECTRODYNAMOMETER.** — The simplest form of dynamometer is that devised by Siemens, shown diagrammatically in Fig. 1. The coils are arranged at right angles to one another as shown, the heavy lines representing the fixed coil and the light lines representing the movable coil. The force of attraction or repulsion is proportional to the current in the fixed coil times the current in the moving coil, and consequently if the same current flows in the two coils, the deflection is proportional to the square of the current. This force is balanced by the torsion of a spring. By turning the torsion head at the top of the instrument the coils are kept at right angles. The torsional force is proportional to the angle  $D$  through which the head is turned; hence the current is

$$I = K\sqrt{D},$$

where  $K$  is a constant which is obtained by sending a known current through the instrument. When arranged with separate binding posts for the fixed or fixed coil and for the potential or swinging coil, as shown in Fig. 2, the instrument may be used as a wattmeter for either direct-current or alternating-current power measurements. The power in watts is then

$$P = K^2 R_1 D,$$

where  $K$  has the same value as before, and  $R_1$  is the total resistance of the potential circuit, including the coil and external resistance  $R$ . This power includes the loss in the potential circuit, which is  $V^2/R_1$ , where  $V$  is the impressed voltage; this correction is usually small.

**Uses of Siemens Electro-dynamometer.** — The instrument may be used on direct current and may be used to measure either direct or alternating current or power, since when properly designed its readings are independent of frequency and wave form. High-grade standard wattmeters suitable for the precise calibration of commercial indicating wattmeter or watt-hour meter on alternating current and non-unity power-factor circuits are made on the electro-dynamometer principle (see *Wattmeters*).

**Design of Siemens Electro-dynamometer.** — The movable coil is suspended by a silk thread. Attached to the coil, at the point of suspension is a spiral spring, the other end of which is attached to a movable collar. This collar carries a pointer which moves over a scale and denotes the torsion of the spring. A second pointer is rigidly attached to the movable coil and registers with a fixed mark on the scale, when the fixed and movable coils are at right angles. The current is led in and out of the movable coil through mercury cups.

Dynamometers and wattmeters for use with alternating current should contain as little metal used in their construction as is practical, as eddy currents set up in the metal parts that will influence the coil system and change

Fig. 1. Dynamometer.

Fig. 2. Dynamometer used as a Wattmeter.

of the instrument. The case and supporting frames should therefore be insulating material.

**Range of Siemens Electro-dynamometer.** — Commercial instruments of this type for measuring currents are not suitable for measuring currents of less than 0.02 ampere. Precision wattmeters (q.v.) built on the same principle may be used to measure power of the order of 1,000,000 watts on unity power factor.

**Sources of Error.** — The interaction of the earth's magnetic field and the current in the movable coil may be appreciable when the instrument is used for direct-current measurement unless the movable coil is perpendicular to the earth's field. This action may be detected by sending a direct current through the *movable coil only*; any deflection will be due to the earth's field.

When the instrument is used to measure alternating currents the earth's field has no effect. However, eddy currents induced in the various parts of the windings or case, or in neighboring conductors, may produce a disturbing force. This may be tested by sending an alternating current through the *movable coil only*, the other coil being open; any deflection will be due to eddy currents. The "zero" position of the pointer should also be such that there is no mutual induction between the two coils when in the "zero" position. This can be tested by short-circuiting one coil and sending an alternating current through the other; any deflection will be due to mutual induction.

The instrument can be used for measuring the power input to circuits of low power factor only when the self induction of each coil and of the external so-called "non-inductive" resistance (see Fig. 2) is negligible (see Fleming, *Handbook of the Electrical Laboratory and Testing Room*).

**Degree of Precision.** — When properly calibrated and properly used the readings of a good Siemens electro-dynamometer may be relied upon as accurate within  $\frac{1}{10}$  per cent for a full-scale deflection. The smaller the deflection the greater the percentage accuracy.

**Rowland Electro-dynamometer.** — This instrument is identical in principle with a Siemens electro-dynamometer, except that instead of noting the angle through which a torsion head must be turned, the moving coil is allowed to deflect and the deflection is noted by means of a telescope and scale. Its chief application is for measuring small alternating currents and small amounts of power in alternating-current circuits. It is seldom used except in special investigations requiring a high degree of precision or for the measurement of alternating quantities of small magnitude; e.g., alternating currents of the order of 0.1 ampere or power of from 0.01 to 1 watt. Its uses are fully described in Rowland's "Physical Papers," Johns Hopkins Press, Baltimore, 1902.

**Irwin Astatic Electro-dynamometer.** — This instrument has two fixed circular coaxial coils of the same diameter through which the current circulates in opposite directions, producing a field which is directed radially outward. The movable element is suspended by a wire or silk fibre and consists of two semi-circular coils mounted on a thin disc of mica, the current in each being in opposite directions. Any effect which may be due to a non-uniform stray field is reduced by the fact that the movable coils are close together.

**COSTS (Pre-war prices).** — A simple Siemens electro-dynamometer suitable for measuring currents of from 0.025 to 5 amperes costs about \$75. A Rowland electro-dynamometer with shunt box costs about \$450. An Irwin astatic galvanometer costs (in 1920) about \$150.

**ELECTROLYSIS OF UNDERGROUND STRUCTURES.**

also *Electrochemical Processes, Industrial; Electrochemistry, Principles of* following discussion will be limited to the electrolysis of underground structures that is, to the corrosion of metal work in the earth, due to the action of currents from the grounded rails of electric railroads.

The track rails of electric railways practically always form part of the circuit feeding the cars. As these rails are either laid in the ground or on the ground, and as the ground is a partial conductor, some of the current leaves the rails and flows in the ground. If pipes, lead-sheathed cables or structural foundations happen to be in the ground near the railway, part of the current from the rails will enter these underground structures and flow from them, leaving them at some other point to return to the station bus. If the current is direct, the underground structure from which current leaves the earth, becomes the anode of an electrolytic cell, the earth containing the electrolyte. This anode corrodes, due to the liberation of acids from the salts retained in the earth. Occasionally the cathode, or underground structure to which current enters from the earth, is liable to corrosion by secondary currents. In the case of railways using alternating current for distribution, the electrolytic effects are usually a large proportion of the total current, but the electrolytic effects are negligible. (See J. L. R. Hayden, *Trans. A.I.E.E.*, p. 221.)

In the case of direct-current railways, it is therefore desirable to connect the current to the track rails as far as practicable. This may be done by maintaining the rail bonds in a high degree of efficiency and by keeping the voltage drop in the rails by means of insulated negative feeders, as described by G. I. Rhodes, *Trans. A.I.E.E.*, Vol. 26, p. 237, 1907.

While such means will assist materially in mitigating electrolysis it is often necessary to take special steps to protect underground structures without relying upon the railway companies to confine their current to the rails.

**MINIMUM VOLTAGE TO PRODUCE ELECTROLYSIS.**

The conduction of current through moist ground is almost entirely electrolytic, ordinary conduction being almost negligible. Electrolytic corrosion occurs whenever current flows from metal into the ground, regardless of the difference of potential may exist between different parts of the circuit. In fact that current may flow, however, it is in general necessary that the difference of potential between anode and cathode exceeds the algebraic sum of the potentials of combination and separation of the compounds involved in the electrolytic process. An iron anode in a soil containing iron salts in solution will be attacked when the e.m.f. is infinitesimal.

**CORROSION EFFICIENCY AND PASSIVITY.** —

When an electric current is passed through an electrolyte, the mass of the anode dissolved is calculated theoretically by Faraday's law (see index). In practice this may be exceeded, or the reverse. The term "coefficient of corrosion" or "corrosion efficiency" is used to designate the ratio of the actual to the theoretical mass of the anode dissolved. The corrosion efficiency is usually less than 100 per cent owing to the occurrence of secondary reactions. Thus the corrosion of iron, which primarily occurs by the formation of ferrous salts, theoretically occurs at the rate of 1.045 grams per ampere-hour, but in practice the rate may be anywhere from zero to forty per cent more than the theoretical value. In the case of iron in soil, without protection, the corrosion efficiency is practically independent of the temperature over a range from 0° C. to 100° C. It is also independent of the kind of iron, whether wrought iron, cast

machined cast iron. The efficiency is greater the lower the current density, varying from 20 to 140 per cent for a range of current densities between 5.0 and 205 milliamperes per square centimeter. It is greater with increasing moisture content up to saturation of the soil. Data on steel encased in concrete are given below, under "Protection of Steel by Concrete."

**DISTRIBUTION OF EARTH CURRENTS.**—The distribution of any currents in the earth depends not only upon the resistance of the earth but also upon the resistance and distribution of the conducting structures in the earth.

**Earth Resistance.**—As the earth conducts electrolytically, its specific resistance can be calculated from the concentration of the salt solutions it contains. Such calculations are, however, generally useless, as, even with moderate specific conductance, the extent of the current path in the earth is so great that its resistance is very low, except near the electrodes. The effect of the electrodes is to concentrate the current streams into limited areas, thereby increasing the effective resistance of the earth. It is, therefore, obvious that the resistance of the earth depends more upon the electrode area than anything else.

The resistance of the earth is low when the electrodes consist of considerable lengths of track rails. This is particularly noticeable in the case of single phase lines due to the skin effect and inductance of the rails. Thus J. Dalziel and J. Sayers (Inst. Civil Engineers, London, 1909) found that, on the Midland Railway, the current did not continue along the rails for any considerable length, but within a few hundred yards of the car sank gradually into the earth to re-enter the ballast at a very short distance from the power station. I. F. Parshall found that on a line eight miles long, the earth-return current was 60 per cent of the total. Probably the most exact data of this kind are those due to A. W. Copley (*Trans. A.I.E.E.*, Vol. 27, p. 1171, 1908) who stated that on the New York, New Haven & Hartford Railroad, before the adoption of the three-wire system, the percentage of current in the earth was 25 per cent on the four-track sections and 60 per cent on the single-track sections.

**Electrolytic Zone.**—When a drop of potential occurs in a track rail, the current spreads out from it into the soil in much the same way that the leakage lines of magnetic force from a long electromagnet spread out into the air; that is, almost the entire leakage current is confined to a limited zone of the earth, the extent of this zone depending upon a complicated function of both the potential gradient and the total drop in the rails themselves. The stream lines of the current will tend to crowd into a pipe or cable sheath (on account of its low resistance) if such conductor is within this zone, but this tendency rapidly diminishes as the distance between the conductor and the rails increases. Compare with the tendency of an iron bar to become magnetized when placed in the leakage field of an electromagnet; the induced magnetization rapidly diminishes as the distance of the bar from the magnet is increased. Conductors at a comparatively short distance from the rails are, therefore, not liable to electrolysis unless the difference of potential between them and the rails is large or the leakage path of the current from the rails to the conductors is of low resistance. Thus in England, where the drop in the grounded return is limited to a total of seven volts, Messrs. Cunliffe found experimentally that the electrolytic zone is confined to within three feet of the track. The voltage drop under this rule is taken as the mean between the average and the momentary maximum values during a 15 to 30 minute period of a schedule run, at the time of maximum traffic, exclusive of exceptional occasions.

**STRUCTURES AFFECTED BY CORROSION.**— Stray currents set up corrosion of the rails, rail spikes, cross-bonds, steel columns, etc., which they escape into the earth, and they can set up corrosion of gas pipes, cable sheaths, building structures, etc., which they may enter in their course through the earth. The protection of the former class of structures is entirely the concern of the railroad company which originates the currents; not so with the latter class, which is often of great concern to municipalities or public-service corporations which own them. Electrolytic surveys should, therefore, be made with a clear understanding of which property is under suspicion of danger. As a rule, electrolysis is most destructive to the grounded metal of the railroads; foreign pipes, cable sheaths, etc., being affected in comparatively rare instances. Of all properties foreign to the railroads, the thin sheaths of telephone cables are most susceptible to electrolytic corrosion.

**Destruction of Concrete by Electrolysis.**— Some experimenters have shown that where iron imbedded in concrete becomes an anode, not only is the iron corroded but the concrete also is cracked. This action is due to the stress set up by the increase of volume which the iron suffers when it is oxidized to an oxide or salt. The current has no direct effect upon the concrete at the anode even when sufficiently strong to liberate chlorine from the brine impregnate it. (C. E. Magnusson, *Trans. A.I.E.E.*, June, 1911.) At the cathode, however, the concrete becomes softened and loses its bond with the electrode. See papers by E. B. Rosa, B. McCallum and A. S. Peterson, *Trans. Assn. of Cement Users*, 1912, and abstracted in *Eng. News*, Vol. 68, p. 111. No action, however, occurs on concrete through which current flows, between the electrodes.

**ELECTROLYTIC SURVEYS.**— An electrolytic survey is an investigation made to determine the condition of grounded metallic structures in the soil in which they are imbedded and of their electrical conditions with the view of ascertaining what conditions tending to produce damage, may exist.

**Potential Readings.**— Random readings between rails and pipes give no quantitative information about electrolytic conditions. As a matter of fact, a difference of potential between a pipe and rail at any point is often greater the less the stray currents at that point. To illustrate this, we may assume a pipe to be outside the electrolytic zone and, therefore, safe from electrolytic corrosion. If, at any point, the rail is at the same potential as the pipe, the potential of the rail at every other point will differ from the pipe. Also, if the part of the rail which is at the same potential of the pipe happens to be at some distance from the power station, the pipe will be positive to the rail at all points between the pipe and the power station. Hence the fact that the pipe is positive to the rail does not indicate that it is subject to electrolysis. A more important illustration is the case of a pipe carrying little current itself but connected to some distant pipe which is carrying considerable current. In such a case the pipe may be highly electropositive to the rails and yet be quite free from electrolytic tendencies. These illustrations are merely specific cases

Fig. 1.

general principle that potential readings are useless unless taken with reference to the resistance of the earth between rails and conductors, which in turn depends upon the direction and distribution of the current stream lines. The potential difference between the structure tested and earth affords more complete information than can be secured from any other noticeable class of observations. For this purpose, it is necessary to use a non-polarizable electrode such as that shown in Fig. 1. The zinc sulphate paste shown therein is made by adding saturated zinc sulphate solution to zinc sulphate crystals until the mixture has attained a semi-fluid condition. The Bureau of Standards is developing improved types of electrodes.

**Measurement of Leakage Current in Grounded Return System.**—The columns and foundations of elevated structures and subways, rail spikes, negative cables and bonds are the parts most likely to be attacked electrolytically.

In the case of the elevated railways of New York City, after about nine years' operation with the steel structure a part of the return system, it was found necessary to remove all metallic connections in the Borough of Manhattan between the track rails and structure and to install negative feeder cables to compensate for the conductivity thereby sacrificed.

The corrosion of rail spikes, while happily rare, is a matter of such grave consequence to the railroads and public that it should be carefully watched for. It occurs when ties are old and water-logged or when improperly treated with preservative. Timber is ordinarily classed with the non-conductors, because, when dry and well-seasoned, it has a high dielectric strength and practically infinite resistance. When green or moist, however, it becomes an electric conductor of comparatively low resistance. The resistance along the grain is much less than across it, and porous woods, such as oak, are better conductors than the non-porous woods such as pine. The conductivity of wood is due primarily to the presence in its pores of electrolytes formed from the salts found in natural timber, from preservatives and from salts originating from coal fumes or ashes. The flow of current, from the rails and spikes into the ties, fills the pores of the wood with iron salts, which add to the electrolytic conductivity and permit the leakage of more current. The effect is, therefore, cumulative, the leakage current increasing until the pores of the wood are completely saturated with electrolyte. Cases have been known where spikes were rotted more than half way through and where the rail flanges were badly corroded. Ties creosoted by the hollow-cell process, which leaves the fibers empty, are particularly likely to acquire high electrolytic conductivity. Red oak treated with zinc chloride is also a bad tie from the electrolytic point of view.

Columns of elevated railroads, subways, passenger stations, etc., are best tested for electrolytic trouble by means of a sensitive galvanometer used in the following way. Iron clamps with pointed tips are fastened to the column at points four or five feet apart, care being taken that the points penetrate the paint and make metallic contact with the steel. Wires are run from these clamps to a galvanometer and the deflection noted. The galvanometer having been calibrated, this gives the drop of potential in the column. The cross-sectional area of the column being known, its resistance may be calculated from the known resistivity of steel (usually 11 times that of copper). The potential drop, divided by the resistance, gives the flow of current in the column. Knowing the direction of flow, its amount and the efficiency of corrosion, the actual damage being done by electrolysis may be calculated as a definite weight of metal per annum. This method is being pursued with great success on the Electric Zone of the New York Central Railroad, the galvanometer employed

being a Queen & Co.'s E-8010 with tube E-8011, a calibration resistor on a tripod. A deflection of one scale division is equivalent to about one volt. Considering an average column with a resistance of 0.000,004 ohms per foot, a 4-foot length, a deflection of one scale division corresponds to three-tenths of an ampere. Where the columns are to be encased in concrete, permanent terminals should be provided, preferably in the form of small iron rods screwed into the steel and ending flush with the concrete.

**Measurement of Leakage Current in Pipes, Cable Sheaths, etc.** It is not uncommon to find potential readings taken between different systems of pipes, without regard to the location of the connections, the results being as differences of potential between those systems of pipes. The potential between two points in a pipe system, however, may vary from point to point, and consequently such readings have no significance unless the points between which the difference is measured are specified. The significance of potential readings between specific points is that they afford an indication of the potential normal to the tracks and thereby help to determine the electrolytic zone.

Making use of all possible connections to the pipe, the potential difference between these points and the anode end of the grounded system is determined as described below and the limits of the "electrolytic zone" are obtained by noting where the potential gradient in the pipe becomes normal. For this purpose, water hydrants and water pipes constitute the best connection points.

Potential readings between points on the same pipe line or cable sheath are sometimes made the basis of potential curves showing the drop in the potential along the sheath. Such potential curves may be very significant when taken for cable sheaths, but are of little use for pipes on account of the variable joint resistance of the latter. Thus in case of a cable sheath of uniform resistance along its entire length tested, where the potential curve is flat, the sheath carries no current; when it is a straight sloping line, the sheath carries current in the direction giving current to or taking current from the earth; where it changes from a straight line to a curve, current is either entering or leaving the sheath.

**Hering's Method.**—The current in a pipe may also be measured by the following method. (*C. Hering, Trans. A.I.E.E., June, 1912.*) The fundamental principle is as follows. Let *P*, Fig. 2, be a part of an underground pipe which has been uncovered and through which an unknown current *I* is flowing. Let *D* be a sensitive galvanometer, millivoltmeter or any other suitable form of detector; there should preferably be no variable resistance like an unbonded pipe joint between the two contact points. Let *A* be an ammeter, *B* a few battery cells and *R* an adjustable resistance; the shunt circuit containing them is connected as shown, anywhere outside of the points of application of the voltage to be measured, the farther away the better; they may even be on the other side of a

Fig. 2

To find the current flowing in the pipe adjust the resistance *R* until the current in the shunt circuit is zero; then the current due to the battery *B* will be exactly equal and opposite to the current in the pipe. Hence the reading of the ammeter *A* will be the current in the pipe.

If *D* is a galvanometer with proportionate deflections, instead of a millivoltmeter, then by taking a deflection immediately after the shunt circuit is opened a reading proportionate to the drop of voltage for that current is obtained. The instrument *D* is thereby calibrated to read the pipe current directly and can be used for this purpose thereafter; the test with the millivoltmeter is therefore merely of the nature of a preliminary calibration, and need not be carried out only once for each station.

Instead of attempting to adjust the current in the shunt to bring the

venient to use a regular measuring instrument  
ector, and to pass a definite current through the  
es, reading the two deflections of  $D$  when this  
this had best be repeated several times. The  
adings then corresponds to the current in the  
is that which will reduce the original deflection  
using the difference between a large and a small  
lose zero, which are so common with highly  
ced.

uating currents are given by Hering in the paper

oltmeter  $V$  at each of two neighboring stations,  
ve the pipe between them may be determined,  
y taking the readings of the two instruments  
ual or telephonic signals, preferably at times  
ily steady.

**Leaving Pipe at Any Point.**—The strength  
it is leaving the sheath may be determined by  
es the use of a temporary bond in the form of  
ly connected through an ammeter with both

the rails from *their* anodic center to the point  
bond is connected.

" $s$ " is meant the center of gravity of the leak-

etween the sheath and rail at the bonding point  
of the bond.

of a bond which carries  $I$  amperes. The current  
m the ammeter.

er the insertion of the bond will be

$$i = I \cdot \frac{k}{1 - k},$$

$$k = \frac{r_1}{r} \cdot \frac{V - v}{V - v_1}.$$

pipe, without bonding, would be

$$\frac{V - v}{V - v_1} (I + i).$$

l drop in the rails to be 100 volts and the differ-  
ipe and the rails at the bonding point to be five  
d, and one volt after. Suppose the current in  
eres.

$$= 5. \quad v_1 = 1. \quad I = 50.$$

$$\frac{5}{1} = 0.19.$$

$$\frac{50}{19} = 12 \text{ amperes, approximately.}$$

would be

$$12) = 26 \text{ amperes approximately.}$$

The above formula is based upon the following assumptions:

- (1) That the drop in the rails  $V$  is not affected by the insertion of the cable.
- (2) That the area over which the current from the pipe or sheath enters the earth is short. For proof of formula, see *Elect. World*, 1910, Vol. 35.

**MITIGATION OF ELECTROLYSIS.**—Where stray currents are troublesome, electrolysis may be mitigated by the use of drainage bonds, insulated cables, or electric shielding.

**Protection from Electrolysis by Drainage Bonds.**—Bonds are useful for testing purposes; they may be applied permanently to reduce earth currents. There are certain effects, however, which may render their use inadvisable.

1. If one piping system is connected to the rails or bus, a difference of potential will be established between it and all other underground metallic structures. It will, therefore, attract current from the latter and expose them to electrolytic danger. A bonded piping system thus becomes a part of the trolley circuit and the owner may become a party to whatever damage may be done to the other structures.

2. A considerable current in a gas pipe is a serious fire hazard and a gas cable sheath is a menace to continuity of service.

3. Electrolysis is promoted at all imperfect joints and connections.

4. In the case of power cables, the sheath currents may be great enough to cause unduly to the heating of the cables.

In spite of these objections bonds are very largely used to protect cable sheaths from corrosion. To be most effective, the sheath should be connected to the negative bus by an insulated cable and the bus itself should be connected to the track rails by insulated cables only.

**Protection of Steel by Concrete.**—The conductivity of concrete varies greatly upon its porosity and wetness. Tests have shown that when wet the resistance may be as low as 20 or 30 ohms per yard cube and when dry, as 2000 ohms. When the potential gradient in the concrete around a steel pipe exceeds about 2 volts per centimeter, the temperature rises and the rate of iron corrosion is usually so rapid as to cause the concrete to crack open. At high temperatures, the efficiency of corrosion of iron in concrete is low, but

Temperature, degrees, Centigrade	Corrosion efficiency, Per cent
10	2.0
20	3.5
30	3.0
40	3.5
50	5.0
60	11.5
70	22.5
80	37.5
90	44.5
100	47.0

to the high current density or external causes, become quite high, as shown by the preceding *No. 18 of the Bureau of Standards*. For any corrosion for a given number of ampere-hours length.

atures is due principally to the drying of the (see *Endosmose*) and to a less extent to the concrete near the cathode, where it becomes converted of the concrete. Both of these actions have the effect from anode to cathode, but the effect of the principal one while the current flows, does not last long. (W. A. Del Mar and D. C. Woodbury, *ibid.*)

is good protection to steel work if the current does not excessively heat the concrete.

concrete if there is the slightest probability of the addition of even a fraction of one per cent to the rate of corrosion a hundred fold.

at. — Experiments by M. Toch, C. E. Magnusson have shown that unpainted steel imbedded in concrete corroded at the anode, but that a good insulating material prevents such corrosion. Acid-proof paints are commonly used to protect steel imbedded in concrete, but are ineffective. A typical paint of this kind has the following ingredients: coal-tar paint, 4 parts Portland cement, 3 parts

anode and ground does not exceed 5 volts the potential so protected, is usually less than 1 per cent.

**Tape or Braid.** — H. W. Fisher found that covering the lead with a weatherproof tape or compound. With such coverings the electrolysis is concentrated in spots and thus eat through the lead in places. Lead-covered cables, laid in wooden boxes, deteriorate rapidly under electrolytic action.

St. Louis (*Elec. World*, Vol. 57, p. 1103, 1911) have had experience with tape protection. Their wrought-iron pipe, was coated with a tar and pitch mixture, which was allowed to flow easily, and onto this a 4-inch paper covering with edges overlapping. This paper covering was covered with paper, the process being repeated until the pipe was completely insulated. Pieces of pipe thus insulated were placed under distinctive conditions of electrolysis, along with pieces of bare pipe. After being taken up at the end of two years the bare pipe was almost consumed, while the insulated pipe was as good as when laid. Although no test has yet been made as to total disintegration, it is believed that pipe life is at least doubled, and if this is true an expenditure of the cost of the bare pipe is justified. Only service pipes of cast-iron mains being less subject to corrosion and deterioration. The tar and paper coating is very hard when cured and should be handled with no more care than bare

tests. — In a number of installations, flow of current has been prevented by the use of a sufficient

number of insulating joints. It is found that where a pipe line is laid joint insulated, the line has such a high electrical resistance that negligible current flows, although considerable potential gradient may exist earth parallel to the pipe line. Insulating joints in cable sheathings are found to afford an effective means of preventing electrolysis.

**Protection by Shielding.** — Underground structures have been protected from electrolysis by connecting to the structure an auxiliary metallic conductor located so as to cause the current to flow to earth from the auxiliary conductor. The shielding conductor must be so placed as to prevent the current from entering the structure to be protected, or at least, to cause its magnitude to be reduced.

**Protection by Booster.** — It is often proposed to render ground work electronegative to the rail return by means of a booster, but such a scheme is seldom carried into execution on account of the expense involved.

A scheme adopted with success at Karlsruhe, Germany, involves the use of a booster which does not have to carry the main current and which is comparatively small. At places where there is danger for gas pipes, electrodes are placed in the earth in the neighborhood of the pipes, these electrodes are connected to the positive pole of a low-voltage generator storage battery, while the pipe to be protected is itself connected to the negative pole. In this way electric current is forced to enter the pipe from the earth so that anodic destruction of the pipe is impossible. The power consumption is said to be insignificant. (Geppert & Liese, *Elek., Kraftb. Bahnen*, 1912.)

Boosters are used to prevent the pitting of condenser tubes, especially when salt water is used for cooling. An example of such an installation is at the Power Station of the Long Island Railroad on the East River, New York.

**BIBLIOGRAPHY.** — A very complete bibliography of the subject up to 1908 is given in a paper by W. H. Gee, *Electrolytic Corrosion*, Jour. Inst. Chem. Eng., 1908, Vol. 41, p. 425. In addition to these references and those given in this text, the following more recent papers should be consulted:

*Report of the American Committee on Electrolysis, 1921.* (This contains a great deal of valuable information on the subject, including a description of the practice and protective legislation. It also contains a bibliography of contributions which are regarded by the Committee as having permanent value.)

*Bureau of Standards Technologic Papers, 15, 18, 25, 26, 27, 28, 32, 62, 63, 72, and 75.* (These papers cover almost every phase of the subject.)

**FINDINGS.** — (See also *Electricity and Magnets, Lifting and Plunger; Generators; Motors;* winding carrying an electric current forms an electromagnet is also generally used for such a coil, particularly core, whether it is actually carrying a current or not. The winding of electromagnets is in the form of a cylindrical coil. Such a winding is called a solenoid. This winding may be fixed rigidly to a magnetic core, or it may be movable, in which case the electromagnet is called a solenoid. The electromagnet may also be built upon a movable yoke or "armature" which is attracted to the core established in the winding. See *Electromagnets,*

**CONSTRUCTION OF WINDINGS** — The problem of designing a given voltage across its terminals, will produce a current, and which will not overheat. Usually one or two coils are also fixed by the conditions under which they are used. The following factors must be taken into account in

**Design of Bobbin.** — When the core is fixed, two layers of glass fiber are forced on at either end of the core. The core is wrapped with a wrapping of paper, mica or oiled linen, and is then the core is movable, the two end washers are made of brass tube or a tube made of the same material as the core. If the core is used the washers are sometimes made of the same material. In the case of a quick-acting plunger magnet a metallic bobbin, made of brass, is used in order to avoid eddy currents; this also applies to the design of electromagnets.

**Insulation Between Layers; Baking.** — The wire between the layers of cotton, silk or asbestos wind or by a coating of varnish. Between the various layers of wire are insulated with mica or oiled linen wrappings, or the entire winding may be separated by vertical washers of insulating material. The winding may be further insulated by dipping it into an insulating oil or at atmospheric pressure, after which it is either

insulations are used extensively by some manufacturers, but the layer of oxide on the wire is the only insulation which as this insulation cannot be destroyed by heat, and which is of special value for high temperatures, which is of special value for high temperatures. The oxide layer will stand a potential test. See article on *Use of Naked Aluminum Wire in Electro-Elec. Wld., 1912, Vol. 60, p. 400.*

**Winding; Watts per Square Inch.** — The rise of temperature will depend primarily upon the average rate at which the electric current and the amount of exposed surface to be radiated; the temperature rise will also depend upon the circulation of the air, etc. The hottest spot in the winding is such a higher temperature than 105° C. When the temperature is 105° C. the temperature of the external surface, as will usually be much less (15° C. less), as will also be determined by the change of resistance method.

As a rough approximation a solenoid winding should be so designed that the average power developed will not exceed 0.5 watt per square inch of radiating surface for an open winding, and will not exceed 0.7 watt per square inch of radiating surface for an iron-clad solenoid. In figuring the radiating surface of an open winding, the surface of the hole through the solenoid is not included and the end surfaces are included only when the solenoid is short. By the radiating surface in the case of an iron-clad solenoid is meant the surface of the winding which is in contact with the iron. A radiation of 0.5 watt per square inch and 0.7 watt per square inch for an open and an iron-clad winding respectively corresponds roughly to an average temperature rise of approximately 60° C.; for other rates of radiation the temperature rise will be approximately proportional to the watts per square inch radiated.

For short-time service, i. e., when the solenoid is energized only for short intervals with long intervals between the applications of power, the thermal capacity of the solenoid will permit of a greater dissipation of energy in the winding without overheating it.

**Space Factors; Round Versus Square Wire; Layer Versus Haphazard Windings.**—By the space factor of a winding is meant the ratio of the space occupied by the conductors to the total space occupied by the conductors and the insulation on the conductors and the voids between conductors. The space factor for strips and square wires is greater than for round wires, but as square wires are not extensively used in small sizes because of the large amount of insulation required for a given section of conductor, and because of the tendency of such wires to twist in winding so that they lie upon their edges instead of upon their faces. However, for conductors of larger section No. 10 B. & S. gauge, square wire is often used.

In winding wires larger than No. 18 B. & S. it always pays to wind them fully in smooth layers ("layer" wound), but for smaller sizes used for solenoids (as distinguished from iron-clad solenoids) the gain in space does not as a rule warrant this care and the wires are wound in a more haphazard fashion ("haphazard" wound). For iron-clad solenoids, however, a layer winding is always used, for economy of material requires that the winding space be kept as small as possible. The dotted curves A and B in Fig. 1 for haphazard windings are taken from an article by F. A. Willard (*Electrical Engineering*, 1906, Vol. 37, p. 823).

Round wires are sometimes so wound that the wires of one layer lie in the hollows between the wires of the layer underneath; the wires in this case are said to be embedded. Objections to this procedure, however, are that the layer must be started from the same end and the insulation on the wires is not tightly compressed and therefore is less effective; in most instances the extra labor and the diminution of insulating quality offset the small gain in space factor, which seldom exceeds 3 per cent.

The space factor  $s$  for a layer winding of round wire without embedded wires, making no allowance for extra insulation between layers is

$$s = \frac{\pi}{4} \left( \frac{d}{d + 2t} \right)^2,$$

where  $d$  is the diameter of the conductor and  $t$  the thickness of the insulation. Values of  $s$  for various sizes of wire and various thickness of insulation are given by the curves in Fig. 1. The "over-all" space factor, including the allowance for the space occupied by the extra insulation, if any, between layers, is the value of  $s$  from these curves multiplied by  $(1 - e)$ , where  $e$  is the ratio of the space occupied by this extra insulation to the total winding space.

Magnet wire is usually referred to as "single" and "triple covered," depending upon the number wrapped around it. Different manufacturers

### Space Factor Curves

these layers, with the result that the thickness of "ton covered" wire of a given size or gauge number of the wire. In the following table is given the space factor, taken from the catalogues of several large

37-40	2.0-4.0	1-2	.....	0.3

\* "For double covered" multiply these thicknesses by 2, and for triple covered multiply by 3.

**Winding Calculations for Direct-current Solenoids.** — Round solid wires are assumed throughout. Let

$s$  = space factor, from Fig. 1.

$k$  = ratio of specific resistance of conductor used to that of standard annealed copper at 20° C. For copper of 100 per cent conductivity at 20° C.,  $k = 1$ ; for copper of any other per cent conductivity  $C$  per cent, at any other temperature, say  $t$ ° C.,

$$k = \frac{100}{C} + 0.004(t - 20). \text{ See also } \textit{Wires and Cables, Barnes}$$

*Wires, Resistor.*

$A$  = cross section of wire in circular mils (= square of diameter in hundredths of an inch).

$n = \frac{1,270,000 s}{A}$  = number of conductors per square inch, the square being taken perpendicular to the direction in which the wire is wound.

$\rho = \frac{1,100,000 sk}{A^2}$  = resistance of the winding per cubic inch of the winding space, excluding the space, if any, occupied by extra insulation between layers;  $\rho$  is in ohms.

$w = 0.271 s + 0.040$  = weight of the winding (copper and cotton insulation) per cubic inch of the winding space, exclusive of the space, if any, occupied by extra insulation between layers;  $w$  is in pounds.\*

$E$  = impressed volts.

$(NI)$  = ampere-turns, where  $N$  is the total number of turns and  $I$  the current in amperes.

\* This formula also holds approximately for other kinds of insulation and for alloy resistance wires. Calling  $\epsilon_1$  the specific gravity of the conductor and  $\epsilon_2$  the specific gravity of the insulation, the exact formula is

$$w = 0.0362(\epsilon_1 - \epsilon_2)s + 0.0284\epsilon_1$$

Underhill gives  $\epsilon_1$  as 1.6 for asbestos, 1.4 for cotton, and 1.0 for silk.

$\rho$  = allowable watts per square inch of radiating surface (may be taken approximately as 0.5 for open and 0.7 for iron-clad solenoids, see above).

$S$  = radiating surface, in square inches, calculated as described above under *Temperature Rise of Winding*.

$l$  = mean length of turn in inches (see Fig. 2 for a simple solenoid).

$T$  = depth of winding space in inches (see Fig. 2), excluding the space occupied by the extra insulation, if any, between layers.

$L$  = length of winding space in inches (see Fig. 2).

$V = LT$  = volume of winding space in cubic inches, excluding space occupied by the extra insulation, if any, between layers.

The problem is usually to find the size of wire and necessary winding space for a coil which will give, without overheating, a required number of ampere-turns ( $NI$ ) at a given impressed voltage  $E$ . The diameter of the core or spool is also usually known, or at least must not exceed certain fairly well-defined limits, depending upon the service for which it is to be used. The procedure is then to assume a reasonable value for the mean length of turn  $l$ . The size of wire is then immediately fixed by the relation

$$A = \frac{k(NI)}{1.16 E} \quad (2)$$

From Fig. 1 the corresponding size of wire (A. W. G. or B. & S. gage) and the corresponding space factor  $s$  may then be found.

The volume  $V$  and radiating surface  $S$  of the coil must then satisfy the relation

$$\frac{LTS}{l} = \frac{k(NI)^2}{1,470,000 \rho s} \quad (3)$$

The length  $L$  and depth  $T$  of the winding space must be so chosen that this relation will be satisfied; as a rule this can be done only by cut and try. Note that increasing the depth  $T$  of the winding space will also change the mean length of turn  $l$ , unless the diameter of the core or spool is so altered as to keep  $l$  constant.

The cross section of the wire varies directly as  $l$ , as shown by equation (2), and therefore the value of the space factor  $s$  to be used in (3) will depend upon  $l$ , but only to a slight extent except in the case of very small wires.

Having determined the cross section of the wire ( $A$ ), the mean length of turn  $l$  and the dimensions ( $L$  and  $T$ ) of the winding space so that both (2) and (3) are satisfied, the total number of turns in the winding will be

$$N = \frac{1,270,000 sLT}{A} \quad (4)$$

and the current is then equal to the given number of ampere-turns divided by  $N$  and the total length of wire is equal to  $Nl$ .

The total resistance  $R$  and total weight  $W$  (including insulation) of the wire may then be found directly from a wire table, or may be calculated from the formulas

$$R = \rho V = \frac{kN}{1.16 A} = \frac{1,100,000 s k L T^2}{A^2} \quad (5)$$

$$W = wV = (0.271 s + 0.040) L T^2 \quad (6)$$

See note at bottom of preceding page regarding  $w$ .

**Calculation of Open Solenoid of Circular Cross Section.** — case of a coil wound on a spool of diameter  $D$ , see Fig. 2, the mean length of turn is  $l = \pi(D + T)$ . Assuming that the outside cylindrical surface of the winding is the only radiating surface, which is only approximately true, as pointed out above,  $S = \pi(D + 2T)L$ . Whence, putting

$$Q = \frac{k(NI)^2}{1,470,000 \rho s}, \quad (7)$$

Fig. 2.

the required length of coil for a given diameter of core  $D$  and depth of winding  $T$  is

$$L = \sqrt{\frac{(D + T)Q}{(D + 2T)T}}$$

When  $L$  is given instead of  $T$ , then the required depth of winding is

$$T = \frac{1}{4} \left[ \left( \frac{Q}{L^2} - D \right) + \sqrt{\left( \frac{Q}{L^2} - D \right)^2 + \frac{8QD}{L^2}} \right]$$

In either case, the number of turns, total resistance, weight, etc., are found as described above for the general case.

**Example.** — Required to design an open solenoid 10 inches long having an internal diameter of 1.5 inches, to give 12,000 ampere-turns at 100 volts, the heat developed not to exceed 0.5 watt per square inch of radiating surface (taken as the outside cylindrical surface of the coil). Assume length of turn equal to 10 inches, then from (2) the required cross section of wire, assuming copper at 70° C., is  $A = 1130$  cir. mils. From Fig. 1 the space factor is then  $s = 0.62$ , assuming single cotton-covered wire with 2-mil insulation wound in layers. From (7) the value of  $Q$  is then  $Q = 380$ , whence from (9) the required depth of winding is  $T = 2.36$  inches. The actual mean length of turn is then  $l = 12.1$  inches which substituted in (2) gives for the cross section of the wire required,  $A = 1368$ . This wire section gives a space factor of  $s = 0.63$ , which agrees practically with the value  $s = 0.62$  used. The nearest commercial size of wire is No. 19 B. & S., having a cross section of 1288 cir. mils. If this size of wire is used the actual ampere-turns will be 11,300. From (4) the total number of turns will then be  $N = 14,700$ , and from (5) the total resistance will be  $R = 14.5$  ohms. The current is then 8.3 amperes. The total weight of the winding is then from (6),

$$W = 60 \text{ pounds.}$$

**BIBLIOGRAPHY.** — Hedges, G. L., *Solenoid and Electromagnet Windings*, A.I.E.E., Proc. 34, Nov., 1915; George and Pender, *Calculation of Electromagnet Windings*, El. World, 65, p. 529, Feb. 27, 1915; see also *Bibliography in Electromagnets, Lifting and Plunger*.

**LIFTING AND PLUNGER.** — (See also *Principles of; Electromagnet Windings.*) A solenoid with a magnetic core, or with a fixed core and movable "armature," means of causing an electric current to produce a magnetic field.

This principle is utilized in various forms (relays, contactors (see *Switches*), electric brakes, etc.). The following are given the formulas required in the design of solenoids in terms of their dimensions and a brief statement of the applications of the

**Leakage Factor.** — In applying the formulas it is assumed that in general the effect of magnetic leakage is negligible or varies so greatly with the different forms of solenoid that it is not possible to go into this matter in detail in the limited space available. The designer, in making an allowance for leakage, should refer to his previous experience with other magnets of the same type. Merely as a rough guide to the designer it may be stated that for magnets of reasonable dimensions the pull given below may be relied upon to be correct to within less than  $\pm 10$  per cent, the actual pull usually being somewhat greater. Under certain conditions the agreement between the calculated pull may be much closer than the differ-

**PULL ON A PLUNGER.** — The simplest type of electro-magnet is shown in Fig. 1, consisting of a cylindrical coil of wire wound on a core and an iron plunger which fits into the inside of the coil. Through the coil the plunger is attracted.

Fig. 2.

**Pull on a Solenoid During the Stroke.** — The pull of a solenoid is zero when the plunger is at the end of its stroke and reaches a maximum which is nearly constant over a certain length of the coil. The maximum is reached when the plunger is at a distance of approximately 40 per cent of the coil length from the end. At the end of the coil 80 per cent of its length, the pull de-

creases again, reaching a value of about 0.6 of the maximum pull when the plunger is even with the top of the coil. The approximate pull variation is shown in the diagram, Fig. 2; of course the actual variation is a smooth curve such as shown by curve *A* in Fig. 8.

**Calculation of Pull of Simple Solenoid.** — The calculation of the pull of such a magnet is very complicated, being dependent not only upon the number of turns, but also upon the shape of the coil, the size and length of the plunger, and the induction in same. For practical purposes the maximum pull, when the plunger is at least as long as the coil, can be represented by the formula:

$$P_1 = \frac{cANI}{l_0} \quad \text{pounds,}$$

where *c* = the pull in pounds per square inch per ampere-turn per inch of coil length,

*A* = the area of the cross-section of plunger, in square inches,

*I* = the current in the coil, in amperes,

*N* = the number of turns in the coil,

*l*<sub>0</sub> = the length of the coil, in inches.

It has been found by the author that *c* varies between  $9 \times 10^{-7}$  and  $10.5 \times 10^{-7}$  when the plunger is magnetically saturated. For practical purposes sufficiently close results for a saturated plunger are obtained if *c* is taken equal to  $10^{-7}$ . The formula shows that the maximum pull for a saturated plunger is proportional to the current, which makes this type of magnet especially suitable for relays and instruments which should be very sensitive. When the density in the plunger is well below the knee of the *B-H* curve, the pull varies almost directly as the ampere-turns, and the maximum pull, *P*<sub>1</sub>, varies approximately as the square of the ampere-turns.

The pull at any point in the stroke for a saturated plunger may be expressed by the formula

$$P_1 = \frac{10^{-7}ANI}{l_0} \cdot k \quad \text{pounds,}$$

where *k* is a factor which gives the ratio of the pull at any point of the stroke to the maximum pull; Fig. 2 gives the approximate value of *k* at various points of the stroke.

#### IRON-CLAD ELECTROMAGNET WITH FLAT-END PLUNGER

The simple solenoid is a very inefficient type of magnet, because a large percentage of the reluctance of the magnetic path is found in the long air path outside the coil. Therefore, the plunger magnet is modified by putting an iron return circuit around the outside of the coil, thus reducing considerably the reluctance of the path and increasing the work which can be obtained with a certain amount of power, and with a certain expenditure of energy in the coil. Fig. 3 shows this type of "iron-clad" magnet. In its highest position the plunger strikes against the frame, so that in reality the magnet represented is a special form of magnet with stop, which is described below. If it is desired to have the pull decrease towards the end of the stroke, a hole similar to the one on the lower end is drilled in the upper end of the frame, and the plunger is permitted to protrude through it.

Fig. 3.

**Use of Stop to Increase Pull.** — The total pull on a plunger depends on the total number of flux lines which pass through it. For a given number of amperes the total number of flux lines may be increased by decreasing the reluctance of the magnetic circuit. This reluctance may be still further reduced by using a stop or stop in the upper part of the solenoid of such a length that the air-gap is central to the coil for the maximum travel which is required. This form is shown in Fig. 4.

**Pull of Stop on Plunger; "Air-gap Pull."** — The pull  $P_2$  between the stop and plunger may be expressed by the formula

$$P_2 = \frac{B^2 A}{72 \times 10^6} \quad \text{pounds,} \quad (3)$$

where  $B$  is the flux density in the air-gap\* perpendicular to the end surface of the plunger, in lines (maxwells) per square inch, and  $A$  the area of the end of the plunger, in square inches (see *Electricity and Magnetism, Principles of*). The value of  $B$  may be calculated from the ampere-turns of the coil and the dimensions of the magnetic circuit in the same manner as the flux due to the coils of a generator is calculated; see *Generators, Direct-current*. Or, neglecting leakage and the reluctance of the iron part of the path,  $B$  may be calculated approximately from the formula

$$B = \frac{3.19 NI}{l_0} \quad \text{lines per sq. in.,} \quad (4)$$

where  $NI$  is the total ampere-turns of the coil and  $l_0$  is the length of the air-gap in inches. Combining (3) and (4) gives

$$P_2 = 1.4 \times 10^{-7} A \left( \frac{NI}{l_0} \right)^2 \quad \text{pounds.} \quad (5)$$

This pull of the stop on the plunger is usually referred to as the "air-gap pull." The actual variation of this air-gap pull with the length of the air-gap, for a particular magnet, is shown in curve  $B$ , Fig. 6.

**Total Pull of Iron-clad Solenoid with Stop.** — The total pull of the iron-clad solenoid with stop may be looked upon as due to two components, the solenoid effect  $P_1$  given by equation (2) and the pull  $P_2$  between stop and plunger given by equation (5); hence the total pull is

$$P = 10^{-7} ANI \left( \frac{k}{l_0} + \frac{1.4 \times 10^{-6} NI}{l_0^2} \right) \quad \text{pounds.} \quad (6)$$

When the air-gap is short and at the center of the solenoid  $k = 1$ . The variation of this total pull with length of air-gap for a particular electromagnet is shown in curve  $C$ , Fig. 6.

**IRON-CLAD SOLENOID WITH CONED PLUNGER.** — It will be noted that for a given air-gap pull  $P_2$ , the ampere-turns required are directly

\* Strictly,  $B$  in this formula is the actual air-gap flux density less the flux density which would be produced by the solenoid were there no iron whatever in its magnetic circuit. This correction, however, is smaller than the probable error in calculating  $B$  and may therefore be neglected.

Fig. 4.

proportional to the length of the air-gap. If, therefore, for the same length of the path for the magnetic lines through the air-gap can be the pull for the same ampere-turns will be increased, or if the pull constant the ampere-turns to obtain it can be decreased. This is accomplished by the coning of the end of the plunger, as shown in Fig. 5. For such a magnet should not be much in excess of the plunger diameter, as the leakage considerably with longer strokes, and this defeats the object of the coning. As the induction in the iron plunger is greater than the induction in the air-gap, there is a limit to the practicable value which may be given to the cone angle; this limit is about reached for cast iron for a cone angle of  $28^\circ$  and for cast steel for a cone angle of  $19^\circ$  degrees.

**"Air-gap Pull" on Coned Plunger.**—In the following it is assumed for simplicity's sake that a uniform flux at right angle to and distributed over the entire surface of the cones passes between plunger and plug. This is not strictly correct, especially for long strokes and the pull calculation is therefore only approximately correct.

Let

$l$  = length of stroke, in inches,

$A$  = total cross-section of plunger, in square inches,  $= \pi r^2$  where  $r$  = radius of the plunger, see Fig. 5,

$\alpha$  = angle of the cone, in degrees, see Fig. 5,

$NI$  = total ampere-turns of coil.

Then the flux density in the plunger is

$$B_i = \frac{3.19 NI}{l \sin^2 \alpha} \quad \text{lines per sq. in.}$$

and the air-gap pull in the direction of the stroke is

$$P_2 = 1.4 \times 10^{-7} A \left( \frac{NI}{l \sin \alpha} \right)^2 \quad \text{pounds.}$$

The solenoid pull, as found by experiment, is practically the same as for a flat-end plunger, equation (1). Whence the total pull on the coned plunger

$$P = 10^{-3} ANI \left( \frac{1}{l_s} + \frac{1.4 \times 10^{-8} NI}{l \sin^2 \alpha} \right) \quad \text{pounds,}$$

where  $l_s$  is the length of the solenoid winding assuming the gap at the end of the solenoid ( $k = 1$ ).

Note that  $l \sin \alpha = l_s$  is the "effective" length of the air-gap, i.e., the length perpendicular to the surface of the cone. Hence, comparing with equation (1) it is seen that the pull on a coned plunger for the same effective air-gap is the same as on a flat-end plunger, but the length of the stroke is increased in the

ratio of  $\frac{1}{\sin \alpha}$ . Comparing equation (7) with equation (4), it is seen that the advantage is gained by increasing the flux density in the plunger in the square of  $\frac{1}{\sin \alpha}$ . For small air-gaps, therefore, the coned plunger becomes attracted much more quickly for the same current than does the flat-end

Fig. 5.

the leakage and the reluctance of the iron part of the path produces a variable effect, causing the pull to become almost constant for small air-gaps instead of increasing as shown by the approximate equation (9). This is clearly shown by the curves *D* and *E* in Fig. 6.

4. Pull Curves of D-C. Magnet. — Length of solenoid 3 inches; internal diameter of solenoid  $1\frac{1}{4}$  inches; external diameter  $2\frac{1}{4}$  inches; diameter of plunger  $1\frac{1}{4}$  inches; angle of cone  $20^\circ$ ; stop projects 1 inch inside coil; number of turns 300; current 57 amperes.

**HORSESHOE-TYPE ELECTROMAGNETS.** — Another type of electromagnet which is used quite extensively is the horseshoe-type electromagnet, as in its simplest form in Fig. 7. This magnet is not suitable for very long gaps, because the leakage increases very rapidly with increasing distance from armature and poles. The total pull on the "armature" *K* of such a magnet, neglecting the leakage, may be expressed approximately by the relation

$$P = 2.8 \times 10^{-7} A \left( \frac{NI}{2l_g + l} \right)^2 \text{ pounds,} \quad (10)$$

where *A* = cross-section of each pole, in square inches, *NI* = total ampere-turns, *l<sub>g</sub>* = length of each air-gap in inches, and *l* = length of air-gap equivalent to the

reluctance of the iron. This last depends on the permeability and diameter of the iron part of the circuit; calling  $l_1$  the mean length of this iron circuit,  $\mu$  its permeability, and assuming the mean cross-section of this path to be the same as the cross-section  $A$  of each pole, then  $R = l_1/\mu$ . A more exact calculation of the pull may be made by calculating, as for a generator field (see *Generators, Direct-current*), the ampere-turns required to establish a given flux density of  $B$  lines per square inch in the gap, and then applying equation (3) to determine the pull.

**Applications of Horseshoe Type.** — This type of electromagnet is frequently used where it is only desired to hold a weight after the armature has come into contact with the poles. A form of this magnet whereby the winding is put on the yoke connecting the two poles is used extensively as a no-voltage release on handstarters for current motors (see *Starters, Motors*).

**Lifting Magnets for Handling Magnetic Materials.** — Various horseshoe electromagnets are used for lifting magnetic material. For long pieces, such as pipes and rails, the magnet may be designed with a large distance between the poles, with the winding on the yoke; this is usually referred to as the "bi-polar" type. For lifting shorter pieces, plates, slabs, billets, etc., a magnet with a relatively short distance between poles is better. This is readily secured by making the magnet with one pole carrying the winding, with the second pole surrounding the winding, central pole. Accordingly as the magnet has a rectangular or circular cross-section it is called a "rectangular" or "concentric" magnet.

The concentric magnet is used for the greatest variety of purposes, frequently referred to as a "general duty magnet." This type of magnet is especially suited for lifting pig iron, billets, skull-crackers, scrap, and other magnetic material of high reluctance.

In all types of lifting magnets the voids inside the coil winding are filled with impregnating material which also serves to make the magnet proof.

**Magnetic Disc Brakes.** — A similar magnet is used for magnetic brakes. The magnet is usually mounted on the end plate of the motor and attracts a disc-shaped armature which operates against a spring. When the magnet is energized and is under the influence of the spring pressure and the magnet decreases, the armature presses against a series of stationary and movable discs, the latter being connected with the motor shaft, and causes friction between these parts which tends to retard and stop the motor. The movement of the armature in disc brakes is very small, being of the order of  $\frac{1}{4}$  inch.

**Magnetic Clutches.** — Of similar construction are magnetic clutches. In this case the magnet is mounted on the end of the shaft of the driving motor, whereas the armature, which consists of a circular ring, mounted to the driven shaft by means of a somewhat flexible connection, is connected with the driven shaft. When the magnet is energized the disc is attracted and takes part in the rotation, thereby driving the second shaft. A pair of collector rings are provided to convey the current from the stationary wires to the rotating magnet. In this case also the movement of the armature is very slight. In order to release the brake quickly a non-magnetic material is often provided between the magnet and the armature which prevents sticking, due to residual mag-

Fig. 7.

according to a sine curve when the current is sinusoidal. The average pull is one-half of the maximum pull. Whenever the pull is the load, there is a tendency for the plunger to move away from the this causes rattling or humming of the magnet. This humming may come in different ways, one method being to use a "shading coil," below.

**Polyphase Electromagnets.** — It can be shown that if three magnets are used and each is supplied with current from one phase of a three-phase source or if two magnets are used and each is supplied with current from one phase of a two-phase source, then the resultant pull will be constant at any moment if the plungers are rigidly connected there will then be no chattering. The most common form of three-phase magnet is shown in Fig. 9. This consists of a core having three poles and a plunger of similar construction. On each pole there is wound a coil which is supplied from one of the three phases of the circuit. There are various modifications of the polyphase magnet, but their general principle is the same. In calculating the total pull, the pull at each pole is figured separately and the several pulls, which are equal in magnitude, are combined vectorially, since they differ in time phase (see *Alternating Currents*).

**Calculation of Pull of Single-phase Electromagnets, or of One Phase of Polyphase Electromagnets.** — The formulas for pull given above for d-c. current electromagnets also hold for alternating-current magnets, provided  $I$  is taken as the effective value of the current,  $B$  as the effective value of the flux density and  $P$  as the average or effective value of the pull.

In contrast to the d-c. electromagnet, the flux in an a-c. electromagnet for a given impressed e.m.f. is approximately constant irrespective of the length of the air-gap. This is due to the fact that the opposition to the flow of current through the winding is due almost entirely to the back e.m.f., due to the alternation of the flux, and only to a very small extent to the resistance of the winding, the action in this respect being similar to that of a transformer (q.v.) or a synchronous motor (see *Motors*). The back e.m.f. being practically equal to the impressed e.m.f., the flux producing this back e.m.f. is also proportional to the impressed e.m.f., and is therefore practically constant when the impressed e.m.f. is constant.

Since the flux remains practically constant, the current  $I$ , as may be seen from equation (4), must vary approximately proportionally to the length of the air-gap  $l_a$ ; this proportionality holds only approximately, since equation (4) neglects the magnetic leakage and the reluctance of the iron part of the circuit. The actual variation of the current with the length of the air-gap for a particular a-c. electromagnet is shown in Fig. 10.

Using the same notation as used above for d-c. electromagnets and in putting  $E$  = effective value of impressed voltage per phase, and  $f$  = frequency of impressed voltage in cycles per second, the current taken by each

Fig. 9.

losses, leakage and reluctance of the iron part

the current, taking into account the losses and corrected by the method used for calculating the transformers).

Distance Parallel to Axis of Coil, in Inches

of A-C. Magnet. — Length of solenoid 5 inches; inches; external diameter  $4\frac{1}{2}$  inches; diameter of is  $1\frac{1}{2}$  inches inside of coil; turns 144; voltage 220;

the current given by (11) in equation (6) for the t end gives the approximate formula

$$\frac{k l_0}{l_0} + \frac{72 E}{JNA} \text{ pounds.} \quad (12)$$

ed plunger, when  $l_0$  is taken equal to the length be face of the cone.

of an alternating-current magnet with flat-end

stop and plunger. It will be noted that the current is roughly proportional to the air-gap. The solenoid pull reaches a maximum at an air-gap of about 1/4 inches and then falls again approximately proportional to the air-gap; the gap pull is constant over a wide range of the travel. The result is a curve which has a maximum at approximately 2 1/4 inches and which drops to zero at an air-gap of approximately 3/4 inch is reached, and from there on it increases again, due to the increase of the air-gap pull, the latter being caused by the diminution of the leakage flux as the air-gap decreases.

**Limiting Flux Density and Losses in A-C. Electromagnets.** — Attention must be paid to the fact that the iron losses, similar to those of the transformer, increase with the flux density and therefore the design must be such that the flux density is not too high. The flux density in the iron in the case of a coned plunger, from equation (4), which neglects the magnetic leakage, and the reluctance of the iron part of the magnetic path, is

$$B = \frac{1.6 \times 10^8 E}{fNA} \quad \text{maxwells per sq. in.}$$

and in the case of a coned plunger, under the same assumptions, from equation (7), is

$$B = \frac{1.6 \times 10^8 E}{fNA \sin \alpha} \quad \text{maxwells per sq. in.}$$

where  $\alpha$  is the cone angle, see Fig. 5.

These relations are approximate only. The magnetizing component of the exciting current, and from it the flux density can be more accurately calculated by the methods employed in the design of transformers or induction motors. See *Transformers and Motors, Polyphase Induction*.

The iron and copper losses can also be calculated by similar methods, and from these losses the energy component of the exciting current can be determined. The total current and power factor of the electromagnet can then be determined.

**Shading Coil for Single-phase Electromagnets.** — The humming of single-phase magnets may be greatly reduced by introducing a so-called "shading coil" in the pole face. This shading coil is nothing more than a short-circuited secondary winding, consisting of one or more turns, which encloses only a portion of the total flux passing through the plunger. Due to the leakage reactance of this turn, the current induced in it is out of phase with the inducing flux, so that at the moment when the inducing flux, due to the main winding, is zero, there still remains a flux due to the current in the shading coil, which flux produces a pull. The result is that the combined pull from the main flux and the shading coil flux never becomes zero. Fig. 11 shows the arrangement of the shading coil. This coil is mounted in the plunger or in the plug close to the pole face, in order to reduce the length of the path for the magnetic lines which are interlinked with the shading coil. Naturally the shading coil has no effect with long air-gaps, and it is therefore imperative that a good magnetic contact be obtained when the plunger is in the sealed position to get the greatest possible effect of the shading coil.

Incidentally the shading coil also increases considerably the maximum pull for a given impressed e.m.f., as the maximum pull is also due to the com-

Fig. 11. Shading

an example, a plunger magnet without shading pull of zero and a maximum pull of 28 pounds. The shading coil, a minimum pull of 18 pounds pounds.

#### DIMENSIONS OF ELECTROMAGNETS.

In the designs, it is not possible to give unit costs of the most economical magnet design has been (*A.I.E.E., 1911, Vol. 30, p. 2019*), but unfortunately will usually be found not to be suitable for results in a magnet which is too long compared to it cannot be incorporated in the machine with other magnets as they are found in practical applications. The most economical design. Also for the same reason (expressed as inch-pounds or foot-pounds) there is a dependence upon the service conditions as to speed which they have to meet. The following table of sizes and dimensions of some typical electro magnets is given.

Total weight of active iron and copper, pounds	Length of stroke, inches	Pull at beginning of stroke, pounds	Voltage	Watts input at end of stroke	Power factor at end of stroke	Factory cost, 1914
2.9	1/4	0.15	110-500	9	....	\$5.10

**ELECTROMETERS.**—(See also *Electrodynamometers*; *Voltmeters*.) An electrometer is primarily an instrument for measuring differences, but under certain conditions may also be used as a wattmeter; in the latter case it is usually called an electrostatic wattmeter. The operation of the instrument is due to the attraction or repulsion of electrostatic forces. It may be used for either direct- or alternating-current measurements. There are a great variety of forms of electrometers. On account of the delicacy required in its use, the ordinary quadrant electrometer is seldom used except for laboratory purposes, but various modifications of the type are provided with pointer and scale so as to be direct reading are used especially for high voltage measurements. Such instruments are known as electrostatic voltmeters; for description see article on *Voltmeters*.

**Electrometer versus Galvanometer or Electrodynamicmeter.**—The chief advantage of the electrometer over the galvanometer or electrodynamicmeter is that it takes no current when used for constant (d-c.) voltage measurements. Due to its electrostatic capacity, however, it does take a certain amount of charge which should always be allowed for if the capacity of the electrometer is appreciable compared with any other capacity which affects its operation. Also, when used for a-c. measurements, the charging current taken by the electrometer should be allowed for, if this charging current is appreciable. This charging current is usually considerably less than would be taken by an electrodynamicmeter of the same degree of sensitiveness.

**KELVIN QUADRANT ELECTROMETER** (Fig. 1).—Two brass quadrants *a* and *a'* are connected together and two quadrants *b* and *b'* are connected together and these respective pairs are well insulated from one another. The "needle" *n* (a light aluminum vane) is suspended by a silk, silvered quartz or other fiber and insulated from the quadrants.

A light aluminum vane *v* is suspended from the needle by a fine conducting wire and dips into a conducting solution, usually 60 per cent sulphuric acid, which serves as a means of connecting the needle to any external source of p.d. or to the ground. If a conducting suspension is used this may be employed to connect the needle to the external source of potential. The sulphuric acid also keeps the air dry in the case containing the quadrants, and the motion of the vane in the acid damps the vibrations of the needle. The suspension carries a mirror *m* by means of which the deflection of the needle may be read.

**Formulas for Quadrant Electrometer.**—In order to obtain a linear calibration curve the needle must be properly shaped and must be suspended midway (vertically) between the two quadrants and must have a geometrical zero position with respect to the two quadrants. Under these conditions when the two pairs of quadrants are charged to potentials  $V_a$  and  $V_b$  and the needle is connected to the potential  $V_n$  above any fixed potential, say that of the earth, the angular deflection is

$$D = \frac{\pi}{K} (V_a - V_b) \left( V_n - \frac{V_a + V_b}{2} \right),$$

where  $K$  is a factor, which is practically a constant. The value and order of magnitude of the factor  $K$  should be determined by calibration.

There are three ways of using the instrument, as indicated in the c

Fig. 1. Kelvin Quadrant Electrometer.

$V$  the p.d. to be measured,  $a$  and  $b$  the two pairs

n  $E$ , the + sign if  $V$  is greater than  $E$ , and call the de-

very small amounts of power, of the order of 1 watt, when the voltage is 5000 volts or more. It therefore serves as a very convenient means of measuring the power loss in small samples of insulating material at high voltages. See paper by E. H. Rayner, *Jour. Inst. Elec. Eng.*, 1912, Vol. 41, p. 100.

The connections used by Rayner are shown in Fig. 4.  $R$  is a non-inductive resistance. The needle of the electrometer is connected to the middle of the high-tension winding of the transformer. On the assumption that the charging current of the electrometer and the difference in phase between  $V$  and  $E$  are neglected, the power supplied to the load is

$$P = \frac{2K}{R} D,$$

where  $K$  is the instrument constant and  $D$  the deflection. The range of the instrument as thus used depends upon the value of  $R$ , the higher  $R$  the smaller the amount of power which may be read.

However, the higher the value of  $R$  the greater the phase difference between  $E$  and  $V$  if the load current is out of phase with  $V$ , and therefore for such measurements when the load has a low power factor e.g., when it is a capacitor, an allowance must be made for this difference in phase angle. Also, the charging current of the electrometer is comparable in magnitude with the load current a correction must also be applied on this account. These corrections are discussed in detail in Rayner's paper.

**COST (Pre-war prices).**—An ordinary Kelvin quadrant electrometer for measuring potentials of from 400 to 1300 volts costs approximately £10.

**BIBLIOGRAPHY.** — Laws, F. A., *Electrical Measurements*; Ericsson, *Mesures Electrique*; G. D. Aspinall Parr, *Electrical Engineering Instruments*.

*T.* — (See also *Electricity and Magnetism, Principles of.*) The electron is the smallest known separate entity. The basic assumption of the electron theory is that all substances contain one or more electrons. The atoms, in their normal condition, become positively charged by the loss of electrons. This assumption that in every body, whether charged or not, the electric charge is of both signs distributed not continuously but as discrete units, introduced, long before the discovery of the separate electron, accounts for certain discrepancies found in applying the theory of light to the optical properties of material media.

Crookes on the cathode rays J. J. Thomson was led to the theory of conduction of electricity through gases at low pressure. The cathode ray, it is assumed, is carried by extremely small particles called electrons. The work of Thomson, Wilson and others led to the separate existence of the electron together with its charge and of its mass.

**Effective Electron.** — The results of numerous experiments have led to the following assumptions regarding the electron.

1. The charge of a single electron is the smallest possible charge. No charge of electricity can be produced which is smaller than this charge. The value of the charge carried by a single electron is

$$1.6 \times 10^{-19} \text{ c.g.s. electrostatic units}$$

(in electromagnetic units). This charge is also equal to that of a hydrogen atom in electrolysis. (There is also considerable evidence that the charge of an electron is electricity pure and simple, having no mass. See below.)

2. The mass of an electron may be defined as the force required to accelerate it. All experiments indicate that the "effective" mass of an electron, when at rest, is approximately

$$9.1 \times 10^{-28} \text{ grams,}$$

when moving with a velocity greater than one-tenth the velocity of light. For velocities greater than one-tenth that of light the "effective" mass increases with increase in velocity (see below). The mass of an electron is about one-seventeen hundredth ( $\frac{1}{1700}$ ) that of a hydrogen atom.

3. Whenever the expression "mass of an electron" is used, it should be understood that this effective mass is meant.

4. An electron carrying a charge  $e$  and moving with velocity  $v$  produces the magnetic field of an elementary length  $ds$  of a conduction current of  $ev$ . (See *Electricity and Magnetism, Principles of.*)

5. Every piece of matter contains at least one electron which is held in place by elastic forces, that is, an electron may oscillate about its normal position when displaced by an impressed electrostatic field. The same is true of all matter of the same nature irrespective of the substance in which it is located.

6. An electron is ejected from the atom by the influence (mutual repulsion) of other electrons moving at a high velocity in its immediate vicinity.

7. See the report of the Amsterdam Academy, 1878.

8. The force,  $F$ , the acceleration, and  $m = \frac{F}{a}$  is the "effective"

This action is usually spoken of as a bombardment, or collision, although not necessary to assume that the free electron actually hits the atom.

6. When an electron is expelled from an atom the atom manifests the properties of a positively charged body.

7. In every substance there exists in addition to the electrons within atoms a certain number of "free" electrons, i.e., electrons which can move in the inter-atomic spaces; these free electrons may also pass from one substance to another. Under certain conditions, e.g., in a gas at ordinary pressures, a free electron may attach to itself one or more atoms or molecules.

**Properties of the Positive Particle.** — Experiment also justifies the following assumptions regarding the positively charged particles:

1. The smallest positive charge that it has been found possible to produce is numerically equal to that of an electron, viz.,  $4.9 \times 10^{-10}$  c.g.s. electrostatic units.

2. The smallest possible positive charge is always associated with a mass having a mass of the same order of magnitude as that of an atom, the being never less than that of a hydrogen atom.

3. The positively charged particle may be looked upon as an atom from which one or more electrons have been expelled; its mass therefore depends upon the nature of the atom. A "free" positively charged particle may also attach to itself one or more neutral atoms or molecules.

**Relation between Electrons and Ions.** — The term "ion" is reserved to designate any charged body having a mass of the order of magnitude of that of a molecule or atom. In this sense an electron is not an ion, but a positively charged particle is an ion. If, however, the electron becomes attached to an atom or molecule, then this combination forms an ion. In the case of the discharge of electricity through gases at low pressure, the electron, although not attached to an atom or molecule, is sometimes called an ion. See *Electrochemistry, Principles of*.

**APPLICATIONS OF THE ELECTRON THEORY.** — All of the foregoing conclusions have received ample experimental verification. The phenomena which have presented the most important evidence are the cathode ray, the condensation of water drops on free electrons, the emission of electrons from metals at high temperatures, and from certain metals under the influence of ultra violet light, and the properties of radio-active substances. From the mass of evidence it is now certain that the atoms of all substances contain one or more electrons; that many of the common properties of matter are determined by the numbers and arrangements of the electrons in the atoms; that neutral atoms may lose or gain electrons and so become charged ions; that an electron may be separated from an atom and its independent existence is possible; and that in all substances there are always present a certain number of free electrons in motion among the molecules and atoms due to their mutual collisions in accordance with the kinetic theory of matter; it appears probable that the same theory governs also the motion of the free electron.

The electron theory has led to simple explanations of many of the electrical and optical properties of matter, and the study of the properties of electrons has opened a number of useful applications in the field of electrical engineering. Some of the more striking results in both fields are briefly described in the following paragraphs.

**Electron Emission from Hot Bodies (Thermionic Discharge.)** (See also *Radio Communication*.) When a metal is heated to a high temperature in a high vacuum it gives off electrons freely. This fact was first studied by Richardson. Langmuir by improvements in methods of obtaining high

much further, clearing up many disputed questions of practical applications of far-reaching value. The phenomenon is subject to the temperature of the metal or cathode and the electric field at its surface, as due for example to a neighbor-

ing body. In accordance with the kinetic theory of matter the electrons are in a constant state of motion, and that of those which do not escape, a few at high, the greater number at low, velocities with Maxwell's Distribution Law. When an electron leaves a metal becomes positively charged, thus putting a positive charge on it and tending to make it return. The distance it travels before returning is greater the greater its initial velocity, and in the case of a metal or positively charged surface it may not return at all. The temperature of the heated metal or cathode affects the number of electrons leaving it, and the greater the volume of the cathode the following law due to Richardson has been observed:

$$i = a\sqrt{T}e^{-\frac{b}{T}},$$

where  $i$  is the current per unit area from the cathode,  $T$  its absolute temperature,  $e$  the natural system of logarithms, and  $a$  and  $b$  are constants.  $a$  is 0.0047 ampere at 2000° C. and 31.7 amperes at 3000° C.  $b$  is 54,000. The value of the current given by the foregoing is called the "saturation current," and it is independent of the temperature of the cathode and the voltage of the circuit.

As the voltage of the circuit increases, a condition is reached in which the current is independent of the temperature and increases with the voltage. The value of the current for a cylindrical cathode of radius  $r$  is:

$$i = \frac{2\sqrt{2}}{9} \sqrt{\frac{e}{m}} \frac{V^{3/2}}{r},$$

where  $e$  is the charge and  $m$  is the mass of the electron.

The negative electric field at the surface of the cathode due to the positive charge existing in the stream of electrons in the anode-cathode space; this is known as the "space-charge effect." It tends to pull back into the cathode all electrons leaving it and to reduce the field of the positive electrode. Thus the current is independent of the potential of the anode and independent of the temperature of the cathode.

The current characteristic of the thermionic tube is thus regulated by the space-charge effect. In the first region, best observed at low voltages, the current is low, the space-charge effect is absent, and the initial velocities of the electrons emitted by the cathode are not very obscured for the hotter cathodes commonly used. The current characteristic is determined at the lower end of the voltage scale. At higher voltages the third region is reached, in which the current is reached, dependent on the temperature of the cathode and the voltage.

The thermionic tube conducts in only one direction and is an excellent rectifier. This is the principle of the vacuum tube diode.

**Fleming valve and kenotron.** If a third electrode, in mesh or grid placed between the cathode and anode, very small potentials on the cause wide variations in the potential gradient at the surface of the and so cause wide changes in the value of the electron discharge. This has proved of immense value as a relay for magnifying radio signals, phonic speech, as exemplified in the audion and thermionic amplifier. The same principle is used in larger tubes for generating sustained oscillations for radio transmission, as exemplified in the pliotron. At present rectifying and generating tubes are limited to small current capacities (*Radio Communication*) owing to difficulties of tube construction.

**Cathode Rays.** — When an electric discharge is passing in a vacuum at a certain value of the pressure of the gas contained in the tube it is that a greenish phosphorescence occurs on the walls of the tube. By solid bodies in the tube it is found that the phosphorescence is due to proceeding in straight lines perpendicularly from the surface of the cathode. The name "cathode rays" has been given to this agent which produces phosphorescence. These rays are deflected by both electric and magnetic fields and communicate a negative electric charge to an insulated conductor. The "rays" consist of a rapidly moving stream of electrons. The amount of deflection of the rays, under the action of magnetic and electrostatic fields, can be calculated on the assumptions of the electron theory, and a comparison of the calculated with the observed deflections shows the two to be in close agreement.

The cathode rays give rise to X-rays when they strike a target or obstacle. The use of a hot cathode with a focusing negative shield for raising the velocities of emission has led to great improvements in X-ray tubes and to further knowledge of the X-rays (see *X-rays*). In this way it is possible to obtain X-rays of single values of frequency and these by interference experiments have led to important evidence as to the molecular structure of matter.

**Kanalstrahlen.** — If the cathode of a tube producing cathode rays is perforated, faint luminous streaks are seen to proceed through these perforations in a direction opposite to that of the cathode rays. The name "kanalstrahlen" has been given to this phenomenon (the German name is very generally used in English). These rays are also deflected by both electric and magnetic fields, but to a lesser extent and in relatively the opposite direction from the cathode rays, and communicate a *positive* charge to an insulated conductor.

In terms of the electron theory these rays are positively charged ions. Calculations from actual measurements, making this assumption, show that the charge carried by each of these ions is numerically equal to that of an electron and that the mass of each ion is never less than the mass of a hydrogen atom but may be greater, depending upon the nature of the gas and the pressure in the tube. That is, the cathode particle is an electron traveling in one direction and the kanalstrahlen particle is what is left of the atom which has lost an electron, traveling in the opposite direction.

**Electrical and Thermal Conductivity.** — One of the fundamental assumptions of the electron theory is that in conductors there are many electrons free to move about among the molecules besides those electrons in fixed positions of equilibrium. It is likely that these electrons are not all the same ones; the molecules are probably continually gaining and losing electrons. It is reasonable to assume that the more free electrons (on an average) in a body the better electrical conductor it is. According to the theory of matter, the molecules of all substances not at the absolute zero temperature are in a state of ceaseless agitation; if the assumption is made that the *free* electrons share in the motion of the molecules, then the a

al the more rapidly will kinetic energy be communi-  
o neighboring ones, that is, the better conductor of

tively with the matter some assumption as to numer-  
the one that has been made is that the mean kinetic  
equal to the mean kinetic energy of the molecules.  
on and also making one as to the relation between  
er unit volume and the temperature, it has been  
1. Joule's law for the production of heat in a con-  
current; 2. the Wiedemann-Franz law, which states  
ratio of the thermal to the electrical conductivity is  
of the metal and is proportional to the absolute tem-  
and Thomson effects. The theory also throws much  
Hall effect.

's laws of electrolysis (see *Electrochemistry, Principles*  
in terms of the electron theory. It is only necessary  
e univalent ion in the solution is an atom from which  
ed, each positive bivalent ion is an atom from which  
pelled, etc., and that each negative univalent ion is  
e electron has attached itself, each negative bivalent  
ich two electrons have attached themselves, etc.

The magnetic properties of bodies may be explained  
ory by assuming that the electrons in the molecules  
olve in orbits within the molecule, thus making each  
ic field similar to that produced by a single turn of  
rent.

Gases at or near atmospheric pressure are normally  
ave an extremely high insulation resistance. How-  
t a fairly good conductor in a number of ways, viz.,  
it, letting ultra-violet light fall upon a metal plate  
t to the influence of the rays given off by radium,  
a hot piece of metal or by establishing in it a brush  
A gas rendered conducting in any of these ways is

theory the conductivity thus given to a gas is attributed  
of the molecules of the gas into positive and negative  
observed facts it is necessary to assume that, at  
by barometer, the electrons and positive ions thus  
molecules to themselves just as an electrified rod  
ce the force of attraction is independent of the sign  
vely and negatively charged particles thus produced  
same manner. In gases at low pressures, however,  
ion, would rarely come within attracting distance of  
id collect molecules about itself a *collision* with a

bly has the same effect but the ion ver; soon reforms  
e of molecules in its vicinity.

ion. — The electron theory assumes that at least  
charged particles or electrons with one or more  
every substance. The fewer these free ions, the  
rties of the substance. Under the action of an  
given a velocity which depends upon their mass and  
ey can travel before colliding with other molecules

or ions. In the case of a gas the "mean free path" is relatively large, the greater the less the density.

The ions present in a gas may therefore acquire, under the action of a field, a very considerable velocity. When one of these rapidly moving ions comes very close to a molecule of the gas it exercises a large force of attraction on the electrons in the molecule and may thereby expel one or more from the atom. The electric field therefore causes a large increase in the number of ions present in the gas and consequently the conductivity of the gas is largely increased.

Townsend has explained spark-over in terms of this theory. So long as the current is due only to the free electrons originally present and those created by collision the current for a given voltage cannot continue indefinitely. If the voltage is high enough to give ionizing velocities to the positive ions, the cumulative generation of both positive ions and negative electrons will give an indefinite increase of current, i.e., a spark-over.

Efforts have also been made to explain the arc, but these are not completely satisfying. The hot cathode is essential for the arc, and its temperature is probably due to the bombardment of the positive ions.

**Theory of the Corona.** — (See also article on Corona.) The electric field is strongest at the surface of a transmission wire, and stronger the smaller the radius. Thus with increasing voltage, ionization sets in first at the surface. This results in conductivity of the surrounding air or gas, causing an increase in the effective diameter of the wire to a point where the decreasing field is just balanced by the electric strength of the air. The law of corona formation on a clean round wire in air is, very closely:

$$E = 33 \delta \left( 1 + \frac{0.26}{\sqrt{\delta r}} \right),$$

where  $E$  is the surface electric intensity in kilovolts per cm.,  $\delta$  the relative density of the air, and  $r$  the radius of the wire in cm.

Townsend has given an explanation of the above law in terms of the theory of ionization by collision. Corona is a spark phenomenon. The influence of the radius of the conductor is satisfactorily shown, but the explanation of the influence of the density of the air depends on experiments made at very low pressures and is not so clear. The law of the power loss between transmission lines, due to corona, has not been explained.

The above law of corona formation is obeyed with great constant accuracy when clean round wires are used. This fact, together with the form of the law has led to the suggestion of the use of corona as a standard and a means of measurement of high voltage (*Whithead*).

**Optical Phenomena.** — A number of otherwise obscure optical phenomena are satisfactorily explained in terms of the ionization theory, on the assumption that in general there exist in a given molecule one or more electrical systems of electrons capable of vibrating at different frequencies. In this way it is possible to explain the change of refractive index with the wave length, selective absorption, emission and reflection, the Zeeman effect, the Faraday effect, and other optical phenomena.

**MASS OF THE ELECTRON.** — Since to account for the various facts noted above it is necessary to assume that a moving electron produces a magnetic field (which assumption is in accord with the experimental fact that a moving charged body of finite dimensions produces a magnetic field), it follows that the total energy of motion of an electron is

$$W = \frac{1}{2} m_0 v^2 + W_m.$$

presents the energy which would be required to give it had no electric charge whatever, and  $W_e$  is the energy established by the motion of the charge carried by it. This expression may also be written

$$\frac{1}{2} (m_0 + m_e) v^2,$$

where the quantity  $m_0$  is the ordinary or mechanical mass of the electron, and  $m_e$  is called the "electromagnetic mass" of the electron. However,  $m_e$  is more analogous to the coefficient of self-inductance of a mechanical mass, since it is part of the expression for the energy established by the moving electron.

The total mass of the electron is then

$$m = m_0 + m_e.$$

The "rest" mass that enters into all calculations of  $\frac{e}{m}$  from

is not possible by direct experiment to determine  $m_0$  and  $m_e$  can be calculated in terms of the charge  $e$  and the velocity  $v$ . The assumptions are made regarding the distribution of the charge. Several different formulas have been proposed, based on different assumptions regarding the distribution of the charge. All these formulas are independent of the velocity, and this constant term, *experimental error, is found to be equal to the total mass  $m$*

of the electron. Determinations of the ratio  $\frac{e}{m}$  and the charge  $e$ , pro-

vided the mass of the electron is less than one-tenth that of light (see next section), the mechanical mass  $m_0$  of the electron is negligible, within a small error, compared with the electromagnetic mass  $m_e$ . The formulas are the basis of the assumption, now generally accepted, that the mass of the electron is entirely electromagnetic in origin, i.e., electricity pure and simple. In fact, some physicists claim that all mass is in terms of electricity. A satisfactory theory, however, cannot be developed until the properties of the electron are better understood. See J. J. Thomson, *The Cathode Rays*.

**Mass of the Electron with Velocity.** — When the velocity approaches that of light both theory and experiment show that the electromagnetic mass increases. The formula which best agrees with the facts is that deduced by Lorentz, viz.,

$$m_e = \frac{8.9 \times 10^{-28}}{\sqrt{1 - \left(\frac{v}{V}\right)^2}}$$

where  $v$  is the velocity of the electron and  $V$  the velocity of light. For  $\frac{v}{V}$  less than 0.1, the value for  $m_e$  constant to within an error of 1 per cent of the rest mass of the electron (if there is such) is negligible. The above formula also represents, within the limits of experimental error, the variation of the total effective mass with velocity.

Campbell, N. R., *Modern Electrical Theory*; written in terms of electron theory and sets forth at considerable length all the facts in the case. Thomson, J. J., *Conduction of Electricity through Gases*. Thomson, J. J., *Corpuscular Theory*

*of Matter*; gives an account of the structure of the atom and other matters of similar nature. Rutherford, E., *Radioactivity*; detailed information on active processes; J. T. Townsend, *Ionization of Gases by Collision*; the statement of the theory of ionization by collision; later papers on this subject by the same author; recent work in this field by Paul D. Foote and others in the publications of the National Bureau of Standards. An excellent review of the earlier work on hot cathode tubes is found in Thomson's *Conduction of Electricity through Gases*. The recent work by Langmuir and associates is published in the *Physical Review*, (Vol. 2, p. 450, 1913, and later numbers) and several other prominent scientific journals. The most recent work (1920) on the structure of the atom and kindred topics in the electron theory is A. S. Eddington's *Structure of the Atom*.

**PRECIPITATION OF SUSPENDED PARTICLES** (*Electricity and Magnetism, Principles of*.) The removal of solid or liquid particles carried in suspension is accomplished by the application of a high potential current to such gases.

Processes embodying this principle have been installed in a large number of installations by the Research City and by the Western Precipitation Company of

The essential elements of an electrical precipitator are two sets of electrodes, one set, known as the discharge electrodes, are of such form as to project from their surface, as for instance a wire or a light rod, having relatively sharp edges, while the other set, known as the collecting electrodes, are of such shape as to present as far as possible a smooth surface, as for instance, a flat plate or a pipe with a smooth surface. These electrodes are so arranged in the precipitator that they oppose each other and between them a silent or glow discharge is maintained by supplying to the discharge electrode electrical energy at a relatively high voltage.

The discharge electrodes are grounded for reasons of convenience. The frame of precipitator, for example, consists of a grounded metal structure of which is placed a wire connected to a source of electrical direct power.

The suspended liquid or solid particles which are present between the discharge and collecting electrodes. During the passage of suspended matter are charged and are driven away from the discharge electrode over to the collecting electrodes upon which they are deposited. Other gases are unaffected and pass on out of the precipitator.

The most effective precipitating action is obtained when the potential difference between the electrodes is sufficient to produce a glow discharge between the discharge electrodes (*see Corona*), and when the discharge electrodes are charged negatively rather than positively.

The efficiency of a precipitator depends upon the size and type of electrodes, the gap distance between the discharge and collecting electrodes, the nature and other characteristics of the gas being treated, the velocity of the gases through the precipitator, the length of the path between the electrodes. In other words, the efficiency depends upon the influence of the electric field for a suitable period of time upon the satisfactory removal of these particles from the gases. The efficiency depends to a considerable extent upon the character of the particles precipitated. If the particles are fluffy in character, light in weight, and of a sticky nature, a longer time will be required than if they are relatively heavy and of a liquid or sticky nature.

The electrodes are usually made of metal pipes ranging from 2 to 4 inches in diameter and from 6 to 15 feet in length, and gas velocities from 10 to 20 feet per second.

If the collected material is liquid in nature it will be removed from the collecting electrodes and will drop into a suitable hopper or tank beneath the precipitator. In such cases the cleaning is accomplished by the action of gravity. If the collected material is dry or at all sticky in nature it is necessary to dislodge it from the collecting electrodes by means of a mechanical cleaning device. Usually the cleaning is accomplished by striking or rapping the electrodes with a hammer, whereupon the material falls into hoppers placed beneath the electrodes.

In some cases it is also necessary to clean the dis-

charge electrodes occasionally, and when such a condition is anticipated is also made for rapping the framework which supports the high to discharge electrodes.

The power consumption of an electrical precipitator is governed by the area of electrodes and their length, type and size, as well as by the character of the gas to be cleaned, as regards temperature, conductivity, etc. The consumption is in no cases excessive and is usually quite small. The consumption of energy is from 1 to 2 kilowatt-hours per 100,000 cu ft of gas.

**Typical Installations.**—The Cottrell Processes are in use for the removal of suspended particles from the gases given off by sintering machines, rotary furnaces, lead and copper converters and blast furnaces, drying, and calcining kilns, electric furnaces, and gas producers. They are also used for cleaning the hot gases from furnaces burning pyrites or other sulphuriferous materials in sulphuric acid manufacturing plants, and for the removal of mist from the gases given off by sulphuric acid concentrators, nitrating pickling vats, etc. They have been applied also for cleaning gases from blast furnaces and the recovery from such gases of potash, manganese and other valuable materials.

At Garfield, Utah, 200,000 cubic feet of gas per minute coming from blast converters are treated for the recovery of material containing lead, bismuth, etc.

At Duluth, Minnesota, 5000 cubic feet per minute of producer gas is treated in a Cottrell precipitator having twenty-five collecting electrode tubes 10 inches in diameter and 12 feet in length, the suspended particles of tar and gases being completely removed so that the gas is readily available for engine use.

At the plant of the Davison Chemical Company at Baltimore, Md., 30,000 cubic feet of gas per minute coming from sulphuric acid concentrators are treated by the Cottrell processes, with the recovery of over 20 tons per day of 40° Bé. sulphuric acid.

At the Washoe smelter of the Anaconda Copper Company, at Anaconda, Montana, Cottrell precipitators are being installed to handle all of the dust going to the main smelter stack, amounting to some 3,000,000 cubic feet per minute. The Cottrell Processes will also be used at this plant for the precipitation and recovery of arsenic from the flue dust recovered in the main precipitation installation.

At the plant of the Security Cement and Lime Company at Hagerstown, Maryland, the gases from four cement kilns are treated, recovering approximately 20 tons per day of dust containing from 8 to 10 per cent water-soluble  $K_2O$ .

At the plant of the International Smelting Company at Miami, Arizona, Cottrell installations are in service collecting and recovering suspended particles from the gases from four Wedge roasters used as driers and from three converters.

**BIBLIOGRAPHY.**—A few recent articles describing the Cottrell Process and its applications are: Schmidt, W. A., *Trans. Am. Inst. Chem. Eng.*, p. 35, 1915; Cottrell, F. G., *Eng. and Min. **ICAL.** — (See also *Electrochemistry, Principles of* and *Heat Effects*.) An element is a substance which cannot be broken up into simpler substances by any known means of chemistry. At the present time about 100 elements (including the noble gases) have been discovered. Recent investigations in radio-chemistry have shown that substances now regarded as stable elements may be transformed into other elements, the rate of which is, however, too slow to be observed by ordinary means. In the case of other highly radioactive elements transformation is relatively great; thus it has been found that an element resulting from the disintegration of a radioactive element formed in the process of its breaking up has a half-life which varies from a few minutes to many

years. Elements always combine in definite proportions (or simple proportions). It is possible to assign to each element a relative atomic weight (by mass) in which two or more elements combine in simple multiples of these numbers. The minimum atomic weight has been chosen as 16, for certain practical purposes, this standard the smallest combining weights of the elements have been determined by experiment. The numbers thus obtained are called the relative atomic weights. Formerly hydrogen was taken as unity, in which case the atomic weight of oxygen was 15.98. On the atomic theory the atomic weights are the relative masses of the atoms. The values of the atomic weights of the elements as determined in 1921 by the International Committee on Atomic Weights are given in the following table.

The most important relation between the atomic weights of the elements is that of Mendelejeff and Lothar Meyer and is known as the periodic law. It states that "the properties of the chemical elements are periodic functions of their atomic weights." Thus the elements may be arranged in a table in which their atomic weights in groups or families in which their chemical and physical properties of the elements are related. The discovery of several elements have been predicted by the periodic law.

Recent investigations on the X-ray spectra of the elements have shown that the atomic numbers may be assigned to them which are of more importance than their atomic weights. These numbers are determined by the number of electrons in the atom; the frequency of the lines in the X-ray spectrum of an element is determined by them. See Rutherford and Harkins.

**TRIC.** — (See also *Hoists; Motors, Industrial Appli-*  
 be divided in two general classes, freight and passen-  
 divided into (1) slow-speed elevators (75 feet per  
 duty elevators and (3) high-speed (250 feet per  
 handling elevators provided with accurate means for  
 date wheeled vehicles. The latter may be divided  
 per minute and less), which requires rapid rates of  
 landing; and high-speed express (600 feet per minute  
 smooth acceleration and efficient landing. These  
 s must be operated as local elevators for a few floors  
 and are often of the two-speed type.

The horse-power of an elevator motor depends on the  
 of travel and the elevator efficiency, that is, the com-  
 er, and the gear and the drive. It is customary to counter-  
 cage, and if it is under or overbalanced this amount  
 d from the live load to get the actual load.

$$\frac{\text{Load in lb.} \times (\text{Speed of elevator in ft. per min.})}{33,000 \times (\text{Efficiency})}$$

generally used in problems of this kind.

ent the motors are generally rated on the basis of  
 or one-half hour. The starting torque should be from  
 que.

**Alternating-current Systems** are both in general use  
 c. systems the induction motor, either of the squirrel-  
 is used. These motors may be either single-speed,  
 upon the kind of service.

**Freight Elevators**, single-speed motors of either  
 compound wound direct-current motor whose series  
 fully up to speed, or the single-speed squirrel-cage  
 single-speed slip-ring induction motor. Squirrel-cage  
 sometimes not permitted on power systems, which lack  
 ally permitted up to 25 h.p.

**Material-handling Elevators**, which are intended  
 it is necessary to provide an extremely positive and  
 ding, and for this purpose the adjustable-speed direct-  
 ith dynamic braking control is suited.

**Passenger Elevators** for 450 feet per minute and less  
 of about 150 feet per minute and require extremely  
 eleration. For this purpose the single speed, a-c. or  
 to about 150 feet per minute. Between 150 and 450  
 stable speed motor in either a-c. or d-c. is necessary.  
 ith direct current, the direct-coupled motor is some-  
 ing current the geared motor is necessary in all speeds.

**Express Passenger Elevators**, the direct-coupled,  
 d exclusively at present. This motor is direct-coupled  
 ns at 60 revolutions per minute. Its speed is con-  
 ns at 45 revolutions per minute and below this by  
 o about 15 revolutions per minute. Sometimes this  
 necting its armature to a multi-voltage supply system  
 lts.

must fulfill the most exacting service requirements

They must insure a smooth acceleration, afford positive speed control under widely varying loads, bring the elevator quickly, but smoothly, to a stop from high to low speeds, regardless of load. Accurate stops at the top and bottom must be made and devices should be provided to protect against slacking, overtravel, overloads, failure of voltage, etc. Controllers may be of the magnet type, the semi-magnet type or the mechanically operated type. In speed passenger elevators running from about 100 to 600 feet per minute, practically always installed with full-magnet controllers.

**Direct-current Control Equipment.** — With a direct-current controller the car is started by moving the car switch or car-controller handle to the full on position. This releases the solenoid brake, after which the motor starts with full field strength and with resistance in the armature circuit. After the motor has started, the contactors on the contactor panel automatically cut out the dynamic brake resistance, the armature resistance and the series field (if used), when the motor reaches its normal speed. Current relays are provided to limit the current taken during the acceleration to a predetermined value. An overcurrent circuit breaker is provided which opens the circuit, while running, in case an abnormal current would tend to flow. This overload circuit breaker is interlocked with the car switch in such a way that should the motor be stopped by the action of the circuit breaker relay, this can be reset from the car by moving the control lever to the off position. The control equipment is arranged to give two speeds — one, a range of from rest up to the normal speed of the motor, secured by cutting out the armature resistance step by step; the other, a higher range, up to twice normal speed, secured by inserting resistance in the shunt field of the motor.

In stopping, the controller handle can be brought back to the second point, giving half speed, and then to the first point, which introduces the dynamic brake in series with the armature and shunts the armature with the dynamic brake resistance which is relatively low. In this way it is possible to give a stopping speed of about 25 per cent of the normal speed and which does not vary much with the load in the car. Moving the control handle to the off position stops the car. It causes the motor to be disconnected from the circuit at the same time applying the solenoid brake, which is actuated by a spring over the motor. The coil of the dynamic brake is connected to the motor armature so that the circuit is kept closed in stopping until the motor comes practically to rest. The braking effect of the current generated in this local circuit is available to assist the mechanical brake.

Limit switches actuated by the elevator winding drum are provided to stop the elevator at predetermined limits of travel. In addition to these, overtravel switches are also ordinarily provided in the elevator hatchway as a precaution. These switches are arranged to open the control circuit in case of overtravel of the car. The first-named switches are generally connected so that, after the car has been automatically stopped at either limit of travel, it is possible for the operator to start the car in the reverse direction only. When the overtravel-way-limit switches open, it is, however, generally impossible for the operator to reverse the car without first going to the elevator machine, thus insuring against a further increase in the slack to the cause which made it necessary for the hatchway-limit switches to stop the car.

An auxiliary switch which will automatically stop the motor in case the cable slackens from any cause, such as the breaking of the cable or the catching of the cable in the cage, is also generally provided. It is mounted on one side of the winding drum and operated by a cross arm extending across the drum. Should the cable become slack the movement of the cross arm will serve to trip the switch, cutting out the control system and stopping the elevator. The slack-cable switch

after having tripped out must be reset by hand thus to go to the source of trouble before the elevator can

**Control Equipment.** — As with the direct-current types of controllers made for the alternating-current are those known as the full-magnet controllers, which are controlled from a car switch in the same manner.

All controllers should be protected by a relay which opens the line when the phase rotation in the supply circuit for other reasons, reversed.

Direct-current motors are preferably not to be used for elevators. For higher elevator speeds the two-speed motor speed corresponding to the slowest motor speed is 150 or 200 feet per minute.

Control equipment generally comprises a combination of one or more limit switches, a slack cable switch and a solenoid brake is designed to be connected directly to the circuit to the motor is closed the solenoid is energized. Upon the opening of the main-line circuit, the solenoid is deenergized and the brake is instantly applied. The solenoid is so arranged as to permit of a gradual rather than an instantaneous stop to avoid jarring the car by stopping it too suddenly. This is accomplished by a number of alternating-current relays connected in series as to cut a section out of each of the three phases simultaneously, and also to change the pole connections so that the rate of acceleration or retardation being governed by time limit relays.

— In all elevators, particularly in those electrically operated, the power consumption increases in proportion to the number of starts and stops. The result of the use of the electric motor, in which the energy is required for the process of acceleration, the next process is mechanical retardation, and a lesser amount for the deceleration. A small proportion devoted to the continuous excitation of the motor. Therefore follows that in this form of elevator, which is the most common, the part of the consumption of power is directly related to the number of starts and stops which result from the number of persons in the car. Results which have been reported from time to time show that the power consumption by electrical elevators may therefore be attributed to these conditions. The results of a series of tests made upon one traction elevator in a ten-story building as reported in the *Transactions of the American Society of Mechanical Engineers*, 1910 are given in the table on the following page.

**HOW TO SPECIFY FOR ELECTRIC ELEVATORS.** — The following are the items to assist in writing specifications. See also article on "Elevators."

1. Location of elevator is to be situated. Purpose, i.e., whether for passenger or freight. Characteristics of current supply. Length of run. Full running speed and number of feet traveled. Degree of noiselessness outside of spaces occupied by machinery. Cost per car mile. (This is often supplied by bidder for comparison.)

2. Hoisting machinery. Who supplies supports and framing. Material of drum and shaft materials, and minimum diameter.

**ENERGY CONSUMED BY AN ELECTRIC ELEVATOR AT VARIOUS LOADS AND STOPS**

**Machine: One-to-one Electric Traction.**

**Total Weight of Car: 3956 pounds; Overbalance: 1060 pounds.**

**Capacity: 2500 pounds at a speed of 500 feet per minute.**

(Drums are usually of gray cast iron and shaft of forged open-hearth steel. Worm and gear details. The worm shall be of open-hearth steel and the gear of phosphor bronze. Motor details (*see articles on Motors.*) Method of mounting of up thrust of shaft and drum. Details of brake.

**Safety Devices.**—(a) Centrifugal governor: When the speed exceeds a certain amount, the car shall be gradually retarded. (b) Machine governor: When the speed of car reaches a certain amount, greater than that at which the centrifugal governor acts, and less than that required to throw the safety clutches out of gear, the circuit breaker shall open. (c) Limit stops, upper and lower: When the car approaches the limits, the controller circuit shall be automatically opened, and the brake applied. (d) Circuit-breaker details.

**Cables.**—Description, diameter and minimum number. The number of cables shall be sufficient to prevent any slipping of the cables on the drum when the car is operated under maximum load and contract speed.

**Switchboard and Wiring.**—Details of switchboard. Details of wiring of cable, which should be extra flexible and insulated with the best quality of rubber.

**Shaft Equipment.**—Description of shaftway inclosures, with details of

ion; whether elevator contractor will find it ready, machinery may be installed below the pit. Penthouse whether elevator contractor will find it ready for machinery may be installed outside or above penthouse part of sheaves, guides, governors, bumpers, etc. Whether to be supplied by elevator contractor. Counterweights, description; the material of shaftway fittings, including supports, oil buffers, material of sheaves (usually tough grey cast iron), guide rails. The guide rails are usually steel tees of a certain size. Details of their attachment to the shaft structure and counterweight details.

Position, including statement of sides where door or window cutch, details. Slack-cable device, details. Counterweight attached to bottom of car to compensate for weight of counterweight.

Protection, fireproofing, floor details, including finish of floor, lighting, emergency door, etc. There shall be no such safety devices operate. Operating equipment, including emergency switch, lighting switch, safety lever, annunciator system, etc.

Control mechanism, description. Number of speeds by means of release of lever. Controller shall be out of way of car operator to keep one hand on the gate while the other hand shall be made to operate the car from the switch-stand located from within. If the operator reverses while the car is in motion, the change of direction shall be gradual and without shock. All starting operations shall be accomplished by controller: including starting and reverse motor without destructible arcing at the brushes.

(b) Give easy acceleration of car independently of starting without shock or jar. (c) Lift brake, cut out and operate fields by successive steps in starting. (d) Insert special field resistance in series with armature in order to retardation of the car prior to the pressure of the car on the alley. (e) Other control will be considered.

**System.**—Details of signaling system. Signals shall indicate position of the car whatever the motions of the car. Signals shall give the operator in the car a clear signal as to whether passengers want to go up or down.

**Tests of test.** Instruction by contractor in use of the operation of the cars in the shaft and before its final installation shall install on the cars a 6-inch gong, which will ring up and down the shaft as a warning signal. Lubrication. Tools to be supplied.

**ENDOSMOSE OR ELECTRIC OSMOSIS.** — (See also *Electricity, Principles of*.) If a current is passed along a film of water insulating surface, the water will be attracted to the negative. Similarly an electric current flowing through a porous partition, or opening, filled with conducting liquid, causes a flow of the liquid to the partition or opening. This phenomenon is known as endosmose or osmosis. While various physicists have offered explanations of this phenomenon, none have received general acceptance.

The quantity of a given liquid which is carried through a given diaphragm in a definite time varies directly with the current strength and is independent of the area and thickness of the diaphragm. The quantity varies also with the nature of the solution, being greater with liquids of high specific gravity and high specific capacity. The direction of flow is generally from the positive to the negative electrode, but under certain conditions the flow may be in the opposite direction.

**Applications of Endosmose.** — Endosmose may be utilized to draw water from wet substances. Thus if a wooden box be equipped with perforated metallic plates at opposite ends and be filled with wet turf, the current circulated through the turf from one end to the other, water will flow out of the perforations of the cathode plate. Endosmose is utilized in tanning processes to accelerate the passage of tanning fluids through hides, and efforts are being made to utilize it for drying peat, extracting oils, and similar purposes.

**Endosmose of Negative Feeders.** — If electric conductors covered with saturated braid or a number of such braids be made the cathode of a battery and say 110 volts applied between anode and cathode, the braid will be saturated in a few minutes and the blisters will finally burst, grounding the conductors to the water. The same action goes on at lower voltages at a proportionally lower rate, but with equal certainty. No action is observable if the wire be made the anode instead of the cathode. The same phenomenon is said to be observable with rubber insulation, but the writer has tried several samples of American compounds made with 30 per cent of Para rubber and observed no signs of endosmose after subjecting them for a week to a pressure of 100 volts. C. H. Wordingham (*Elec. Engineer, London, Vol. 26, 1900, p. 100*) has shown, however, that certain makes of rubber insulation are porous and will eventually destroy the whole of the rubber on the negative conductors. For this reason insulation of low specific resistance should not be used on negative feeders. For the same reason it is not practicable to use a negative contact rail on electric railways, below earth potential, as the insulators soon become saturated with moisture and thereby become conductors. Thus S. B. Fortenbaugh, relating the experience of the London and North Western Railway in London, says:

1. That the difference of potential between the positive conductor and the negative conductor is always normally considerably greater than the potential existing between the negative conductor and earth.

2. That a reversal of polarity is always instantly accompanied by a considerable increase in the normal leakage current between the positive and negative conductors.

3. The insulation of the negative conductor to earth cannot be maintained.

**Effect of Endosmose on Insulation Measurements.** — When wires having insulation of low specific resistance, endosmose may furnish a low resistance if the wire is negative to the water bath.

rs, Horace G., and Walter, C. H., *Electrolytic Soc.*, 1914, Vol. 36, p. 2284; Fortenbaugh, S. B., *Trans. A.I.E.E.*, Vol. 28, 1908, p. 1215; Gee, *Journ. I.E.E.*, 1908, Vol. 41, p. 425; Le Blanc, *Chemistry*, London, 1907, Chap. VI.

QUADRATIC EQUATION - The solution

$$B = \frac{-A \pm \sqrt{A^2 - 4AC}}{2A}$$

CUBIC EQUATION - The solution of the form

$$x^3 + px + q = 0$$

$$x = \sqrt[3]{-\frac{q}{2} + \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}} + \sqrt[3]{-\frac{q}{2} - \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}}$$

The solution of the cubic equation is given by the above formula. The discriminant is given by  $\Delta = \frac{27}{4}q^2 + p^3$ . If  $\Delta > 0$ , there are three real roots. If  $\Delta = 0$ , there are two real roots and one complex root. If  $\Delta < 0$ , there are three complex roots.

$$\frac{d}{dx} \left[ \frac{1}{x^2} \right] = -\frac{2}{x^3}$$

$$\frac{d}{dx} \left[ \frac{1}{x^3} \right] = -\frac{3}{x^4}$$

$$\frac{d}{dx} \left[ \frac{1}{x^4} \right] = -\frac{4}{x^5}$$

The above formulas show that the derivative of  $x^{-n}$  is  $-nx^{-n-1}$ .

$$\frac{d}{dx} \left[ \frac{1}{x^n} \right] = -\frac{n}{x^{n+1}}$$

For example, if  $n=2$ , then  $\frac{d}{dx} \left[ \frac{1}{x^2} \right] = -\frac{2}{x^3}$ .

$$\frac{d}{dx} \left[ \frac{1}{x^3} \right] = -\frac{3}{x^4}$$

**EQUATIONS.** — (See also *Complex Numbers; Errors of Observations; Risks; Vectors.*) The subjects treated in this article are

Quadratic Equation  
 Cubic Equation  
 Simultaneous Equations  
 Determinants for solving simultaneous equations  
 Equations of Common Curves  
 Differential Equations

**QUADRATIC EQUATION.** — The solution of

$$ax^2 + bx + c = 0$$

$$\text{is } x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} = -\frac{b}{2a} \left[ 1 \pm \sqrt{1 - \frac{4ac}{b^2}} \right]$$

**CUBIC EQUATION.** — The solution of the general cubic equation form

$$ax^3 + 3bx^2 + 3cx + d = 0$$

is obtained as follows: Put

$$y = ax + b$$

$$H = b^2 - ac$$

$$G = a^2d - 3abc + 2b^3$$

then (1) becomes

$$y^3 - 3Hy + G = 0.$$

The nature of the roots of this equation depends upon the algebraic sign and the relative numerical magnitudes of  $G$  and  $H$ .

*Case I.*  $H$  positive and  $G$  numerically less than  $2H\sqrt{H}$ . ( $G$  either positive or negative.) Put

$$\phi = \frac{1}{3} \sin^{-1} \left[ \frac{G}{2H\sqrt{H}} \right]$$

then the three roots of (2) are

$$y_1 = 2\sqrt{H} \sin \phi$$

$$y_2 = 2\sqrt{H} \sin (\phi + 120)$$

$$y_3 = 2\sqrt{H} \sin (\phi - 120)$$

and all three roots are real.

*Case II.*  $H$  positive and  $G$  numerically greater than  $2H\sqrt{H}$ . Put

$$u = \frac{1}{3} \cosh^{-1} \left[ \frac{\pm G}{2H\sqrt{H}} \right]$$

the plus sign to be used when  $G$  is positive, the negative sign when  $G$  is negative, thus making  $\cosh 3u$  positive in either case.

Then the three roots of (2) are

$$y_1 = \mp 2\sqrt{H} \cosh u$$

$$y_2 = \pm \sqrt{H} \cosh u + \sqrt{-3H} \sinh u$$

$$y_3 = \pm \sqrt{H} \cosh u - \sqrt{-3H} \sinh u$$

ed when  $G$  is positive, the lower when  $G$  is negative.  
 e is real, the other two being complex quantities. See  
*Statistics and Hyperbolic Functions.*

and  $G$  any value. Put

$$u = \frac{1}{3} \sinh^{-1} \left[ \frac{\mp G}{2H\sqrt{-H}} \right]$$

used when  $G$  is positive, the positive sign when  $G$  is  
 h  $\frac{1}{3}u$  positive in either case. Then the three roots of

$$\begin{aligned} &= \mp 2\sqrt{-H} \sinh u \\ &= \pm \sqrt{-H} \sinh u + \sqrt{3H} \cosh u \\ &= \pm \sqrt{-H} \sinh u - \sqrt{3H} \cosh u \end{aligned} \quad (5)$$

when  $G$  is positive, the lower sign when  $G$  is negative.  
 is real, the other two complex quantities.

the sum of the three roots is zero. Also, in the special  
 the angle  $\phi$  is  $30^\circ$ , and therefore from (3) the three  
 $-2\sqrt{H}$ ; this also follows from (4).

$$y^3 - 6y + 2 = 0.$$

$G = 2$  and is less than  $2H\sqrt{H}$ .

$$\phi = \frac{1}{3} \sin^{-1} \left[ \frac{2}{4\sqrt{2}} \right] = 6.90^\circ$$

$$y_1 = 0.3399; y_2 = 2.2618; y_3 = -2.6018.$$

$$y^3 - 3y + 4 = 0.$$

$G = 4$  and is greater than  $2H\sqrt{H}$ .

$$u = \frac{1}{3} \cosh^{-1} 2 = 0.439$$

$$y_1 = 1.098 + 0.785\sqrt{-1}; y_2 = 1.098 - 0.785\sqrt{-1}.$$

$$y^3 + 6y + 2 = 0.$$

$G = -2$  and  $G = 2$

$$\phi = \frac{1}{3} \sinh^{-1} \frac{-2}{-4\sqrt{2}} = 0.1155$$

$$y_1 = -0.3275$$

$$y_2 = 0.1638 + 2.467\sqrt{-1}$$

$$y_3 = 0.1638 - 2.467\sqrt{-1}$$

**EQUATIONS.**—Given  $n$  independent equations in  
 equations fix the values of each of the  $n$  unknowns.  
 simultaneous equations in  $x, y$  and  $z$ , say, solve each of

the three equations for  $x$  in terms of  $y$  and  $z$ . Equating these three for  $x$  gives two equations in  $y$  and  $z$ . Solving each of these two equations for  $y$  in terms of  $z$  and equating these two values of  $y$  gives a single equation. The solution of this last equation then gives the value of  $z$ . Then substitute this value of  $z$  in either of the equations in  $y$  and  $z$ , and solve for  $y$ . Then substitute these values of  $y$  and  $z$  in any one of the original equations for  $x$ .

**Determinants.**— In the case of linear simultaneous equations (if  $x$ ,  $y$  and  $z$  occur only to the first power), the equations may be solved by determinants. This method is a considerable time saver when the number of knowns is greater than three, but when the number of unknowns is less the straight substitution method is preferable.

The determinant of a set of simultaneous equations is formed by placing the coefficients of the unknowns one below the other with the same unknown in the same position in each. The block of numbers forming the coefficients of the unknowns is called the determinant. For example, the determinant of the equations

$$w + x + y + z = 6$$

$$w + \quad \quad y + 3z = 4$$

$$w + 2z + 3y = 1$$

$$w + 3z + \quad \quad z = 3$$

is

$$D = \begin{vmatrix} 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 3 \\ 1 & 2 & 3 & 0 \\ 1 & 3 & 0 & 1 \end{vmatrix}$$

The values of any one of the unknowns, say  $y$ , is found by writing a determinant,  $D_y$ , exactly like the determinant  $D$ , except that the constant terms on the right-hand members of these equations are substituted for the coefficients of  $y$  in the determinant, that is

$$D_y = \begin{vmatrix} 1 & 1 & 6 & 1 \\ 1 & 0 & 4 & 3 \\ 1 & 2 & 1 & 0 \\ 1 & 3 & 3 & 1 \end{vmatrix}$$

Then

$$y = \frac{D_y}{D}$$

and similarly for the other unknowns.

The value of any determinant is found by making use of the following:

- (1) If a determinant has two equal rows or columns, it is equal to zero.
- (2) To any row or column one may add or subtract any number of times any other row or column without altering the value of the determinant.
- (3) To multiply any row or column by a number is the same as multiplying the determinant by that number.
- (4) If all the terms in a row or column except one are zero, the determinant reduces to one of a lower order which may be obtained by striking out that row and column which intersect at the term in question, and multiplying the result by that term, changing the sign of this term, however, if it is removed from an odd number of terms from the principal diagonal. The principal diagonal

at the upper left-hand corner and ending at the  
us,

$$\begin{vmatrix} 2 & 8 & 5 \\ 4 & 6 & 9 \\ 3 & 0 & 0 \\ 7 & 4 & 3 \end{vmatrix} = -3 \begin{vmatrix} 1 & 8 & 5 \\ 3 & 6 & 9 \\ 6 & 4 & 3 \end{vmatrix}$$

at with the figures 1, 4, 0 and 3. It is immaterial  
diagonal is counted along a row or a column.  
nant of the second order is

$$\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} = a_1 b_2 - a_2 b_1$$

nts is effected by altering the terms according to  
r column is obtained in which all terms but one  
action of order to be effected in accordance with  
ued until one of the second order is obtained.

(2), the determinant  $D$  given above may be  
w being subtracted from each of the others.

$$\begin{vmatrix} 1 & 1 & 1 & 1 \\ 0 & -1 & 0 & 2 \\ 0 & 1 & 2 & -1 \\ 0 & 2 & -1 & 0 \end{vmatrix}$$

$$\begin{vmatrix} -1 & 0 & 2 \\ 1 & 2 & -1 \\ 2 & -1 & 0 \end{vmatrix}$$

$$\begin{vmatrix} -2 & 0 & 4 \\ 2 & 4 & -2 \\ 2 & -1 & 0 \end{vmatrix}$$

w to each of the others, this reduces to

$$\begin{vmatrix} -2 & 0 & 4 \\ 0 & 4 & 2 \\ 0 & -1 & 4 \end{vmatrix}$$

$$\begin{vmatrix} -2 & 4 & 2 \\ \times 2 & -1 & 4 \end{vmatrix}$$

$$= -\frac{1}{2}(4 \times 4 + 1 \times 2) = -9.$$

$$= 27$$

$$= -2\frac{1}{3} = -2.333.$$

$$3, s = -2.667, s = -2.333.$$

## EQUATIONS OF COMMON CURVES.

Straight Line. —

$$\frac{x}{a} + \frac{y}{b} = 1$$

or

$$y = x \tan \theta + b.$$

Circle. —

$$x^2 + y^2 = R^2.$$

Ellipse. —

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1.$$

Parabola (Vertical). —

$$y = kx^2$$

where  $k$  is a constant.

Parabola (Horizontal). —

$$y = k\sqrt{x}$$

where  $k$  is a constant.

Hyperbola. —

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1 \text{ (Horizontal).}$$

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = -1 \text{ (Vertical).}$$

bilateral

 $ax - 1$ 

the length of arc

s).

trigonic Functions.

+  $\theta$ ).

ATIONS. — Differential equations of the following  
 eory of alternating and transient currents.

used:  $e = 2.7183 \dots$  = base of natural system  
 riables.  $A, \phi, \gamma,$  and  $\theta$  are integration constants.  
 n constants.

$$\frac{dy}{dx} = ay. \quad (1)$$

$$y = Ae^{ax}.$$

$$\frac{dy}{dx} + ay = 0. \quad (2)$$

$$y = Ae^{-ax}.$$

$$\frac{dy}{dx} + ay = b. \quad (3)$$

$$y = \frac{b}{a} [1 - Ae^{-ax}].$$

$$\frac{d^2y}{dx^2} = -a^2y. \quad (4)$$

$$y = A \sin(ax + \phi).$$

$$\frac{d^2y}{dx^2} = a^2y. \quad (5)$$

$$y = A \sinh(ax + \phi).$$

$$\frac{d^2y}{dx^2} + 2u \frac{dy}{dx} + (u^2 + a^2)y = 0.$$

Solution:

Case I.  $a^2$  positive:—  $y = Ae^{-ux} \sin(ax + \phi)$ .  
 Case II.  $a^2$  negative:—  $y = Ae^{-ux} \sinh(as + \phi)$ .  
 Case III.  $a^2 = 0$ :—  $y = A(x + \phi)e^{-ux}$ .

$$\frac{d^2y}{dx^2} + 2u \frac{dy}{dx} + (u^2 + a^2)y = B \sin(\omega x + \theta).$$

The complete solution of this equation consists of the solution of N the term

$$\left( \frac{B \sin \delta}{2u\omega} \right) \sin(\omega x + \theta - \delta),$$

where

$$\delta = \tan^{-1} \frac{2u\omega}{a^2 + u^2 - \omega^2}.$$

For each additional algebraic term added to the right-hand member of the equation, there will be a corresponding term of the same form as (8) in the

$$\frac{d^ny}{dx^n} + a_{n-1} \frac{d^{n-1}y}{dx^{n-1}} + \dots + a_1 \frac{dy}{dx} + a_0 y = B \sin(\omega x + \theta).$$

Solution:

$$y = A_1 e^{m_1 x} + A_2 e^{m_2 x} + \dots + A_n e^{m_n x} + KB \sin(\omega x + \theta + \delta),$$

where  $m_1, m_2, \dots$  are the  $n$  roots of the equation

$$x^n + a_{n-1} x^{n-1} + \dots + a_1 x + a_0 = 0,$$

and  $K$  and  $\delta$  are found by substituting the  $KB \sin(\omega x + \theta + \delta)$  by its given differential equation and equating the coefficients of  $\sin(\omega x + \theta)$  and  $\cos(\omega x + \theta)$  respectively on the two sides of the resulting equation. The second member of the differential equation is a constant,  $B$ , the sine the solution becomes simply  $\frac{B}{a_0}$ .

Note that all of the preceding equations are merely special cases of the equation (8).

$$\frac{d^2y}{dx^2} + 2u \frac{dy}{dx} + (u^2 - e^2)y = \frac{1}{c^2} \frac{d^2y}{ds^2}.$$

The complete solution of this equation contains an infinite number of the form

$$y = e^{-(u-e)s} [A_1 e^{ms} \sin(\omega s + \phi_1) + A_2 e^{-ms} \sin(\omega s - \phi_2)]$$

where  $A_1, \phi_1, A_2, \phi_2$  and two of the four constants  $\omega, s, m$  and  $u$  are constants (fixed by the terminal conditions). The values of  $m$  and  $s$  of  $\omega$  and  $s$  are

$$m = c \sqrt{ab} \cos \frac{\eta + \epsilon}{2},$$

$$s = c \sqrt{ab} \sin \frac{\eta + \epsilon}{2},$$

$$\epsilon = \tan^{-1} \left( \frac{\omega}{s+q} \right),$$

$$\eta = \tan^{-1} \left( \frac{\omega}{s-q} \right).$$

s of  $m$  and  $n$  are

$$\alpha = \frac{\sqrt{FG}}{c} \cos \frac{\alpha + \beta}{2},$$

$$\beta = \frac{\sqrt{FG}}{c} \sin \frac{\alpha + \beta}{2},$$

$$\alpha = \tan^{-1} \left( \frac{m}{n+cq} \right),$$

$$\beta = \tan^{-1} \left( \frac{m}{n-cq} \right).$$

may also be written as a series of terms of the

$$e^{-(u-s)x} \sin(\omega x + \phi + \mu), \quad (b)$$

$$\cosh 2(ms + \gamma) + \cos 2(ns + \theta),$$

$$\tan(ms + \gamma) \tan(ns + \theta),$$

integration constants, and the relations between the are the same as above.

o, the solution of equation (9) is

$$[f_1(\omega x + ns) + f_2(\omega x - ns)], \quad (c)$$

bitrary functions and  $\omega$  and  $n$  are connected by the

$$\frac{\omega}{n} = \frac{1}{c}.$$

$$\frac{d^2y}{dx^2} + \frac{1}{x} \frac{dy}{dx} = 4a^2y. \quad (10)$$

$$\left[ \frac{(ax)^4}{2^2} + \frac{(ax)^6}{(3!)^2} + \frac{(ax)^8}{(4!)^2} + \dots \right] \quad (a)$$

vergent for all values of  $x$ , but for  $ax > 1$  the is more convenient and sufficiently accurate.

$$\left[ \frac{3^2}{2(16ax)^2} + \frac{3^2 \cdot 5^2}{3!(16ax)^3} + \frac{3^2 \cdot 5^2 \cdot 7^2}{4!(16ax)^4} \right] \quad (b)$$

**ERRORS OF OBSERVATION.** — When a quantity is measured with possible accuracy many times in succession, the numbers expressing the results are found to differ by amounts, which, although generally small, are often considerable in comparison with the quantity measured. Though the errors may be decreased by improved methods, better instruments and greater skill, they can never be entirely removed. They are known as the *errors of observation*. The following formulas, which are derived from the *Method of Least Squares*, apply to such errors and not to errors which can be corrected by correcting mistakes of the observer or defects of instruments or methods of observation. *That is, they apply only to errors which may be either positive or negative, the chance of a positive error occurring being exactly the same as the chance of a negative error occurring.*

**Weighted Observations.** — Sometimes in spite of the care with which observations are taken, there are reasons for believing that some observations are better than others. In this case the observations are given "weights" or numbers expressing their relative practical worth. A *weighted observation* is an observation multiplied by its weight.

**PROBABLE VALUE OF SEVERAL OBSERVATIONS.** — The probable value of a quantity which is observed directly several times with equal care is the arithmetical mean of the measurements.

**Example.** — The length of a room (in feet) is measured ten times with the following results:

20.05	20.06	19.98	19.99	20.00
20.07	20.01	20.05	19.95	19.98

The arithmetical mean of these lengths is 20.01 feet, which is accordingly the probable length of the room.

The most probable value of a quantity which is observed directly several times, but where the observations have different weights, is equal to the sum of the weighted observations divided by the sum of the weights.

**Example.** — In the above example if the fourth and fifth observations are twice as reliable as the others, and the seventh three times as reliable, the most probable value would be the sum of 20.05, 20.06, 19.98, (19.99 × 2), 20.07, (20.01 × 3), 20.05, 19.95 and 19.98, divided by 14, which is equal to 20.01, which happens in this instance to agree with the unweighted average.

**PROBABLE ERROR OF ANY ONE OF SEVERAL OBSERVATIONS.** — The probable error of a number of direct observations made with equal care is found by the following formula:

$$r = 0.6745 \sqrt{\frac{\sum v^2}{n-1}}$$

where

- $n$  = number of observations.
- $r$  = probable error of a single observation.
- $v$  = residual found by subtracting the arithmetical mean from each measurement.

**Example.** — In the example cited above,  $n = 10$ . The values of the order of the observations given above are as follows:

+ 0.04	+ 0.05	- 0.03	- 0.03	- 0.01
+ 0.06	0	+ 0.04	- 0.06	- 0.03

these quantities is 0.0152. The probable error in observations is

$$r = 0.6745 \sqrt{\frac{0.0152}{9}} = 0.0277.$$

Each of a number of direct observations, where the weight, is found by the following formula, in which  $n$  is the number of observations.

$$r = 0.6745 \sqrt{\frac{\sum pv^2}{n-1}}.$$

The example cited above for weighted observations, the values of  $v$  in the preceding example, follows:

0.15	0.0009	0.0008	0.0002
	0.0016	0.0036	0.0009

of a single observation

$$r = 0.6745 \sqrt{\frac{0.0157}{9}} = 0.0282.$$

**OF THE ARITHMETICAL MEAN. — II**

of a single observation,  
 observations,  
 of the arithmetical mean,  
 observations of equal weight, or

of equal weight.

The example cited above for observations of equal weight,

$$r_0 = 0.0277 / \sqrt{10} = 0.0088.$$

For observations of unequal weight,

$$\text{and } r_0 = 0.0282 / \sqrt{14} = 0.0075.$$

the probable error of the mean decreases inversely with the number of observations.

The probable error in making a single reading of a watt-ohmmeter is 5 per cent, after all constant sources of error are considered.

If 25 locomotives are used, what will be the probable error of the mean consumption obtained, by adding the watt-hour consumption of each locomotive per cent?

$$r_0 = \frac{5}{\sqrt{25}} = 1.$$

**OF THE PROBABLE ERROR OF A RESULT CALCULATED FROM THE OBSERVED QUANTITIES. —** Let  $Z$  = a sum of independent quantities.

Let  $r_1, r_2, r_3, \dots$  be the probable errors in these quantities. Then the probable error of the result  $Z$  is

$$\sqrt{r_1^2 + r_2^2 + r_3^2 + \text{etc}}$$

Let  $Z = As$ , where  $s$  is an observed quantity, and  $A$ , a known value, be the probable error in  $s$ . Then the probable error in  $Z$  is  $As$ .

Let  $Z$  be the product of two independently observed quantities whose probable errors are  $r_1$  and  $r_2$  respectively. Then the error in  $Z$  is

$$\sqrt{r_1^2 r_2^2 + r_2^2 r_1^2}.$$

Let  $Z$  be any function of the independently observed quantities  $s_1, s_2, s_3$ , etc. whose probable errors are  $r_1, r_2, r_3$ , etc. Then the probable error in  $Z$  is

$$\sqrt{\left(\frac{dZ}{ds_1}\right)^2 r_1^2 + \left(\frac{dZ}{ds_2}\right)^2 r_2^2 + \left(\frac{dZ}{ds_3}\right)^2 r_3^2 + \text{etc.}}$$

**METHOD OF LEAST SQUARES.**—A set of simultaneous containing more equations than unknowns cannot have any exact solution; the superfluous equations are deducible from the others. They may, however, have a most probable solution which is such that the sum of the squares of the errors after corrections for the deduced values of the unknowns shall be a minimum. This result is obtained as shown in the following example:

$$\begin{aligned} s - t + 2u &= 3, \\ 3s + 2t - 5u &= 5, \\ 4s + t + 4u &= 21, \\ -s + 3t + 3u &= 14. \end{aligned}$$

The coefficients of  $s$  are 1, 3, 4 and  $-1$ . Multiplying by these coefficients

$$\begin{aligned} s - t + 2u &= 3, \\ 9s + 6t - 15u &= 15, \\ 16s + 4t + 16u &= 84, \\ s - 3t - 3u &= -14. \end{aligned}$$

Add these equations and obtain  $27s + 6t = 88$ .

The coefficients of  $t$  are  $-1, 2, 1$  and  $3$ . Multiply the original equations by these coefficients.

$$\begin{aligned} -s + t - 2u &= -3, \\ 6s + 4t - 10u &= 10, \\ 4s + t + 4u &= 21, \\ -3s + 9t + 9u &= 42. \end{aligned}$$

Add these equations and obtain  $6s + 15t + 9u = 70$ .

The coefficients of  $u$  are 2,  $-5, 4$  and  $3$ . Multiply the original equations by these coefficients.

$$\begin{aligned} 2s - 2t + 4u &= 6, \\ -15s - 10t + 25u &= -25, \\ 16s + 4t + 16u &= 84, \\ -3s + 9t + 9u &= 42. \end{aligned}$$

Add these equations and obtain  $1 + 54u = 107$ .

The equations

$$\begin{aligned} 27s + 6t &= 88, \\ 6s + 15t + 9u &= 70, \\ t + 54u &= 107, \end{aligned}$$

are then solved in the ordinary way, the solution being

$$s = 2.47, \quad t = 3.56, \quad \text{and} \quad u = 1.99.$$

**BIBLIOGRAPHY.**—The subject of error of observation is very fully treated in *A Text Book on the Method of Least Squares*, by Mansfield Merriman.

**DEFINITIONS.** — (See also *Roots and Powers.*) When a variable  $y$  and another variable  $x$  is such that  $y$  is equal to one or more terms,  $y$  is said to be an exponential function. Its importance in connection with electric circuits are  $e^{x^2}$  and  $e^{-x}$ , where  $e$  is the base of the natural logarithm.

From the table of common logarithms (see *Logarithms*)  $e^x$  is equal to the number whose logarithm to the base 10 is exactly  $0.4342945 x$ , which may be written symbolically

$$e^x = \log_{10}^{-1}(0.4343 x).$$

$$e^{-x} = \frac{1}{\log_{10}^{-1}(0.4343 x)}.$$

the value of  $e^{10}$ . We have  $0.4343 \times 10 = 4.343$ .

For larger values of  $x$ , the following table giving the value of  $e^x$  and  $e^{-x}$  is given. For larger values of  $x$  use the above relation for  $x < 0.1$  (see *Series*).

with an error of less than 0.47 per cent,

with an error of less than 0.54 per cent,

$\frac{e^x}{x^2}$  with an error of less than 0.016 per cent,

$\frac{e^x}{x^2}$  with an error of less than 0.018 per cent.

A more complete table is given in the *Smithsonian Mathematical Tables of Hyperbolic Functions (No. 1871)*, by G. F. Becker and C. E. Van Orstrand, Washington, 1909. Semi-exponentials, i.e., values of  $\frac{1}{2}e^x$  and  $\log_{10} \frac{1}{2}e^x$ , are given in *Tables of Complex Hyperbolic and Circular Functions*, by A. E. Kelley, Cambridge, Mass., 1914.

**FACTORIALS.** — The multiple product represented by

$$n(n-1)(n-2)\dots 3 \times 2 \times 1$$

called "*n* factorial," and is represented either by the symbol  $n!$  or  $\underline{n}$ . The following table gives the value of  $n!$  up to  $n = 10$ .

1! = 1.	6! = 720.
2! = 2.	7! = 5040.
3! = 6.	8! = 40320.
4! = 24.	9! = 362880.
5! = 120.	10! = 3628800.

and Compressors; Draft, Mechanical.) For venting and for producing mechanical draft, two kinds of the centrifugal fan.

reversed, that is, driven by power applied to the air in large volume at low pressure, and it is then are in common use for blowing air into or out of ventilation. Usually they consist simply of a rapidly or more nearly flat blades slightly inclined to the shaft; these blades are given various curved forms for increasing efficiency of the fan.

Another form of centrifugal fan is that of a paddle wheel from four to twelve radial arms, to which are attached planes. In modified forms the blades are bent at an angle to the direction of rotation, from an axial fan up to 25 feet diameter and 10 feet width used in mines, and in many cases without an external casing is used, with a tangential discharge outlet, inlets, concentric with the shaft, one on each side. A modification of the centrifugal fan known as the vane fan, the number of blades is increased to from 30 to 40, made relatively very long, axially, and narrow, the width being as much as 9 to 1; they are made slightly tipped forward in the direction of rotation and are in a casing and the radial distance of the vanes from the shaft is increased. The pressure produced by centrifugal fans varies with the speed of the tips of the blades and with the diameter, a maximum commercially of about 1 pound per square foot of centrifugal or multivane fans. Much higher pressures are obtained from special forms of fans built on the principle of the centrifugal fan (see *Blowers and Compressors*).

In the article on *Blowers and Compressors* is given the "work done" by a blowing machine. Since an increase in pressure of more than 1 per cent of normal atmosphere results in a decrease in the volume and static pressure of the air as it is compressed, which is negligible small in comparison with the initial volume and pressure, the theoretical horse power reduces to

$$\frac{1}{33000} \left[ \frac{dQ^3}{2g(60A)^2} + 144 p_s Q \right],$$

where  $d$  is the diameter in inches,  $Q$  is the volume of air in cubic feet per minute,  $p_s$  is the static pressure in pounds per square inch, and  $A$  is the area in square feet.

where  $B$  is the barometric pressure in pounds per square inch and at  $F$  F.,

$A$  is the outlet opening in square feet,  $V_a$  is the velocity in feet per second ( $= 32.2$ ),

$p_s$  is the static pressure in pounds per square inch necessary to

accelerate the air to the velocity  $V_a = \frac{Q}{A}$  feet per minute to the air.

This is called the "velocity" pressure.

Useful or "Air Horse Power" of the fan may then be written

$$P = \frac{(p_v + p_s) Q}{229}$$

The total pressure  $p_v + p_s$  developed by the fan is called the "imparted" or "dynamic" pressure. The pressures developed by a fan are usually expressed in inches of water column; hence putting  $H_v$  and  $H_s$  for the corresponding heights of water column required to balance  $p_v$  and  $p_s$ , the above formulas become

$$H_v = 0.832 \times 10^{-4} \frac{d^2 Q^2}{A^2}$$

$$P = \frac{(H_v + H_s) Q}{6360}$$

When the discharge outlet is restricted (e.g., by partially closing the discharge valve), the cross section  $A$  refers to the area of the discharge pipe between the restriction and the fan, not to the cross section of the restricted opening.

**Actual Horse Power.** — The actual horse power required to drive a fan is equal to the value given by the last formula divided by the efficiency. Fan efficiency depends not only upon the design of the fan, but also upon the relative values of the velocity and static pressures. The maximum efficiency of a centrifugal fan ranges from 40 to 70 per cent. The maximum efficiency of axial fans usually ranges from 30 to 40 per cent. The table below, taken from a paper published by F. R. Still of the American Blower Co., in the *Jour. of the Soc. of Mech. Eng.*, 1902, is fairly representative of the performance of ordinary standard centrifugal fans. For a given type of fan and given ratio of velocity within the casing on the outlet side to the static pressure, there is a definite relation between the linear velocity  $V_a = \frac{Q}{A}$  of the air within the casing on

the outlet side and the peripheral velocity  $V_f$  of the fan; the ratio  $\frac{V_a}{V_f}$ , as given from Still's curves, is also given in the table below.

$\frac{H_v}{H_s}$	Efficiency	$\frac{V_a}{V_f}$	$\frac{H_v}{H_s}$	Efficiency
0.00	0.00	0.00	0.4	0.38
0.05	0.30	0.22	0.5	0.37
0.10	0.43	0.30	1.0	0.53
0.15	0.43	0.35	1.5	0.30
0.20	0.42	0.39	2.0	0.28
0.30	0.41	0.43	$\infty$	0.22

More recent fans of the multivane or "Sirocco" type, when properly proportioned, have given efficiencies of 60 per cent and upwards.

**THE VOLUME OF AIR DISCHARGED** per minute is  $Q = V_a A$ .  $V_a$  is the linear velocity of the air in feet per minute. When the speed is constant and the outlet pipe is partially closed, the linear velocity of the air through the full cross section  $A$  of the outlet decreases and the power

A fan running at constant speed requires maximum outlet is wide open; the volume discharge is also a function of the static head.

A fan running at a given speed the maximum volume it can deliver is roughly  $\frac{1}{3} DWV_f = \frac{\pi}{3} D^2WN$ , where  $D$  is the diameter in feet,  $W$  its width (at periphery) in feet,  $V_f$  the velocity in feet per minute and  $N$  the velocity in revolutions

per minute. The discharge against very low resistances is directly proportional to the area of the circle inclosing the fan and to the number of revolutions per minute. The discharge varies with the form and inclination of the vanes. A flat fan of diameter  $D$  feet will deliver  $Q = KD^3N$  cubic feet per minute. The constant  $K$  ranges from 0.4 to 0.7 (depending on the design) and if the static head is small, the delivery decreasing rapidly as the

**ESTIMATION OF FAN DIMENSIONS.**—The full discharge outlet  $A$  of an ordinary fan is about two-thirds the product of the width  $W$  by the diameter  $D$ , that is  $A = \frac{2}{3} DW$ . The width of the fan ranges from  $0.5D$  to  $0.7D$ . Using the latter figure, we have  $D = \sqrt{3} A$ . From the table given above a rough estimate of the dimensions of the fan may be made. For example, 20,000 cubic feet of air to be discharged against a static head of 1 inch of water. The approximate dimensions and speed of the fan and the horse power required? The size of fan and the speed depend upon the linear velocity of the air through the fan. The smaller the fan and the greater the horse power required. As defined above we have  $Q = 20,000$ ,  $H_s = 1$ , the value of the linear velocity  $V_a$  is 2000 feet per minute.

$V_f = 2.74$ ,  $H_v = 0.255$ ,  $\frac{H_v}{H_s} = 0.255$ ,  $\frac{V_a}{V_f} = 0.41$ ,  $V_f = 4850$  feet per minute,  $H.P. = 9.6$ . That is, the diameter of the fan is 5 feet 6 inches, its width 2 feet 9 inches, its speed 4850 r.p.m. will be required to operate it. If  $V_a$  is taken as 1000 feet per minute the required diameter will be approximately 3 feet 11 inches, its speed 650 r.p.m., and 20 horse power will be required.

The selection of the size of fan is extremely rough at best; the reader is referred to manufacturers' catalogues.

**INDUSTRIAL FANS.**—The following memoranda are intended to guide the selection. See also article on *Blowers* and article on *Centrifugal Pumps*.

1. The purpose and service for which it is to be used. Rating, under specified conditions of test. Whether exhaust or suction fan. Whether fixed or oscillating. Details of motor, speed, frequency, phases and voltage.

2. See also *Motors, Industrial Applications of*. The fan should be as light as possible and unless some sort of shutter is provided will be fully loaded when it comes up to speed. Shut-off starting conditions should be carefully considered. The motor is intended for driving the fan. As the torque required is usually small, a motor with low-resistance starting is preferred, without requiring a very heavy current. To keep the

torque  
starting  
to keep the

current down, however, a low tap on the starting compensator may and an intermediate step may be very desirable.

Fig. 1 shows the starting-torque curve of a shuttered centrifugal fan to full speed, and also a speed-torque and a speed-current curve of a synchronous motor with a squirrel-cage starting winding of fairly low resistance plotted for 50, 70 and 100 per cent of normal voltage. If the motor is started from the 50 per cent tap of the compensator it will bring the fan to about 80 per cent of full speed. If the motor is then thrown over to the full-line voltage it may exert an excessive torque, and the current, as shown by the current curve, will rise to a very high value. If an intermediate tap is provided—say a 70 per cent tap—the torque exerted will be less but still enough to bring the motor to about 95 per cent of synchronous speed and the current will be much less. Application of the field would then pull the machine into step after which it could be thrown over to the line with a very little rush of current. For a variable-speed service the synchronous motor is of course not suitable and a varying-speed brush-shifting motor or a phase-wound induction motor must be used.

For direct-current installations shunt motors are preferred, the speed adjustment being accomplished either by field control, armature control or a combination of the two. Field control is generally used where the motor operates for long intervals at speeds between 50 and 100 per cent of maximum speed; the combination control is used if the motor operates for long intervals at speeds between 75 and 100 per cent of maximum speed, and occasionally required to operate at speeds below 75 per cent; and armature control is used advantageously for motors operating at long intervals near maximum speed but where occasionally a lower speed is required. Ventilating fans are one of the best applications for armature control because the torque and current required decreases with the cube of the speed.

With very large mine fans, having a high inertia, the time required for starting is comparatively long—one minute or more—and this must be taken into account when the starting resistances are selected. Starting resistances for fans driving such large fans should therefore as a rule be of a larger size than is ordinarily the case.

Fig. 1. Curves of Synchronous Motor with Low-resistance Starting

**PURIFIERS AND PURIFIERS.** — (See also *Boilers; Purifiers.*) Impurities in the water supplied to a boiler result in (1) the formation of scale on the heating surface of the boiler, resulting in a decrease in boiler efficiency and consequent overheating and consequent weakening of the boiler; (2) the corrosion and consequent weakening of the boiler; (3) an increase in the amount of suspended moisture in the steam from boiler to engine. Sulphates of lime and silica, iron and aluminum and suspended matter are the most common impurities. Acids, organic matter, magnesium chloride and sodium chloride, while priming is induced by the presence of sodium carbonate and other alkalis.

Impurities in the feed water of various chemicals, as, for example, sulphates, may be changed into harmless substances by the addition of soda ash between the impurities and the "boiler compounds" which cause the adhesion of the scale to the heating surfaces may be prevented by the addition into the feed water or boiler of such substances as sodium carbonate. Suspended matter, such as sand, mud, insoluble organic matter, may be removed by mechanical filtration or by allowing the water to settle in settling tanks. Organic impurities usually float on top of the water and may be skimmed off. In making steam and may be blown out through a steam trap. Precipitated matter may be ejected by frequent blowing down. Scale, when it has once formed, can be removed from the tubes with some form of scraper. Very hard scale may be softened so as to be more easily scraped, by dissolving in the water a quantity, say 50 to 100 pounds, of caustic soda in the boiler at atmospheric pressure for from 12 to 24 hours, or by the addition of magnesia, two of the chief scale-forming impurities, may be precipitated by raising the temperature of the water to its boiling point for a pressure of about 60 pounds absolute).

**PREHEATING FEED WATER.** — Although the heating or settling of the feed water results in the elimination of impurities, the primary object of preheating the feed water is to save fuel consumption. The heat required to raise the temperature of the feed water 11° F. is approximately 1 per cent of the heat required to convert the water into saturated steam at ordinary pressure. By preheating the feed water 11° F. the temperature of the feed water is raised to the saturation temperature, which would otherwise be wasted, a saving of approximately 1 per cent is effected in the amount of coal required. Let  $H$  = heat of the water at the given pressure,  $h_0$  = heat of the water entering the boiler,  $h_1$  = heat of the water leaving the heater, then the saving, expressed as a percentage of that which would be required by a boiler without a super-

$$S = 100 \frac{h - h_0}{H - h_0}$$

The saving may be taken from steam tables (see *Steam*). This saving in fuel, provided the boiler efficiency is the same, is independent of the type of water heater. However, if the boiler is overdriven, the water heater will effect a greater saving than that given by the above, inasmuch as the work to be done by the boiler is reduced the more the feed water is preheated.

**WATER HEATERS.** — The heat used for preheating the feed water may be derived: (1) from the exhaust steam; (2) from the flue

gases, in which case the heater is usually called a "fuel economizer." Live steam taken directly from the boilers, in which case the primary function of the heater is to purify the feed water, and it is therefore usually called a "live-steam purifier." The heat may be transmitted from the steam to the water either (1) by allowing the steam to mingle with the water and give up its heat by condensation, or (2) by passing the water and steam through separate chambers arranged so that the heat is conducted to the water through the walls of the chambers. These two types of heaters are referred to respectively as "open" and "closed" heaters. Closed heaters may be either water-tube or steam-tube type; in the former the steam surrounds the tubes through which the water is passed, while in the latter the steam passes through a set of tubes surrounded by water. A closed heater in which the steam pressure is less than atmospheric is called a "vacuum" or "low-pressure" heater; such heaters are frequently used in the exhaust of condensing engines. "Atmospheric" or "secondary" heaters are those in which the steam pressure is that corresponding to the back pressure of the engines or pumps. A heater in which the steam pressure is the same as that in the boiler is called a "primary" heater.

**Open Heaters.** — The essential parts of an open heater are: (1) a heating coil; (2) a set of trays or pans to catch the scale-forming elements precipitated from the water; (3) a filter to take out suspended impurities; (4) an oil separator to extract the oil from the steam before it enters the superheater.

**Dimensions.** — C. L. Hubbard (*Practical Engineer*, Jan. 1, 1901) gives the following:

Exhaust heaters should be proportioned according to the quality of the water to be used, the size being increased with the amount of mud or scaling properties which the water contains, regardless of the quantity of water to be heated. The general proportions of an open heater will depend upon the arrangement of the trays or pans, but an approximation of the dimensions of shell for a cylindrical heater is as follows:  $A = H + 6L$ ;  $L = H$ , in which  $A$  = sectional area of shell in square feet;  $L$  = length of shell in feet;  $H$  = total weight of water to be heated per hour divided by the weight of steam used per horse power per hour by the engine;  $\phi = 2.15$  for very muddy water, 6.0 for slightly muddy water, and 8.0 for clear water.

The pan or tray surface varies according to the quality of the water, and regards the amount of mud and the scale-making ingredients. The surface in square feet for each 1000 pounds of water heated per hour may be taken as follows, for the vertical and horizontal types respectively:

Very bad water.....	8.5 sq ft
Medium muddy water.....	6 sq ft
Clear and little scale.....	3 sq ft

The space between the pans is made not less than 0.1 of the diameter and 0.25 of the diameter for round pans. Under ordinary circumstances it is not customary to use more than six pans in a tier, in order to obtain a low velocity over each pan. The size of the storage or settling tank in the horizontal type varies from 0.25 to 0.4 of the volume of the shell, depending on the quality of the water; 0.33 is about the average. In the vertical heaters, this varies from 0.4 to 0.6 of the volume of the shell, and occupy from 10 to 15 per cent of the volume of the shell in the horizontal type and from 15 to 20 per cent in the vertical.

**Temperature Elevation of Feed Water.** — Let  $A$  = sq. economizer heating surface per boiler horse power,  $T_1$  = temperature of flue gases entering economizer (ranges from about 450 to 600 degrees F.);  $T_2$  = temperature of flue gases leaving economizer;  $I$  = temperature of feed water entering economizer;  $F$  = temperature of feed water leaving economizer;  $W$  = pounds feed water per boiler horse power hour;  $G$  = pounds flue gas per pound coal;  $C$  = pounds coal per boiler horse power hour;  $S$  = specific heat of flue gases;  $U$  = B.t.u. transmitted per sq. ft. per hr. per deg. difference of temperature between flue gas and water.

$$F - I = \frac{A(T_1 - T_2)}{\frac{W}{U} + \frac{(W + CGS)A}{2CGS}}$$

$A$  varies from 3.5 to 5, and  $U$  from 2.25 to 3.3, depending upon the conditions of operation. Putting  $W = 30$ ,  $S = 0.2$  and  $U = 3.3$ , the above formula reduces to

$$F - I = \frac{A(T_1 - T_2)}{9.1 + \frac{(5W + GC)A}{2GC}}$$

which is the formula advocated by the Green Economizer Co.

**Rating and Cost (Pre-war cost figures).** — The ordinary economizer has from  $\frac{1}{4}$  to  $\frac{1}{2}$  square feet of heating surface for each boiler horsepower. Costs from 75 cents to \$1 per horsepower. Economizers are sometimes made of small diameter tubes, the usual area per tube being 15 square feet. From 3.5 to 5 sq. ft. are usually installed per boiler horsepower. Economizers cost approximately \$1.25 per square foot of heating surface, this figure including erection and setting.

**ELEGRAPH.** — (See also *Telegraph Instruments and Systems; Wiring of Buildings for Miscellaneous Devices.*)  
 A telegraph system is to notify the fire-fighting forces of the existence and location of a fire, and also to communicate between the various branches of the fire-department at a fire or in quarters.

A fire-alarm system is shown in Fig. 1, where several boxes are connected in series in the alarm or "box" circuit extending from headquarters throughout the district covered by the boxes. These boxes are operated by a clockwork mechanism, so that when the box is started by a person sending the alarm, a break wheel, carrying notches

Fig. 1. Fire-Alarm System

of the code number of the box, is caused to revolve, thus making a signal in accordance with the code. These signals are sent to headquarters and by means of a local telegraph system the alarm is given at headquarters. As many gongs as may be desired by the same relay, these being placed in the engine-house or wherever else it is desired to give the alarm.

The placing of a number of boxes on the same circuit is liable to confusion, due to two or more boxes being pulled at once, called "interference." A box which makes no provision for this is called an "interfering box." A common type of box, called a "non-interfering box," is so arranged that if two or more boxes are pulled at once the signal of the first box to be started is not interfered with without interference from the others, but the signals of the other boxes are not transmitted. In a later development, and one that is largely used now, is such that if any number of boxes up to four on the same circuit are simultaneously pulled, no interference and no loss of signals occurs, each box securing possession of the line in succession, and giving their turn, so that the signals of all the boxes will be transmitted without confusion. These are called "non-interference succession."

In fire departments which have a number of engine houses and apparatus houses, it is customary to establish a single fire-alarm headquarters, from which other circuits, called "branch circuits," extend to the apparatus houses. An alarm signal may be transmitted to the gong circuits either man-

**Manual Systems.** — In manual systems the box alarm is received at headquarters and then is set up on a transmitter, which, when started, actually repeats the alarm over the desired gong circuits. The manual operation may consist in placing a disc, notched on its periphery with the desired box number, in the transmitter, and then starting the system, the notches on the disc effecting the desired makes and break gong circuits. This method is employed in the fire-alarm system of the Borough of Manhattan, New York.

Another manual method of transmission is to set up the desired box number on a dial transmitter, which, when set in motion, transmits the alarm to the desired gong circuits. Still another method is to actually re-transmit the box number manually by means of a Morse key.

**Automatic Systems.** — In these the relays at headquarters, when operated by the box circuits, automatically perform the making and breaking of the gong circuits, and thus re-transmit the box alarm to the desired gong circuits. This is advantageous in point of time saving, but has certain objectionable features in removing all discretionary power from the operators at headquarters.

**Confusion in Fire-alarm Nomenclature.** — Considerable confusion exists in the nomenclature of the fire-alarm art in various parts of the country. For instance, the term "automatic system," instead of applying to automatic re-transmission of the alarm at fire headquarters, is frequently applied to those systems where the original alarm is automatically set off by the operation of a thermostat in a building under the influence of un-

**FLYWHEELS FOR LOAD EQUALIZATION.** — (See also *Motors, Industrial Application of; Steel Mills, Electric Drive of.*) The methods in general use for equalizing a fluctuating load, the storage and the flywheel. The former is mostly used in connection with a service where the peaks are of considerable duration and for which a flywheel is entirely unsuitable. For short fluctuating loads, such as service, mine hoists, etc., the flywheel is particularly suitable, and is applied either to the driving motor direct or to an intermediate motor for equalizing set, depending on the operating conditions.

**Selection of Flywheel.** — The problem of selecting a flywheel for service is not an easy one, and each case must be treated separately. The problem is to determine what effect a flywheel will have on smoothing load fluctuations; what effect it will have on the motor and supply whether a flywheel is warranted; and what size flywheel will result in economy.

**Flywheel Effect.** — The effectiveness of a flywheel, rotating at a given number of revolutions per minute, in equalizing the load, depends not only on its weight but also upon the square of its radius of gyration (q.v.). The effect of the weight of a flywheel by the square of its radius of gyration is commonly called the "flywheel effect"; it is proportional to the moment of inertia of the flywheel. A factor which limits the usefulness of a given flywheel is the allowable drop in speed, as the energy which a flywheel is able to give up is proportional to the difference between the squares of the initial and final speeds. Another factor to be considered is the fact that a flywheel is not an inexhaustible source of energy. The time during which it can supply a certain number of horse-power is limited, and it can, with a given drop of speed, only supply a given number of horse-power seconds. A certain flywheel, for example, may easily take care of a load amounting to 100 per cent overload for one second, but it may be inadequate to handle a 50 per cent overload lasting for five seconds.

**Induction Motor with Flywheel.** — Let the motor at any instant develop a torque  $T$ , and let the opposing torque of the load at this instant be  $T_1$ .

Then  $T = T_1 + \frac{I}{32.2} \frac{d\omega}{dt}$ , where  $I$  is the moment of inertia of all the

parts and  $\omega$  their angular velocity. In the case of an induction motor the torque  $T$  is practically proportional to the slip (see *Motors, Induction*). By making use of this relation and the above equation the following working formula is deduced for the change in the torque developed by an induction motor during an interval during which the opposing torque of the load remains constant:

$T_2$  = torque, in pound-feet, developed by motor at a given instant.

$T$  = torque, in pound-feet, developed by motor  $t$  seconds later.

$T_1$  = opposing torque, in pound-feet, due to the load, assumed constant.

$R$  = ratio of torque (in pound-feet) to slip (expressed as a decimal) for the given motor, obtained from characteristic curves of the motor.

$N$  = synchronous speed of motor, in r.p.m.

$k$  = radius of gyration of flywheel, in feet (the inertia of the other parts is usually negligible in comparison with that of flywheel).

$W$  = weight of flywheel in pounds.

Calculate the constant

$$A = \frac{308 R}{k^2 W N}$$

the motor  $t$  seconds from the time that its torque

$$T = T_1 - \frac{T_1 - T_0}{e^{At}},$$

of a system of logarithms (see *Exponential Functions*). When the load torque suddenly increases from the value  $T_0$  to  $T_1$ , then the torque developed by the motor does not build up to this value at a rate depending upon  $A$ . The smaller  $A$  the more slowly does the torque of the motor build up. If  $A$  is very small and the load represented by the torque  $T_1$  is very large, the torque of the motor may increase only a relatively small amount and then drops back to its original value. The constant  $A$  may be increased (1) by adding a flywheel with a large flywheel effect; (2) by designing the motor so that for a given torque it has a small secondary resistance.

**FREQUENCY CHANGERS.**—(See also *Generators; Motor Motors.*) Frequency changers are motor-generator sets in which both are designed for operation with alternating current, but for two different frequencies, thus a 25-cycle motor may drive a 60-cycle generator. They are used for three general classes of work which may be typified as follows:

(a) To supply 60-cycle current for lighting from a 25-cycle power source. The 60-cycle current is much more satisfactory for lighting than is the 25-cycle current.

(b) To supply 25- or 15-cycle current for single phase railway from a 60-cycle power system.

(c) To tie together two large power stations which started independent at different frequencies and as a result of growth and changed economic conditions or ownership, find it desirable to be able to exchange energy either for the purpose of evening up the demand or to meet the emergency of an accident at one of the generators of one of them. Most of the large power stations in a given neighborhood are even when owned by different corporations, are tied together to help out in case of trouble in one of them. For this type of service it is desirable that the frequency changers be "reversible," that is, either machine may be made the driving motor.

While several types have been proposed and discussed on paper, only a few types have attained, or are likely to attain, any great commercial success. These are the "Induction-synchronous" and the "Synchronous-synchronous" types. The former is not ordinarily reversible while the latter is reversible.

**INDUCTION-SYNCHRONOUS TYPE.**—An induction motor connected to a synchronous alternating-current generator (either single or three-phase at either end or any combination thereof) may be designed to receive power at any frequency and deliver power at any other frequency. Thus a 10-pole motor operating on a 25-cycle circuit driving a 24-pole generator at 300 r.p.m. will deliver approximately 60 cycles. This combination has the disadvantage that an increasing load causes decreasing speed and decreasing frequency in the load circuit. This can be taken care of in some cases by choosing a ratio of poles which will give a nominal ratio of frequencies, and by added resistance in the secondary of the generator motor, regulate the speed at all loads so that the generator gives the desired frequency. Where the secondary system or load is an independent circuit with its own generators there is no objection to allowing the frequency to vary slightly from the nominal value.

If there are to be two frequency changers in parallel supplying the load, the adjustment of the division of load may be accomplished either by adjusting the resistances of the secondary of the two induction motors, or they have the same slip, or by having an adjustable resistance common to both of these secondary circuits of the motors. The great advantage of the synchronous type is that, due to the characteristics of the induction motor, variation of one or two per cent in the frequency of either of the two motors will not cause a serious overload on the set, as is the case with the synchronous type.

**SYNCHRONOUS-SYNCHRONOUS TYPE.**—This consists of a synchronous motor driving a synchronous alternating-current generator. The constant speed characteristic of a synchronous motor makes it particularly well suited as the driving motor of a frequency changer, as this insures a constant ratio of frequencies irrespective of the load on the set.

Such sets are more generally used than any other type, particularly in the

whose frequencies are fixed by the presence of other considerable variation in the frequency of one system overload on the set and may cause it to pull out of step. It is desirable that the capacity of the set be not too small in relation to the capacity of the system. The synchronous motor usually has a cage winding in its pole faces in order to assure good starting and to reduce hunting (*see Motors, Synchronous*). This type of motor will transfer energy either way between the systems. The reversal of the flow of energy is accomplished by reversing the connections of the motor armatures in its cradle as described under parallel

operation. A synchronous set may operate properly in parallel with other synchronous apparatus on the same circuit. If the motor and generator are respectively connected, the motor and generator must be carefully chosen. Thus, for 60 cycles per second, the highest speed which allows an armature frequency is 300 rev. per min., and this requires 10 poles and 24 poles on the 60-cycle machine.

In less expensive sets it is frequently the custom to use a speed of 1200 rev. per min. on a 4-pole machine on the 25-cycle circuit and a 10-pole machine on the 60-cycle circuit. All the other machines then operate at 62.5 cycles. Other combinations of frequencies and pole counts can be readily calculated from the mathematical relation between poles, speed and frequency; see *Tables, Appendix*, and attached tables. High-speed sets with armatures are smaller and less expensive for a given capacity. A generator set must be provided with direct current for excitation from a direct-connected exciter or from a special exciter

**Synchronous Sets.** — The parallel operation of two synchronous sets involves certain complicated considerations. In the case of a set, the load depends not only upon the voltage regulation of the generator constituting a set, but upon the mechanical position of the set in the shaft. Two sets built apparently the same may not operate in parallel because of inaccuracy in the placing of the key-ways. It is customary to mount the stationary member of the set (the stationary armature) in a cradle, so that the angular phase position of the stationary armature with respect to the base, may be varied. Two sets to be operated in parallel are loaded, and the stationary member of one is rotated in the cradle until the load on the two

is equal. **Frequency Changers.** — The synchronizing of such sets is a complicated matter and conditions must be satisfied. The theory is discussed at length in a paper by J. B. Taylor on *Parallel Operation of Synchronous Motors*, *Vol. 25, p. 113*, from which the attached table is taken. A requirement is that it is necessary to synchronize not only the supply circuit, but also the generator with its load. If the motor has been synchronized properly, it may be found that the generator is out of phase with the load circuit. To bring the generator into proper phase it is necessary to cause the motor to "slip" one or more times. This can be done by increasing the generator speed until it comes into proper phase; this can be done by increasing the motor one or more times depending upon the number of poles on the motor. The necessity for more than one slip is dependent upon the number of poles on the motor and on the motor. The necessity for more than one slip is dependent upon the number of poles on both motor and

generator there are only a few combinations in which the poles of the generator of one set match up with the poles of motor and generator of another set. Thus with a 10-pole motor and 24-pole generator (the common arrangement) when the motor slips one pole or 180 electrical degrees of its circuit, the generator slips  $\frac{24}{10} \times 180$  or 432 electrical degrees of its circuit. It is necessary to make the motor slip 5 poles or  $5 \times 180$  degrees to make the generator slip the first even multiple of 360, that is  $5 \times 432 = 2160$  degrees. In this case it might be necessary to make the motor slip 4 poles to get the right combination. Five reversals would reproduce the original conditions and, after that, more reversals would repeat the cycle of possible combinations. The table shows the possible combinations for various sets of used sets.

In practice, this difficulty is overcome by the use of a special synchronizing indicator (see *Synchronizers*) having two hands on the same dial; one hand indicates the phase relation of each member of the set with respect to its particular circuit. It is necessary to synchronize the set when both hands are stationary but point to the zero position. If only the motor were synchronized it would be found that both hands were stationary, the motor hand pointing to zero but the generator hand pointing to some other position.

#### POSSIBLE COMBINATIONS FOR SYNCHRONOUS-SYNCHRONOUS FREQUENCY CHANGERS

Cycles		Poles		Speed	Kw.	Chances of correct Synch.	Field reversing switches
Motor	Gen.	Motor	Gen.	R. P.M.	Capacity		Motor
25	60	10	24	300	Max.	1 in 5	Yes
25	62.5	4	10	750	600	1 in 2	....
25	62.5	8	20	375	Max.	1 in 2	....
40	60	4	6	1200	150	1 in 2	....
40	60	8	12	600	3000	1 in 2	....
40	60	12	18	400	Max.	1 in 2	....
25	50	4	8	750	600	Certain	....
25	50	8	16	375	Max.	Certain	....
33.3	60	10	18	400	Max.	1 in 10	Yes
30	60	6	12	600	1000	Certain	....
30	60	8	16	450	Max.	Certain	....

**Explanation of Table.** — The first two columns show the frequencies of the two circuits to be tied together, the third and fourth columns, the number of poles on motor and generator respectively, the fifth column, the speed of the set. The sixth column, the maximum capacity in kw. in which such a set is available in commercial practice ("max." means as large as desired). The seventh column states the chances of the set coming in right the first time. The eighth column indicates the maximum number of trials that might be necessary before a right combination is found; thus in the first line, four trials might be necessary to be made to secure proper synchronizing. The last two columns tell whether it is necessary to have field reversing switches on each member. These switches are used to make the motor slip a pole and to reverse the polarity of the generator.

both members of a set reduces the number of trials synchronizing.

ous sets are started by means of a squirrel-cage winding takes the motor start (at a reduced voltage) as an inductor-step without synchronizing.

capacity in the motor, particularly in field copper, these per-factor correction of the motor circuit by over-excitation.

sets is quite high, but is of course the product of the machines. The machines may be wound for high voltage, and of transformers for voltages of 13,000 or less. Two are quite popular in order to economize in space and in

**FREQUENCY CHANGERS.**—When the stator is excited from a supply circuit having a frequency of  $f_1$  the rotor of this motor is driven by another motor in the set in which it would rotate due to the currents in its winding of the current induced in the rotor winding is

$$f_2 = \frac{N_0 + N}{N_0} \cdot f_1,$$

speed of the motor and  $N$  = actual speed at which its combination of two motors (the driven motor really acts therefore be used as a frequency changer.

in the driven motor, the electrical input into its stator is

× (output of set at frequency  $f_2$ )

out of the driving motor is

× (output of set at frequency  $f_2$ ).

on is less expensive than the usual motor-generator set, of poor regulation, as every change in the potential of transmitted to the receiving circuit; it is therefore but

**FREQUENCY CHANGERS.**—See article on *Radio*

—Taylor, J. B., *Parallel Operation of Frequency* E., Vol. 25, p. 113; Funk, N. E., *Operation of Frequency* E., Vol. 32, p. 1713; Harris and Bonnett, *Frequency* E., 1913; Townsend, R., *Frequency Changers*, Br. I.E.E.,

**FREQUENCY INDICATORS.** — The frequency of the current by a generator may be determined directly from its speed,  $N$  revolutions per minute, and number of poles  $p$ , from the formula

$$f = \frac{Np}{120}.$$

The same formula also applies to a synchronous motor,  $N$  and  $p$  being speed and number of poles of the motor. The speed may be measured by a counter and stop watch or by means of a tachometer, or speed indicator. The latter may be calibrated to read the frequency directly for a given generator or motor.

By the term Frequency Indicator or Meter is to be understood an instrument the indications of which are determined directly by the frequency of the current connected to its windings, as distinguished from an electrical Tachometer or Speed Indicator which generally consists of a D.C. Voltmeter operating on a permanent field generator, the scale being calibrated to read "cycles per second." A permanent field generator, or so-called magneto, is directly driven from the A.C. generator, the frequency of which it is desired to measure in the A.C. circuit.

**INDICATING FREQUENCY METERS.** — Indicating frequency meters are made in a variety of types, the most common being (1) the moving-coil type, (2) the induction type, and (3) those operating on the principle of the mechanical resonance of an iron reed acted upon by the field produced by a current from the given source.

Other types, less common, consist of a synchronous motor with an attachment for indicating its speed on a scale which is calibrated in frequency.

A wave meter is a type of frequency meter used for measuring radio frequencies which are much higher in value than the frequencies used in power work. For a description, see *Wave Meters*.

**Moving-vane Type of Frequency Indicator.** — A common form of frequency indicator of this type consists of a moving vane, with pointer attached, mounted so that it is acted upon by two coils set at right angles to each other. One coil is connected in series with a non-inductive resistance and the other with a comparatively large inductance. The vane tends to set itself in the direction of the resultant field due to the currents in two coils, there being a controlling spring, and consequently for a fixed ratio of these currents the vane takes up a definite position irrespective of the values of these currents. The two circuits are so connected to the source of supply that when the voltage of the mains varies, the voltages across the two circuits of the instrument vary proportionally to each other, and therefore the position of the vane and pointer is unaffected by voltage variations. An increase in the frequency, however, decreases the current through the inductive circuit relative to that through the non-inductive circuit, and consequently causes a deflection of the vane and pointer; similarly a decrease in the frequency increases the current through the inductive circuit, producing a deflection in the opposite direction. The resistance and inductance of each circuit is so adjusted that for the standard frequency, e.g., 60 cycles, the pointer stands in the middle of the scale. The instrument is suitable for a range of frequency generally from about 25 per cent below, to 25 per cent above normal frequency.

**Effect of Wave Form.** — Such instruments are affected to a certain extent by the wave form of the voltage on the mains to which they are connected.

This is readily understood by considering that wave forms differing from a sine wave are the equivalent to a superimposed higher frequency harmonic. This affects the frequency meter in the same way as would a higher frequency

umerous expedients have been devised to overcome combinations of resistive and inductive circuits, and by placing a resistance in series with the inductance, this resistance is chosen with the wave form on which the instrument is to

**Frequency Indicator.** — This type is similar to the type in which two moving coils, rigidly fastened together, constitute the moving element and the stationary element is a single coil.

**Frequency Indicator.** — A form of instrument of great sensitiveness is greatly increased, is described by Pratt in *Electrical Engineering*, 1912, Vol. 31, p. 1505. The two moving coils are connected in series with suitable resistances, inductances and capacitances so that the two circuits are nearly in electrical resonance with the impressed frequency. A 6-inch deflection of the instrument is readily obtained for a change of 10% of the frequency. A 6-inch deflection of the instrument is readily obtained for a change of 10% of the frequency. This instrument shows only a trace of variation due to temperature.

**Frequency Indicator (see Fig. 1)** — In these instruments a differential torque in opposite directions by two small shaded pole pieces

Fig. 1.

From the above that the moving vane, moving arm, and other parts of meters do not operate with a control force such as a spring, etc. The introduction of such a mechanical element into the instruments sensitive to changes of voltage and current would vary the electrical torque without changing the frequency, thus producing an error. Therefore, all these instruments and pointers which will remain at rest at any frequency when not connected to the circuit. When the current through the instrument assumes a position at which the differentially-

**Vibrating-reed Type of Frequency Indicator.**— In these instruments a series of vibrating reeds is provided, each tuned to vibrate at a frequency corresponding to a certain number of cycles per second, or sometimes the tuning is done for differences as small as  $\frac{1}{4}$  cycle per second or less. Some arrangement is provided by means of which the frequency of the alternating current is communicated to these vibrating reeds. In one arrangement all of the reeds are mounted on a common support which is vibrated by a single electro-magnet through which the alternating current whose frequency is to be measured flows. In another arrangement the reeds are attached to a rigid support but are constructed of magnetic materials and acted on by one or more electro-magnets directly. These instruments are quite accurate in service if the voltage varied beyond that for which the instruments are intended, in which case a wrong reed may be made responsive.

The frequency of modern power circuits varies but little and the rate of vibration is slow. Thus the pointers of the usual frequency meters are generally either at rest or moving very slowly, introducing a personal element of error on the part of the observer as to operativeness. The argument in favor of the vibrating reed frequency meter is that the indicator is in motion constantly, showing that the instrument is operating. On the other hand, frequency meters indicating by means of pointers and graduated dials in the same way as voltmeters and ammeters, are generally preferred, being more easily read.

**Miscellaneous Indicators.**— Graphic recording frequency meters are constructed on the same principles and have movements similar to those of moving-coil, or induction-indicating instruments, to which are added clockwork, paper charts and pens for recording the frequency variations at different times.

Cycle counters can be considered as a variety of frequency meters and are not intended primarily to measure frequency. They consist of a clock mechanism the escapement of which is controlled by a vibrator oscillated by an electro-magnet connected to an alternating current circuit. The dials operating the clock train indicate the number of alternations elapsed or occurring since the circuit was connected to the circuit. Conversely, if allowed to be connected to an alternating current circuit of unknown frequency for a fixed length of time, as for example, 10 seconds, the frequency may be determined. The principal use of cycle counters is in timing relays, etc., instead of using stop watches, as much greater accuracy is possible than with the stop watch. The frequency of the circuit should be either known or can be readily determined by operating the cycle counter for a period of time which can be readily measured by ordinary means, such as seconds. Then, intervals of time as short as 1 cycle can be readily measured within an error equal to 1 alternation, which is obviously an impossibility with stop watches. By the use of cycle counters, chronographs or oscillographs are avoided for timing purposes, unless time intervals within an error of less than one alternation are to be determined.

**COST OF FREQUENCY INDICATORS.**— Switchboard frequency meters of the moving-vane induction or moving-coil type (not tuned), cost from \$45 to \$65. The tuned, or electrical resonance, switchboard type cost from \$75 to \$85. Vibrating-reed frequency indicators for switchboard service cost from \$35 to \$95; portable indicators of this type cost from \$110 to \$125. The above prices are included in both cases. The various types are made for standard frequencies of 25, 40 and 60 cycles per second and for circuits of 110 or 220 volts. For circuits of higher voltages potential transformers should be used.

**FRICION DRIVE.** — (Adapted from paper by W. F. M. Goss, *A.S.M.E.*, 1907.) A friction drive consists of a fibrous or somewhat driving wheel working in rolling contact with a metallic driven wheel. A drive may consist of a pair of plain cylinder wheels mounted upon shafts, or a pair of beveled wheels, or of any other arrangement which will serve in the transmission of motion by rolling contact.

Suitable fibrous materials for the driving wheel are straw fiber, leather, tarred fiber, sulphite fiber, or leather; suitable materials for the driven wheel are iron, aluminum and type metal. See also P. L. Weston, *Magneto Drive*, *El. Rev.* 81, p. 383, Oct. 19, 1917.

**Crushing Strength and Safe Load for Fiber Wheels.** — The crushing strength of each fibrous material, as determined by finding the load at which the wheel failed before 15,000 revolutions had been made, is given in the following table, together with the safe working load, taken as one-tenth of the crushing load.

**Coefficient of Friction.** —

The coefficients of friction between the various fibrous materials and the three metals are given in the table below, these being maximum values, corresponding to a slip of about 2 per cent. The friction at constant slip was found to be practically independent of the pressure between the limits of 150 and 400 pounds per inch width of face in contact.

Material	Crushing load, lb. per in. width	Safe working load, lb. per in. width
Straw fiber.....	750	75
Leather fiber.....	1200	120
Tarred fiber.....	1200	120
Sulphite fiber.....	700	70
Leather.....	750	75

**Horse-power Transmitted.** — Goss gives the following formula for the maximum horse-power which can be safely transmitted by a friction drive:

$$P = \frac{\pi d}{12} \times \frac{WPN \times 0.6f}{33,000} = kdWN,$$

in which  $d$  = diameter of driving wheel in inches,  $W$  = width of face of driving wheel in inches,  $P$  = safe working pressure in pounds per inch of width,  $N$  = revolutions per minute,  $f$  = coefficient of friction, 0.6 a factor for the decrease of the coefficient of friction in service and for the loss in journal friction,  $k$  a coefficient including the numerical constants.

**COEFFICIENTS OF FRICTION AND HORSE-POWER OF FRICTION DRIVES**

3.—The analyses of the solid fuels given above  
 Wood when freshly felled contains on an average  
 ure, varying with different species. After eight to  
 e open air, the moisture is reduced to 20 or 25 per  
 o greater dryness, it will, on exposure to the atmos-  
 n, and the percentage it will then contain will vary  
 as of the air; that is, wood is hygroscopic.  
 be surface moisture, received from rain while being  
 d which may be dried out on exposure to the atmos-  
 ure, contained inside of the lumps, which cannot be

dried out without subjecting the coal for some time to a temperature ably above 212° F. The anthracite, the semi-bituminous coals and bituminous coals of the Appalachian coal field seldom contain hygroscopic moisture in excess of 1 or 2 per cent, but it is a characteristic of the western coals and lignites that the hygroscopic moisture is much higher; the Illinois coals it is as high as 14 per cent. When this moisture is driven off, the coal will again absorb it on being exposed to the atmosphere. Some coals contain as much as 40 per cent moisture.

**ULTIMATE ANALYSES OF VARIOUS FUELS.**—Typical analyses of various fuels together with the percentage of ash are given in the following table. The analyses are for fuels from which all moisture has been expelled.

	C	H	O	N	S
Wood.....	50	6	41	1	..
Peat.....	59	6	30	1	..
Lignite.....	69	5	16	1	1
Bituminous coal.....	76	5	10	1	1
Semi-bituminous coal.....	86.5	4.5	3	1	0.
Semi-anthracite.....	78.5	3.5	2	1	2
Anthracite.....	77	2.5	2	1	1
Charcoal.....	82	2	..	1	..
Coke.....	89	..	..	..	1
Petroleum (Texas).....	84.5	11	3	..	1.
Natural gas.....	70	25	1	4	..

In the progression from wood to anthracite, the chief change is substitution, as shown in the above table, is a decrease in the oxygen from 41 to 2 per cent. The hydrogen also decreases, but less rapidly. In all types of coal, the ash is exceedingly variable, ranging from as low as 2 per cent to 25 per cent or more. Coals high in ash are usually also high in sulphur. Ash and sulphur may be removed to a considerable extent by coal washing.

**AIR REQUIRED FOR COMBUSTION.**—The theoretical weight of air required for complete combustion of 1 lb. of fuel may be determined by the formula,

$$A = 0.115 C + 0.346 \left( H - \frac{O}{8} \right) + 0.043 S,$$

where *C*, *H*, *O* and *S* are the percentages (by weight) of carbon, hydrogen, oxygen and sulphur in the fuel. This gives about 12 lb. of air per lb. of fuel combustible. In the best boiler practice, the weight of air required is about 20 lb. per pound of coal, but in actual practice, the air supplied varies within much wider limits. See article on *Boilers*.

**COAL.**—The proximate analysis of coal is made by separating the coal by successive heatings at different temperatures, into moisture, volatile matter, fixed carbon and ash. For the determination of moisture, a representative sample, say 2 ounces or 60 grams, should be taken, crushed to about 20 mesh size, and heated for two hours to 140° C. (284° F.) or until the weight has decreased in weight. If a finely crushed small sample is taken, much of the moisture may be lost by air-drying while crushing and weighing.

constituents, a sample of about 1 gram of finely powdered coal is heated in a covered crucible until all the volatile matter is driven off with a blast lamp to a white heat, the cover being removed. The carbon is burned away, leaving the ash, which is weighed. The weight of the combustible is reported as in the example below, the percentage being based on the weight of the combustible.

	Moist coal	Dry coal	Combustible
.....	10.0	.....	.....
.....	30.0	33.33	57.14
.....	40.0	44.15	42.86
.....	20.0	22.22	.....
	<hr/>	<hr/>	<hr/>
	100.0	100.0	100.0

Proper sampling of coal is difficult. So much must be done to be properly done. For instructions in this field, see the Reports of Committee D-5, A.S.T.M.

The percentages of fixed carbon and volatile matter are a means of classifying different kinds of coal. The following are the percentages:

	Fixed carbon	Volatile matter	Heating value per lb. of combustible, B.t.u.
.....	97 to 90	3 to 10	14,600 to 15,000
.....	90 to 85	10 to 15	14,700 to 15,500
.....	85 to 75	15 to 25	15,500 to 16,000
.....	75 to 60	25 to 40	14,800 to 15,500
.....	65 to 50	35 to 50	13,500 to 14,800
.....	Under 50	Over 50	11,000 to 13,500

They classify coals into six groups, as follows: (1) anthracite; (2) semi-bituminous; (3) bituminous; (4) sub-bituminous; (5) lignite; and (6) lignite.

Anthracite is shiny, burns with little or no smoke, is slow to ignite, and does not break into small pieces when rapidly heated. Anthracite is classified into different sizes by passing through screens of different mesh.

Semibituminous is similar to anthracite, but is less hard, less shiny, and can usually be distinguished by its tendency to break into small pieces when anthracite does not.

Bituminous is softer than semibituminous. The combustible matter in bituminous coals is very uniform in composition. The volatile matter is about 22 per cent of the combustible matter. Such fuels

are usually low in moisture, ash and sulphur and rank among the best steaming coals in the world.

The ash content runs from 3 to 8 per cent and for the higher grades heating value is in the neighborhood of 14,500 B.t.u. or better, per pound of dry coal.

**Bituminous** coal is also a soft coal. It is distinguished by high percentage of volatile matter, which causes it to give off dense volumes of steam when heated. It requires careful firing and furnaces especially adapted to prevent smoke. There is a wide variation in its physical properties.

**Sub-bituminous** coal is commonly known as "black lignite." It is generally black and shining, closely resembling bituminous coal, but "weathers" or disintegrates more rapidly on exposure and lacks the crystalline structure of bituminous coal. Its calorific value is generally less than that of bituminous coal.

**Lignite**, or "brown coal," is intermediate between coal and peat. It usually has a woody structure and is distinctly brown in color, even on fracture. It carries a higher percentage of moisture than any other class of coals, its mine samples showing from 30 to 40 per cent of moisture. It is fragile and rapidly splits into fine pieces upon exposure to air.

The following analyses of representative coals of the six classes are given by Prof. N. W. Lord:

- Class 1. Anthracite Culm. Penn.
- Class 2. Semi-anthracite. Arkansas.
- Class 3. Semi-bituminous. W. Va.
- Class 4(a). Bituminous coking. Connellsville, Pa.
- Class 4(b). Bituminous non-coking. Hocking Valley, Ohio.
- Class 5. Sub-bituminous. Wyoming, black lignite.
- Class 6. Lignite. Texas.

er pound of Combustible by Dulong's Formula						
	13,406	15,190	13,951	12,510	11,620	10,288
	15,496	16,037	15,511	14,446	13,235	12,889

— The heating value of coal depends on its percent-  
 and on the heating value per pound of that com-  
 in different districts and bears a relation to the  
 as shown by the above table.

ile matter is less than 40 per cent of the combustible,  
 of combustible may be approximately determined  
 y means of the following table. When the volatile  
 ent, the figures in the table may have a plus or minus  
 ent, since the coals high in volatile matter differ  
 xygen.

Volatile matter, per cent of combustible	Heating value, B.t.u. per pound of combustible	Volatile matter, per cent of combustible	Heating value, B.t.u. per pound of combustible
28	15,660	43	14,220
32	15,480	45	13,860
37	15,120	47	13,320
40	14,760	49	12,420

und of combustible of all the semi-bituminous coals,  
 cent of volatile matter in the combustible, is within  
 u. per pound. This is within the limits of error of  
 sis or of calorimetric determination.

The heating value of any coal may also be calculated from analysis by means of Dulong's formula,

$$\text{B.t.u. per pound} = 146 C + 620 \left( H - \frac{O}{8} \right) + 40 S,$$

in which  $C$ ,  $H$ ,  $O$  and  $S$  are respectively the percentages by weight of carbon, hydrogen, oxygen and sulphur. The probable error of this formula is about 2 per cent for any coal containing less than 40 per cent volatile matter. For coals higher in volatile matter, the error is sometimes 5 per cent. When the percentages are expressed as percentages of the various elements of the combustible, the formula gives the B.t.u. per pound of combustible. When the percentages are percentages of the various elements in a given coal, the formula gives the B.t.u. per pound of coal, which is, of course, the B.t.u. per pound of combustible in proportion to the per cent of combustible present. In general, if  $K$  be the per cent of combustible in a sample, and  $H$  the heating value per pound of combustible, the heating value per pound of coal is  $\frac{KH}{100}$ .

For the direct determination of the heating value of coal or other solid fuel, a bomb calorimeter, in which the fuel is burned in an atmosphere of oxygen, is the most accurate instrument. (See *Calorimeters, Fuel*.)

**Average Heating Values.** — The following figures give the average commercial heating values of the principal power plant fuels, oils and gas.

	B.t.u.
Anthracite.....	14,500
Semi-anthracite.....	13,500
Semi-bituminous coal.....	12,500
Bituminous.....	11,500
Lignite (as fired).....	8,500
Lignite (dry).....	10,500
Coke.....	14,000
Charcoal.....	11,000
Peat (as fired).....	4,500
Peat (dry).....	5,500
Wood (dry).....	8,000
Bagasse (45 to 55 per cent water).....	7,000
Tan bark (65 per cent water).....	6,000
Tan bark (dry).....	10,000
Straw.....	4,000

**The Commercial Value of a Coal** is not always in direct proportion to its heating value. Excessive moisture causes a reduction in its temperature during combustion, which reduction, in steam boiler practice, decreases the efficiency. Excessive ash tends to obstruct the draft and thus cause imperfect combustion. High percentages of volatile matter tend to cause smoke and soot, and require the use of special furnaces.

**Specifications for Coal.** — For the reasons just stated, contracts for the purchase of coal on specifications of quality should penalize excess of moisture and volatile matter above certain stated percentages. For a full discussion of the purchase of coal by specification and specifications used by the U. S. Bureau of Mines see latest Bulletins of the U. S. Bureau of Mines relating to this subject. The specifications are as follows:

**Anthracite.** — The standard is a coal containing not over 2 per cent moisture and not over 10 per cent ash. A reduction of 1 per cent in the price will be given for each per cent of moisture up to and including 15 per cent, and a similar price will be made for each 1 per cent of moisture in excess of 15 per cent.

**Western Bituminous.** — The standard is a coal containing not over 20 per cent volatile matter, 2 per cent ash. A reduction of 1 per cent in the price will be given for each per cent of volatile matter in excess of 25 per cent, and of 1 per cent of ash and moisture in excess of the standard.

For western coals in which the volatile matter differs from the standard in hydrogen, the above specification based on proximate analysis is generally accurate, and it is well to introduce the heat value by a calorimeter or by calculation from the proximate analysis.

For coals containing not over 6 per cent moisture and 10 per cent ash, and having a heating value of 14,500 B.t.u. (free from moisture and ash). For lower heating values, the price shall be reduced proportionally, and the price in ash or moisture above the specified figures, shall be deducted.

**Storage.** — The space occupied by a ton of coal depends on the coal and the size of the lumps. A ton of 2240 lb. size, or smaller, occupies a space of from 36 to 45 cubic feet. A ton of bituminous coal occupies a space of from 36 to 45 cubic feet, depending on the space required for storage, 45 cubic feet being usually assumed.

Anthracite coal when exposed to the weather undergoes, except the oxidation of the sulphur content, which is small, a larger percentage of sulphur, the oxidation of which, in a certain amount, may develop sufficient heat to cause some lignites are rapidly disintegrated when exposed to the weather. A carload lots of Illinois coal (*F. W. Wheeler, Trans.*) showed the screenings and 3-inch nut coal lost 1.3 per cent in three months, and 2 per cent in six months. Pillar coal from a mine worked round twenty-two to twenty-seven years, showed a higher heating value than the fresh face coal from the same mine.

The cost of coal delivered to any power plant depends not only on the coal and the size of the lumps, but also upon the railroads or water facilities for delivering the coal, and the cost of mining. In making an estimate of the cost of coal, one should obtain quotations from the dealers and the mines under consideration.

**Oil Boilers; Gas Engines.** Crude petroleum and its products, such as gasoline, kerosene, etc., are largely used for their use in any locality depending chiefly on their availability with coal. In Texas, California, Russia and other localities where coal is relatively expensive, petroleum is used as a fuel for steam boilers. Gasoline, kerosene and oil are also used in various types of internal combustion engines composed chiefly of hydrocarbons, which distil at

different temperatures, the lightest vapors being driven off as low as and heavier vapors and oils at temperatures rising to 600°, above which and residuum are formed. The crude oil contains small percentages of sulphur and oxygen as impurities. The specific gravity, weight and value of California oil are given as follows by J. N. LeCoute (*Jour. Aug., 1911*):

## CALIFORNIA OIL

Degres Baumé	Specific gravity	Weight per barrel, pounds	B.t.u. per pound	B.t.u. per (42 gal)
10	1.000	350	18,280	6,396
12	0.986	345	18,400	6,345
14	0.972	340	18,520	6,300
16	0.959	336	18,640	6,255
18	0.946	331	18,760	6,210
20	0.933	327	18,880	6,165
22	0.921	322	19,000	6,120
24	0.909	318	19,120	6,075
25	0.903	316	19,180	6,060

Oils from other sources have different densities and heating values. Lima, O., crude is reported to have a sp. gr. of 0.792; Beaumont (Tex.) sp. gr. 0.92, B.t.u. per pound 19,060; Pennsylvania heavy crude, sp. gr. 0.92, B.t.u. 20,736; Caucasian light crude, sp. gr. 0.884, B.t.u. 22,027. A California oil, six lots, used in a boiler test at Redondo, Cal., contained moisture 2.70 per cent; sulphur 2.17 to 2.607; B.t.u. per pound 17,717 to 17,960.

The following table shows the relative heating values of crude petroleum, based on oil of sp. gr. 0.885; B.t.u. per pound 20,000; 1 barrel = 310 pounds.

Coal B.t.u. per pound	1 pound oil = pounds coal	1 barrel oil = pounds coal	1 ton (2240) coal = barrels oil
10,000	2	620	3.5
11,000	1.818	564	3.9
12,000	1.667	517	4.3
13,000	1.538	477	4.7
14,000	1.429	443	5.1
15,000	1.333	413	5.4

## Advantages of Liquid Fuel. —

1. Reduction in number of firemen in proportion of 5 or 6 to 1.
2. Easy lighting of fires and more regular supply of heat.
3. Fires readily regulated to suit demand for steam, and can be extinguished.
4. Small proportion of refuse and its easy disposal.
5. Storage tanks can be located to best advantage, while coal bins must be near the boilers.

no loss by banking.

Oil Fuel. —

limited by some city ordinances.

prohibited by some cities.

mixture with air.

incompatible with roaring noise.

boilers become coated with residue.

creep by valves and leak.

special apparatus to start oil fire or maintain it or both.

Oil Fuel. — Although boiler efficiencies as high as

obtained with oil-burning furnaces, the average is prob-

ably, the efficiency with oil is about 2 per cent higher

and Alcohol. — The following is taken from the

Report (1914):

Spec. grav. at 15° C.	Cal. per gram	B.t.u. per lb.
0.684-0.694	11,210-11,220	21,980-22,000
0.710-0.730	11,100-11,400	19,980-20,520
0.790-0.800	11,000-11,200	19,800-20,160
0.8196-0.8202	6,440- 6,470	11,590-11,650

**FURNACES, ELECTRIC, AND ELECTRIC FURNACE DEVICES.** — (See also *Electrochemical Processes, Industrial.*) Electric furnaces may be classified as follows:

Arc furnaces.

Induction furnaces.

Resistance furnaces.

a. Current conducted by the materials heated:

1. With electrolysis.

2. Without electrolysis.

b. Current conducted by a special resistor.

In the arc furnace the heat is produced by an electric arc (see *Arc Furnaces*) usually between carbon electrodes. The induction furnace is essentially a static transformer (see *Transformers*) with the low-tension "windings" being the material to be heated. In the resistance furnace the current is applied to the material to be heated (i.e., to the furnace "charge") through a special resistor, by connecting the charge or resistor directly to the main current supply. The heat developed in both the induction and resistance furnaces arises from the passage of the current through the resistance of the charge or special resistor.

The arc furnace may be considered a resistance furnace in which the resistor is a gas. Since the resistance of a gas at atmospheric pressure is greater than that of any solid resistor of the same dimensions as the arc, the amount of heat that can be produced in a small space will be greatest with an arc furnace.

#### TEMPERATURE AND DISTRIBUTION OF HEAT. —

The advantage in electric heating is that a higher temperature can be produced without using fuel, that the heat is produced inside the furnace where it is needed, and that the heat can be easily and accurately regulated. In the arc furnace a part of the positive carbon is estimated to be between 3900° C. absolute. (*Waidner and Burgess, Bull. Bureau Stds., Vol. 1, p. 154-160, 1900.*) The temperature of the arc itself increases with the current. (*König, *Abhandl. der Spektroskopie, Vol. 1, pp. 154-160, 1900.**)

The electric energy delivered to the furnace as heat is used as well as to heat the charge to the desired temperature, which involves heating the furnace walls, if cold at the start. This energy is equal to the charge times the temperature rise times the specific heat. If the charge is melted or vaporized in the furnace, additional heat must also be supplied. This item may be reduced by delivering the charge to the furnace as in steel refining. (2) To supply the energy needed for the re-duction and radiation through the walls and electrodes, and the heat carried off by hot gases. A part of the heat carried off by hot gases may be used for heating water in boilers, so that it is not a complete loss.

**MAXIMUM SIZE OF ELECTRIC FURNACES.** — The maximum capacity of an open-arc single hearth with a compact bundle of electrodes has been found in practice to be from 2500 to 3000 kilowatts at from 40,000 amperes and from 75 to 90 volts. These large sizes are possible with the three-phase system, so that the maximum total power absorbed by the furnace is from 7500 to 9000 kilowatts. In carbide furnaces double electrodes are used with six electrodes, in place of three, in the same furnace; the power absorbed is from 15,000 to 18,000 kilowatts. Great progress has been made in electric-furnace construction, by closing the furnace at the top, thus having special means of feeding in the charge, thereby avoiding the dust and protecting the workmen from the heat, as well as dist-

assign, VII Int. Cong. App. Chem., Sec. 10, p. 24, Vol. 5, p. 254, 1900; VIII Int. Cong. App. Chem.,

**WALLS.** — To reduce the conduction of heat losses to a minimum amount, these must be properly designed. The walls of three different shapes may be considered. In all cases

the heat loss, at the mean temperature  $(h_1 + h_2)/2$ , may be expressed in any convenient unit, e.g., gram per cubic centimeter per second per °C., or watts per inch square per second through the walls.

$H$  = heat loss per side surface of the wall.

$h_1$  = temperature of inside surface of the wall.

$h_2$  = temperature of outside surface of the wall.

$$H = \frac{\pi k D d (h_1 - h_2)}{l} + 0.54 \Sigma l + 0.15 n \delta \left( h_1 - h_2 \right),$$

$h_1$  = temperature of inside surface,  $h_2$  = temperature of outside surface,  $\delta$  = thickness of wall,  $\Sigma l$  = the sum of the lengths of the edges,  $n$  = the number of corners. This applies to rectangular walls. If the corners are greater than  $\frac{1}{8} \delta$ . (Langmuir, Adams, *Trans. Am. Electrochem. Soc.*, Vol. 14, p. 53, 1914.)

$$H = \frac{\pi k D d (h_1 - h_2)}{l},$$

$H$  = heat loss per side surface of sphere,  $d$  = inside diameter,  $l$  = thickness of wall.

$$H = \frac{2 \pi k L (h_1 - h_2)}{3 \log_{10} \frac{D}{d}} + \frac{\pi k D d (h_1 - h_2)}{2 l},$$

$H$  = heat loss per side surface of cylinder,  $D$  = outside diameter,  $d$  = inside diameter,  $L$  = length of cylinder,  $l$  = thickness of top and bottom walls, all in the same unit. For heat loss through the cylindrical walls, the second term is neglected. (Hering, *Trans. Am. Electrochem. Soc.*, Vol. 14, p. 53, 1914.)

**Walls.** — The most refractory substances do not have high thermal conductivities. Consequently, it is advantageous to use refractory materials not only for the inner part or lining of the walls, but also for the outer part, so that the drop in temperature will be sufficient to compensate for the resistance of a lower conductivity being used for the next layer. This principle of refractory walls may be employed. See Ray and Kreisling, *Refractory Walls*, Bull. No. 8, Dept. of the Interior, 1912.

**Walls.** — The most refractory substance is carbon, which is a poor conductor. Some of the products of the electric arc, such as silicon (silicon dioxide), stand next to carbon as refractories, and do not have high thermal conductivities. (See Fitzgerald, *Electrochem. Ind.*, Vol. 2, p. 625, 1911, and the table below for graphite and silicon dioxide. For values of heat conductivities of refractories at different temperatures for only a few substances and then only approximate values, see article on *Resistance and Conductance*.)

**DESIGN OF ELECTRODES FOR ELECTRIC FURNACE**  
 electrodes of an electric furnace should be so designed that the energy is carried into the furnace with a minimum energy loss. The loss due to electrical resistance is directly proportional to the electrode's length; therefore be made as short as convenient. The loss due to electrical radiation will be smaller the greater the cross-section of the electrode, but the loss from the furnace through the electrode will be directly proportional to the cross-section. It is therefore possible to find a cross-section of a given length which will give a minimum total loss for a given length. The cross-section which would give the minimum loss on certain assumptions, only approximately is found from the equation

$$S = 0.346 LI \sqrt{\frac{r}{k(h-h_1)}}$$

and the loss itself, watts, is

$$W = 2.89 I^2 \sqrt{kr(h-h_1)}$$

where  $S$  = cross-section of electrode,  $L$  = its length,  $I$  = the current carried by the electrode,  $h_1$  and  $h$  the temperatures, in °C., at the hot and cold ends of the electrode respectively,  $r$  = its mean electrical resistance in ohms per unit cube and  $k$  = its mean heat conductivity for the temperature  $(h_1 + h)/2$ . If  $S$  and  $L$  are in centimeters,  $r$  and  $k$  must be in c.g.s. units; if  $S$  and  $L$  are in inches,  $r$  and  $k$  must be per in.<sup>2</sup>.

The values of  $k$  and  $r$  for carbon and graphite are not known at high temperatures. The following values have been computed from the experiments of Hering (*Trans. Am. Electroch. Soc.*, Vol. 17, p. 166, 1910).

Material	Temperature °C.		Thermal cond. g.-cal. per cm. <sup>2</sup> per °C. per sec.	Electrical resistance ohm
	Hot end	Cold end		
Carbon.....	300	40	0.0891	
	701	50	0.124	
	902	60	0.130	
Graphite.....	355	66	0.399	
	516	70	0.325	
	707	87	0.309	

**SMALL LABORATORY FURNACES.** — A great variety of electric furnaces have been devised. A few typical laboratory furnaces will be described in this section. Some industrial furnaces are described in the next section.

**Moissan's Furnace (Fig. 1).** — Moissan's work was carried out in a furnace consisting of two horizontal electrodes, mounted so that the distance between the two ends could be adjusted longitudinally by a screw thread. An arc was formed between these electrodes in a cavity formed by some refractory material, such as lime. The substance to be heated was placed in a crucible under the arc as shown in Fig. 1. When the substance was not to be exposed to the gases of the arc, a furnace was made with a carbon tube passing through it at right angles to the electrodes and in contact with them below the arc. The substance to be heated was placed inside this tube.

8). — A type of furnace due to Borchers consists in two larger electrodes. The charge is either packed or placed under it. This type of furnace maintains a temperature below that of the

Fig. 2.

9). — A furnace that takes its heat from a crucible with one or more electrodes above the crucible. The crucible is represented by an iron container. Graphite crucibles may be used as electrodes. The charge in the crucible is usually placed between the crucible and the electrode. A variable resistance in series with the electrode may be used so that when melted the electrode may be raised.

Fig. 3.

In case it is desired to melt a substance without the use of an arc, a smaller electrode may be used between the crucible and the charge. If after the substance has been melted it is desired to raise the electrode through the bath itself, as, for example, in case of a graphite electrode, the upper electrode may be raised, the thin rod raised and the electrode then lowered into the bath. This operation is called raising the electrode.

10). — It frequently happens in the laboratory that it is desired to maintain a high temperature in a vacuum or in some inert gas such as nitrogen. A furnace for this purpose has been described by J. H. Van Dine, *Trans. Am. Elec. Soc.*, 1907, p. 100, and has been used for such work. This furnace is shown in the General Catalogue of the General Electric Company, 1907, p. 100, as Fig. 4. It consists of a furnace chamber A made of a material which is a good insulator at the joint. The furnace chamber, forms an air-tight chamber, is fastened down to a base by a tube J through which the furnace is heated. The window E is made of a material 0.005 inch thick and is supported by a frame F.

Fig. 4.

The furnace is surrounded by a cooling jacket R, which is connected to a water supply W and a tank T. The furnace is supported by a base B, and the window E is supported by a frame F. The furnace is connected to a power source S through a switch S. The furnace is surrounded by a cooling jacket R, which is connected to a water supply W and a tank T. The furnace is supported by a base B, and the window E is supported by a frame F. The furnace is connected to a power source S through a switch S.

11). — A vacuum furnace provided with an inlet S and an outlet T. Small size of furnace 9 to 10 kilowatts produce a

**High-pressure Furnaces.** — The Arsem furnace may be of course the internal pressure above an atmosphere, but it is not designed for pressures. A furnace for working up to 200 atmospheres has been described by Hutton and Petavel. (*Phil. Trans., Series A, Vol. 207, p. 421, 1908, inchem. and Met. Ind., Vol. 6, p. 97.*) For a modified form see Pring and King (*VIII Int. Cong. App. Chem., Vol. 21, p. 79, 1912*). For a furnace for microscopic work on gases at pressures up to 200 atmospheres, see King, *A. Physical Journal, Vol. 28, p. 300, 1908*.

**Heraeus Furnace (Fig. 5).** — A very useful type of furnace is of the firm of Heraeus. This consists in a tube wound in its middle portion with an electrical resistor. The ends of the tube are cooled by the air, or may be cooled by a coil of copper pipe through which water flows. The tube may be of some non-conducting substance, such as porcelain, in which case a ribbon of metal may be wound directly on the tube. Furnace tubes with grooves for winding with wire are now made by the Norton Company of Worcester, Mass., from fused alumina. These, however, cannot be used for a vacuum furnace. Glazed German porcelain can be heated up to 1180° C. and a vacuum maintained. At temperatures higher than this the glazing melts and air leaks into the tube. A nickel tube may be used for higher temperatures.

The metallic winding for carrying the current may be of platinum, nichrome, tungsten, molybdenum or any other suitable high-resistance material (see *Wires, Resistors*).

These furnaces are particularly useful when the temperature is to be kept constant over a long period of time. For most purposes a constant current regulator must be used (see *Bodenstein and Kronendieck, Z. f. Physik, Vol. 18, p. 417, 1912*). The Heraeus type of furnace is usually more satisfactory when homemade, as a greater choice of materials is then possible.

**Hoskins Furnace.** — A convenient furnace for heating rather large masses of material is made by the Hoskins Manufacturing Company, Detroit, Michigan. The heater consists of two rows of narrow, thin plates which extend over two sides of the cavity which receives the substance to be heated. The contact resistance between the plates may be varied by adjusting the pressure. This furnace of course requires a very large current at a low voltage.

**Granular Carbon Furnace (Fig. 6).** — A carbon or graphite crucible may be easily heated by placing it in a trough surrounded by granular carbon; this conducts better than coke. The current is passed through the trough, into which it is conducted by carbon rods. Clay crucibles should not be used in this way for temperatures over 1000° C., as at a high temperature they are attacked by the carbon.

**ELECTRIC-FURNACE PRODUCTS AND INDUSTRIAL FURNACES.** — Some typical industrial furnaces and their products are described below.

**Calcium Carbide.** — Willson and Horry Furnaces. Calcium carbide was first made on a large scale by Willson in 1892 at Spray, N. C., by heating calcium and carbon in an arc furnace. The reaction that takes place is

The furnace consisted of a carbon plate 3 by 2.5 feet with a carbon rod suspended above it. The whole was surrounded by brick walls. Similar furnaces similar to this were at first used at Niagara Falls, with the lower

Fig. 5

Fig. 6

is removed when filled with an ingot of carbide. The process was used (*U. S. Pat. 656,156*). The Carbide is their present furnace secret. In Europe the Willson Carbide may be either formed in an ingot in the crucible solid, or it may be drawn off in the liquid state. It has been found better to have the current flow ended over the crucible, in place of having the carbide (*Conrad, Electrochem. and Met. Ind., Vol. 6, p. 307*). The carbide is in the neighborhood of 80 per cent. The yield is about 5 kilograms per 24 kilowatt hours.

**Willson Process.**—Silicon carbide or carborundum was first used by Willson and Acheson. It is produced from quartz and carbon heated in an electric-resistance furnace, according to the following reaction:

$$2\text{SiO}_2 + 3\text{C} = \text{CSi} + 2\text{CO}.$$

The furnace has a carbon core around which the charge, consisting of silicon carbide, is packed. The latest furnaces are 1.5 meters wide, and absorb 1600 kilowatts. The yield is about 1000 kg. (*Ind. and Eng. Chem., Vol. 16, p. 155, 1907; Vol. 17, p. 112, 1908*). On a 750-kilowatt furnace it was found that the yield is about 1000 kg. and decomposes when heated above 2240° C. (*Ind. and Eng. Chem., Vol. 21, p. 425, 1912*.) The yield is about 1000 kg. of carbide for 8.5 kilowatt hours. Silicon carbide is used for furnace linings and as a substitute for ferro-silicon in the production of steel. (*Engelhardt, Carborundum, Vol. 13, in the Engelhardt and Engelhardt, Elektrochemie*.) For description of Norton Company's process for silicon carbide made by exposing hot carbon rods are used for electric heating. (*J. Eng. Chem.,*

Vol. 21, p. 425, 1912.) The yield is about 1000 kg. of carbide for 8.5 kilowatt hours. Silicon carbide is used for furnace linings and as a substitute for ferro-silicon in the production of steel. (*Engelhardt, Carborundum, Vol. 13, in the Engelhardt and Engelhardt, Elektrochemie*.) For description of Norton Company's process for silicon carbide made by exposing hot carbon rods are used for electric heating. (*J. Eng. Chem.,*

Acheson's theory of the formation of graphite is that the carbon first forms a carbide, which decomposes at a higher temperature, leaving the carbon in the form of graphite. This theory is not confirmed by Arsen's experiments. (Pirgerold, *Künstlicher Graphit*, Vol. 15 of the *Engelhardt Monographien angewandte Electrochemie*.)

**Carbon Bisulphide** is made in a specially designed furnace by heating together sulphur and carbon. Most of the disagreeable features encountered in the manufacture of this substance are thus avoided. (Taylor, *Trans. Electrochem. Soc.*, Vol. 1, p. 115, 1902; Vol. 2, p. 185, 1902.)

**Phosphorus** is a substance the production of which the use of the electric furnace has much simplified. It is made in the Readman-Parker furnace according to Wöhler's process:

(*Min. Industry*, Vol. 6, p. 537, 1897; Vol. 7, p. 557, 1898.)

**Alundum** is the trade name of fused aluminum oxide, which is made by the Norton Company of Worcester. Aluminum oxide is fused in an electric furnace. (*Min. Industry*, Vol. 10, p. 28, 1910.) Fused alumina is used as an insulator as a refractory substance for furnace linings, and porous crucibles of this substance are used in analytical laboratories.

**Aluminum.** — **Hall and Héroult Processes.** — Aluminum is now produced by the electrolysis of a solution of alumina in fused cryolite ( $\text{AlF}_3 \cdot 3 \text{CaF}_2$ ), to which other fluorides, such as those of aluminum and of sodium, are added in some factories. The aluminum sinks to the bottom of the crucible and is drawn off. This process was discovered nearly simultaneously by C. M. Hall and P. Héroult. The heat developed by the current in passing through the solution is sufficient to keep the bath melted. The cathode is an iron trough lined with carbon, and the anode consists of a number of carbon rods suspended over the crucible. The Aluminum Company of America uses as an anode for one crucible 48 carbon rods, 3 inches in diameter and 15 inches long. The electromotive force applied to each crucible is 5.5 volts; the current is 10,000 amperes. The yield is 100 pounds of aluminum per horse-power day. For further information see (*Min. Industry*, Vols. 6, 14, 15, 17, 20.)

**Sodium, Potassium.** — **Castner Process.** — Sodium and potassium are obtained by the electrolysis of their fused hydrates, usually in the cell devised by Castner (*U. S. Pat. 453,030, filed 1890; see also Becker, Die Elektrometalle der Alkalimetalle*). At Holcomb's Rock, Va., sodium is made by the electrolysis of fused sodium chloride. (*Mineral Ind.*, Vol. 10, p. 614, 1910.)

**Calcium** is made by the electrolysis of fused calcium chloride, to which sodium fluoride is added to lower its melting point. Calcium is made at Holcomb's Rock, Va., probably in a cell devised by Seward and Von Kugelgen (*U. S. Pat. 880,760, 1908; Min. Industry*, Vol. 16, p. 131, 1907; Vol. 17, p. 99, 1908). Abroad by the method of Rathenau (*Z. f. Elektrochem.*, Vol. 10, p. 508, 1904). In the Rathenau method the cathode is an iron rod which just touches the surface of the melted calcium chloride. The calcium solidifies when deposited on the cathode by electrolysis. As the calcium grows the rod is withdrawn and a rod of calcium is produced. (*Trans. Am. Electrochem. Soc.*, Apr., 1920.)

**Zinc** may be made by the electrolysis of fused zinc chloride. In the Burne-Ashcroft process sodium chloride is added to zinc chloride in such a quantity that the resulting mixture contains 28 per cent zinc. The cell is contained in a lined, sheet-iron vessel. The anode is carbon, the cathode, melted zinc. The cell voltage is 4.5 volts, with a cathode current density of 400 amperes per square foot. The temperature of the fused salt is 450° C. (*Electrochem. and Met. Ind.*, p. 65, 1905.)

the electrolysis of fused carnallite ( $MgCl_2 \cdot KCl \cdot 6H_2O$ ) the salt, which is, of course, anhydrous when melted. Magnesium chloride may be used, which is dried in hydrochloric acid (1  $NH_4Cl$  to 1  $MgCl_2$ ) to prevent decomposition. The hydrochloric acid is then removed by volatilization and con-

centrated by electrolyzing fused cerium chloride ( $CeCl_3$ ). Its use is used in gas lighters.

**USE IN METALLURGY.**— Under special local conditions, where coke is expensive and where power production of iron ore is carried out commercially, as at Luleå, Sweden, and at Héroult, California. The furnaces are used in the open position. (For detailed accounts, see volumes cited.)

More recently it has been found better to have the furnace in the closed position. (*VIII Int. Congress App. Chem., Vol. 21, p. 105.*)

It has been tried on a commercial scale with apparent success (see *Met. Eng., Vol. 9, p. 453, 1911*) as well as the smelting of iron (see *Met. Eng., Vol. 11, p. 22, 1913*), and zinc (see *Met. Eng.*). The use of electric furnaces in steel refining and ferro-alloys is much more extensive for in this case they are much cheaper as in the reduction of iron ore.

The steel which is refined in electric furnaces is usually cast in open-hearth furnaces and poured directly into molds. The advantages of the electric furnaces are (*Walker, Met. Eng., p. 371, 1912*):

1. Complete removal of oxygen, which is accomplished by additions, such as silicon manganese, etc.

2. The production of steel ingots of 8 tons and less that are practically perfect.

3. The production of steel of 0.005 per cent if desired, as compared with 0.005 per cent as in the basic open-hearth process.

4. The complete removal of oxygen.

5. The use of electric refining furnaces in use was increased greatly by

the introduction of electric steel refining consists in an improvement in the method of a reduction of costs. While in 1911 it was common to melt and refine steel scrap in six hours at 750 kilowatts, the operation is now carried out in four hours with 1,000 kilowatts. (*VIII Int. Cong. of App. Chem., Vol. 21, p. 50.*)

The types of furnaces used in steel refining are the following:

(Fig. 7).— This furnace consists of a closed vessel connected to a three-phase system above the metal. The electrodes are used to stir all of the metal. This furnace is used in the open position. (*Met. and Chem. Eng., Vol. 10, p. 66.*)

(Fig. 8).— This furnace consists of a crucible lined with carbon. Two carbon electrodes project into it through the roof. The current passes from each electrode into the slag. The position of the electrical automatic regulator which moves the electrodes is adjusted as required.

to the slag-gate and  
a moves the electrodes

**Grid Steel Furnace.**— This furnace consists of a crucible with soft-steel rods projecting through the base. These form one electrode;

Fig. 7.

Fig. 8.

is one or more carbon rods suspended from above. The steel electrode course melt several inches below the surface of the refractory lining of the crucible. The furnaces are sold by C. W. Leavitt and Co., 30 Chambers Street, New York, from whom the following data have been obtained.

These furnaces require from 65 to 70 volts at frequencies from 25 to 30 cycles per second. The power factor is about 80 per cent and the duration of heat when a charge is charged in the melted state is  $1\frac{1}{2}$  to  $2\frac{1}{2}$  hours. The number of electrodes are from 1 to 3, according to the capacity of the furnace. For a furnace of 12 tons capacity, the maximum power required is 1200 kilowatts at the terminals of the electric generator; the energy consumption when metal is charged cold is 900 kilowatt hours per ton of steel; with a melted charge it does not exceed 5 amperes per square inch of cross-section. The number of consecutive heats possible without repairs is:

	Linings	Cover	Electrodes
With cold charge.....	30 to 40	20 to 30	
With melted charge.....	60 to 90	40 to 50	

To handle the furnace 6 persons are necessary: a melter, 2 assistants, 2 workmen and a boy.

**Other Arc Furnaces** more or less similar to the Héroult furnace are the Keller furnace (*Trans. Am. Electroch. Soc.*, Vol. 15, p. 96, 1909), the Naylor furnace (*Met. and Chem. Eng.*, Vol. 10, p. 227, 1912) and the Snyder furnace (*Trans. Am. Electroch. Soc.*, Vol. 28, pp. 221-230, 1915).

**Induction Furnaces.**— Induction furnaces are transformers in which a ring of steel is the secondary. The Kjellin furnace, Fig. 9, consists of a single deep ring of metal. It has only a small area of contact between the metal and slag, and the slag is not easily heated. The use of this furnace is

 At the Keller-Leleux works at Livet it has been  
 20 tons of 30 per cent ferro-silicon with 4000 horse-

power during a day. (See preceding reference.) For an account of the other ferro-alloys, see *Electrochem. Ind.*, Vol. 1, p. 583, 1903; *E. and Met. Ind.*, Vol. 4, p. 237, 1906.

**Brass Melting.**— Electric furnaces are now used to a considerable brass melting. (*St. John., H. M., Electric Brass Melting, Elec. J. Sept.*, 1919.) Some of the types of furnaces used are the Borth furnace (*Trans. Am. Electroch. Soc.*, Vol. 33, p. 247, 1918); the furnace (*Met. and Chem. Eng.*, Vol. 12, p. 275, 1914; *Trans. Am. Soc.*, Vol. 29, p. 497, 1916; Vol. 31, p. 87, 1917); and the Helberg (*Met. and Chem. Eng.*, Vol. 12, p. 644, 1914).

**FIXATION OF ATMOSPHERIC NITROGEN.**— One of the important applications of the electric furnace is the fixation of atmospheric nitrogen. The various processes employed are described below.

**Carbide Method.**— In this method calcium carbide is heated with nitrogen, forming calcium cyanamide according to the reversible reaction

The carbide is heated in iron drums by a thin carbon conductor running through the center of the drum. Heat is evolved by the reaction. The product is called "nitro-lime" or "lime-nitrogen," and contains 12 to 15 per cent nitrogen (*Met. and Chem. Eng.*, Vol. 5, p. 78, 1907.) It is used directly as a fertilizer or may be converted into ammonia by superheated steam. The yield of ammonia by the carbide method is about 51.6 grams per kilowatt hour, including the manufacture of the carbide.

**Direct-Oxidation Method.**— In this method the nitrogen and oxygen in air are caused to combine in a high-voltage arc according to the reaction

On cooling the NO is further oxidized to nitric dioxide. The nitric dioxide, on treatment with water gives nitric and nitrous acids:

Only about 1 to 3 per cent of the air treated is oxidized. The yield in the Birkeland-Eyde furnace is 12.7 grams of nitrogen fixed per kilowatt hour. (*Faraday Soc.*, Vol. 2, p. 98, 1906.) Furnaces of three different designs are now in operation for oxidizing nitrogen: that of Birkeland and Eyde, that of Schönherr, and that of H. and G. Pauling.

**Direct Synthesis of Ammonia.**— In this method, due to Haber, ammonia is formed directly from a mixture of nitrogen and hydrogen by passing the mixture over a catalyzer between 500° C. and 700° C. at 200 atmospheres, according to the reversible reaction

(*Zeit. f. Elektroch.*, Vol. 16, p. 244, 1910; Vol. 19, p. 53, 1913.) The details of this process has not been made public.

**Bucher Process.**— This process was discovered in 1846 by Lewis (Bucher, *Am. Inst. Chem. Eng.*, Vol. 9, p. 335, 1916) and is represented by the following reaction:

which requires metallic iron as catalyzer. The temperature is between 1000° and 1050° C. Many attempts have been made to use this process, but

on. A plant was built at Saltville, Va., to make  
nts. The furnaces were 8-inch iron tubes heated  
he reacting mixture is finely ground, briquetted hot  
n treated with nitrogen. See also Ferguson and  
*Chem.*, Vol. 11, p. 946, 1919; Posnjak and Merwin,  
Vol. 9, p. 28, 1919.

his process aluminum nitride is made by heating  
nd nitrogen together. On heating the aluminum  
s and aluminum hydrate are formed. The product  
s said to contain 20 to 24 per cent of nitrogen, and  
of nitrogen is said to be only one-half of that used  
od. (*Bull. de la Soc. ind. de Mulhouse*, Vol. 79,  
1932, 1911.)

**FUSES.**—(See also *Circuit Breakers; Wiring of Buildings.*) Metal wires which open electric circuits by melting or fusing when the current reaches a predetermined value are called fuses. They were used in the earliest plants to furnish automatic protection for feeder and generator circuits and use is now confined largely to low-voltage distribution circuits and protection of small pieces of apparatus such as motors and small transformers.

All fuses have an inherent time-element feature due to the fact that the current must heat the fuse metal up to its melting temperature. This varies with the size and type of fuse, the large ones in general taking longer to reach their fusing temperature than the smaller sizes, due to their greater capacities. There are three designs of fuses in general use, namely, the open, the link, the expulsion, and the enclosed or cartridge types. The choice depends upon the service for which the fuse is intended.

**RATING OF A FUSE.**—The rating of a fuse depends somewhat upon its type and general design. Fuses will, as a rule, carry their normal rating indefinitely but will blow at a certain overload varying from 10 per cent to 100 per cent in an enclosed fuse to about 80 per cent in an open fuse if the overload continues for a sufficient length of time. For greater overloads the length of time before blowing diminishes rapidly.

**OPEN OR LINK FUSES** were the original type of automatic protection. The early ones were small copper wires and had the drawback of forming globules and of possessing a high fusion temperature. In order to reduce the temperature of the molten metal there were employed alloys of low fusion temperature made of lead, tin, or other metals. These fuses were soft and were often damaged when tightening up the contact nuts. The next step was to use fuses with copper tips, and these are still used to some extent.

As the price of aluminum was reduced this material was used for open fuses as it has a high conductivity (thus reducing the amount of metal that must be fused), a fairly low melting point and almost complete vaporization of the metal when fused. By using wide strips of aluminum cut to form two or more parallel strips, fairly reliable open fuses can be made up to 1200 amperes capacity.

Any metal strip which is exposed to drafts is apt to be very erratic in its behavior as a fuse. To protect link fuses from drafts, and also to avoid the danger from molten metal which may be thrown at the time of blowing, it is desirable to install them in porcelain fuse boxes.

**EXPULSION FUSES** consist essentially of open fuse wires or strips held in a holder, so designed that the expulsion of the gases formed by the melting of the fuse blows out the arc. The earliest designs of this type consisted of a removable fuse holder of lignum vitæ or similar tough, close-grained material, equipped with terminals which fitted into suitable blocks. Later types of fuses had the fuse placed in a fiber tube and arranged to blow out through one end like a bomb.

The fuses used for the protection of distributing transformers and for street lighting poles or houses are usually of the expulsion type. For such outdoor use a combination fuse and disconnecting switch is frequently used. Most of the expulsion-type fuses were formerly used to advantage in railroads, but in recent car equipments circuit breakers have practically replaced fuses and cut-outs.

**ENCLOSED OR CARTRIDGE FUSE.**—This type of fuse consists essentially of a fusible wire, strip or sets of wires and strips enclosed within a fiber or cartridge usually of fiber. The tube is filled with a material to ex-

ing of the circuit when the fuse blows by absorbing  
out the arc. Suitable terminals are provided so  
ed in a fuse block.

**Fuses.** — When inclosed fuses were first put on  
r developed his own spacings and designs of termi-  
niformity and the fuse of one manufacturer could  
of another manufacturer. To avoid this confusion,  
e builders and the National Board of Fire Under-  
standard dimensions and types of contacts given in  
to 60 amperes ferrule type contacts (i.e., cylindrical  
m 61 to 600 amperes knife-blade contacts are em-  
ons are used for fuses up to 250 volts and another  
Fuses that correspond to the accepted dimensions  
ments agreed on are known as National Electrical  
re interchangeable. Fuses are made for higher  
larger currents than 600 amperes, but they have  
National Board of Fire Underwriters.

9	$2\frac{1}{4}$	$\frac{1}{4}$	$2\frac{1}{4}$	3	2

**Cost of N. E. C. Fuses.** — In moderate quantities of standard sizes the price of 30-ampere 250-volt fuses is about 21 cents each, 15-ampere 600-volt fuses about \$4.65 each. The others fall between these figures.

**Plug Fuses.** — A plug fuse is a fuse mounted in a plug of the Edison-lamp base dimensions. They are in common use on lighting circuits up to 30 amperes capacity. The outer face of the plug is covered with mica which is discolored by the blowing of the fuse. A mica cover is also sometimes used as a cover.

**RENEWABLE FUSES.** — The standard enclosed fuse when blown has usually to be returned to its manufacturer for refilling. Some fuses have been designed that fit in the standard N. E. C. fuse blocks arranged so that the fuse elements can be readily renewed. These have been accepted by the National Board of Fire Underwriters.

For high voltage work fuses have been made using carbon tetrachloride or some similar liquid to extinguish the arc when the fuse blows.

**SPECIFICATIONS FOR FUSES.** — The following memoranda are suggested to assist in writing specifications. See also articles on Specifications for Fuses.

Open or inclosed. Wire or ribbon. Current to blow fuse in a specified time. To blow without violence at a stated current. Voltage of circuit at which to blow.

**METAL.** — (See also *Copper; Gages, Wire; Iron,*  
are two principal gages for sheet iron and steel used in  
established by Act of Congress in 1893 and the other  
committee of the American Society of Mechanical  
an Railway Master Mechanics Association.

. — The former gage, which is known as the U. S.  
on the fact that a cubic foot of iron weighs 480 pounds.  
been arranged so that each gage number represents  
s in weight, or an equal number of 640ths of an inch  
used for determining duties and taxes levied on sheet  
and in its application a variation of  $2\frac{1}{2}$  per cent either

latter gage, which is known as the Decimal Gage, is  
but upon the thickness of the metal. Each number  
of thousandths of an inch of thickness. This gage  
by the Association of American Steel Manufacturers,  
Master Mechanics' Association, and by most of the  
United States, Canada and Mexico. The decimal  
recommended by the American Institute of Mining Engi-  
American Society of Mechanical Engineers in 1895.

ge. — Copper and brass plates are rated by the Brown  
te thicknesses on this gage correspond to the diameters  
ge. (See *Gages, Wire.*)

The sizes of wires having a diameter of certain arbitrary scales of wire refers to the cross-sectional area of a wire, irrespectively of the diameter of the wire, usually described in terms of circular mils is equal to the area of a circle whose diameter is the diameter of the wire.

**Conversion Factors.**  
The following are the conversion factors.

**WIRE GAGE.** — This gage is used for copper, aluminum and steel. The abbreviations A. W. G.

The diameter of wires having a diameter of regular gage size with an area of  $\sqrt[3]{92}$  ( $= 1.1229$  approx.) of No. 35 A. W. G., therefore, until No. 0000 is reached,

which is 1.1225. This circumference of regular gage size with an area of regular gage size.

Resistance 25 per cent.  
Resistance 60 per cent.  
Resistance 100 per cent.  
Resistance 10 times.

Approximate size, resistance, weight, etc. of 12 A. W. G. copper wire has 1000 feet approximately. Its diameter is 50 circular mils; its diameter

is 20 pounds per 1000 feet.

It is known also as the "Washburn and Moore Wire Co.'s" gage, is used for steel and iron wire. It is often in confusion with the British gage, abbreviated "Stl. W. G." or "A.

## BROWN AND SHARPE GAGE FOR COPPER AND BRASS PLATES

\* The specific gravity of copper plate is taken as 8.89 and of brass plate as 8.4

**BIBLIOGRAPHY.**—*Report of Committee on Standard Thickness Gage Metals*, Trans. A.S.M.E., 1895, Vol. 16, p. 641; *Report of Committee on Standard Gages*, Proc. Am. Ry. Master Mech. Assn., 1895, p. 149.

See also *Gages, Sheet Metal*.) The sizes of wires having which are usually stated in terms of certain arbitrary scales. The size or gage number of a solid wire refers to the cross-section perpendicular to its length; the size or gage number of a rope refers to the total cross-section of the constituent wires, irrespective of spiraling. Larger wires are usually described in terms of circular mils. A circular mil is the area of a circle whose diameter is 1 mil. The area of any circle in circular mils is equal to the square of its diameter in mils. See *Units and Conversion Factors*.

Of wire gages in use, the principal ones being the following.

**BROWN AND SHARPE WIRE GAGE.** — This gage is used in the United States for copper, aluminum and iron wire. It is designated by either of the abbreviations A. W. G.

**A. W. G. or B. & S. Gage.** — The diameter of wires having which are in the ratio of  $\sqrt[3]{92}$  ( $= 1.1229$  approx.) to the diameter of the next larger size. No. 35 A. W. G., therefore, has a diameter of 5 mils. No. 36 A. W. G., therefore, has a diameter of  $5 \times 1.1229 = 5.61$  mils and so on until No. 0000 is reached, which has a diameter of 0.0008 mils.

The diameter of wires having which are approximately equal to  $\sqrt{2}$ , which is 1.4142. This circumstance has the advantage of having a group of wires of regular gage size with an area approximately equal to that of another regular gage size. The following approximate relations are also useful:

The number of wires increases the resistance 25 per cent.

The diameter of wires increases the resistance 60 per cent.

The length of wires increases the resistance 100 per cent.

The number of wires increases the resistance 10 times.

Copper wire has the following approximate characteristics:

Weight per 1000 feet .....	1
Resistance per 1000 feet .....	10,000
Resistance per 1000 feet .....	32

Aluminum wire has the following approximate characteristics:

Weight per 1000 feet .....	1.6
Resistance per 1000 feet .....	10,000
Resistance per 1000 feet .....	9.5

By using these tables it is easy to find the approximate size, resistance, weight, etc. of a wire. For example, a No. 12 A. W. G. copper wire has a resistance of 16 ohms per 1000 feet approximately. Its weight is 1.6 pounds per 1000 feet. Its resistance, is  $\frac{10,000}{1.6} = 6250$  circular mils; its diameter is  $\sqrt{6250} = 79.1$  mils and its weight,  $\frac{32}{1.6} = 20$  pounds per 1000 feet.

**STEEL WIRE GAGE.** — This gage, known also as the "Washburn & Moench," "American Steel and Wire Co.'s" gage, is used in the United States for steel and iron wire. It is designated by the letters "S. W. G.," but to avoid confusion with the British Standard Wire Gage (see below) it should be abbreviated "Stl. W. G." or "A. S. W. G."

**BIRMINGHAM (OR STUBS') WIRE GAGE.**—This gage used in the United States for some purposes, e.g., to designate the size wire, and is also employed to a limited extent in Great Britain. It is abbreviated "B. W. G." It is sometimes referred to as the "Stubs' but it should not be confused with the Stubs' Steel Wire Gage.

**BRITISH STANDARD WIRE GAGE.**—This gage, usually simply the "Standard Wire Gage," and abbreviated "S. W. G.," is also as the "New British Standard" (abbreviated "N. B. S."), the English Standard, or the Imperial Wire Gage, and is the legal standard of Great for all wires, as fixed by order in Council, August 23, 1883. It was come by modifying the Birmingham Wire Gage, so that the differences between sive diameters were the same for short ranges, i.e., so that a graph repre the diameters consists of a series of a few straight lines.

**EDISON WIRE GAGE.**—The size of a wire on this gage is its cross-sectional area in circular mils divided by 1000. For example wire 0.2 inch in diameter has the number  $(200)^2/1000 = 40$ . This gage rarely used.

**OTHER GAGES.**—In addition wire sizes are sometimes specified of the "Old English Wire Gage," known also as the "London Gage," "Stubs' Steel Wire Gage."

**COMPARISON OF WIRE GAGES.**—A comparison of the gages, in terms of the diameters (in mils or thousandths of an inch) wires corresponding to the various numbers, is given below. The cross in circular mils is the square of the diameter in mils.

### COMPARISON OF WIRE GAGES

**GALVANIZING FOR IRON OR STEEL, Specification for Acceptance Test.**—These specifications give in detail the test to be applied to galvanized material, as recommended by the Electric Railway Engineering Association, the National Electric Light Association, etc. All specimens shall be capable of withstanding these tests.

(a) **Coating.**—The galvanizing shall consist of a continuous coating of zinc of uniform thickness, and so applied that it adheres firmly to the surface of the iron or steel. The finished product shall be smooth.

(b) **Cleaning.**—The samples shall be cleaned before testing, first with kerosene, benzine or turpentine, and cotton waste (not with a brush), and then thoroughly rinsed in clean water and wiped dry with clean cotton waste.

The sample shall be clean and dry before each immersion in the solution.

(c) **Solution.**—The standard solution of copper sulphate shall consist of commercial copper sulphate crystals dissolved in cold water, about in the proportion of 36 parts, by weight, of crystals to 100 parts, by weight, of water. The solution shall be neutralized by the addition of an excess of clean pure cupric oxide (CuO). The presence of an excess of cupric oxide shall be shown by the sediment of this reagent at the bottom of the containing vessel.

The neutralized solution shall be filtered before using by passing through filter paper. The filtered solution shall have a specific gravity of 1.186 at 65° F. (reading the scale at the level of the solution) at the beginning of the test. In case the filtered solution is high in specific gravity, clean water shall be added to reduce the specific gravity to 1.186 at 65° F. In case the solution is low in specific gravity, filtered solution of a higher specific gravity shall be added to make the specific gravity 1.186 at 65° F.

As soon as the stronger solution is taken from the vessel containing the filtered neutralized stock solution, additional crystals and water must be added to the stock solution. An excess of cupric oxide shall always be kept in the unfiltered stock solution.

(d) **Quantity of Solution.**—Wire samples shall be tested in a glass jar at least two (2) inches inside diameter. The jar without the wire samples shall be filled with standard solution to a depth of at least four (4) inches. Hardware samples shall be tested in a glass or earthenware jar containing at least one (1) pint of standard solution for each hardware sample. Solution shall not be used for more than one series of four immersions.

(e) **Samples.**—Not more than seven wires shall be simultaneously immersed, and not more than one sample of galvanized material other than wire shall be immersed in the specified quantity of solution.

The samples shall not be grouped or twisted together, but shall be separated so as to permit the action of the solution to be uniform upon all portions of the samples.

(f) **Test.**—Clean and dry samples shall be immersed in the required quantity of standard solution in accordance with the following cycle of immersion.

The temperature of the solution shall be maintained between 62° and 68° F. at all times during the following test.

First. Immerse for one minute, wash and wipe dry.

Second. Immerse for one minute, wash and wipe dry.

Third. Immerse for one minute, wash and wipe dry.

Fourth. Immerse for one minute, wash and wipe dry.

After each immersion the samples shall be immediately washed in clean water having a temperature between 62° and 68° F., and wiped dry with clean cotton waste.

4 galvanized iron or steel wire, the time of the fourth  
ced to one-half minute.

after the test described in section "f" there should be  
r deposit upon the samples, the lot represented by the  
d.

inc or within one inch of the cut end shall not be con-  
sion.

re of only one wire in a group of seven wires immersed  
a reasonable doubt as to the copper deposit, two check  
these seven wires and the lot reported in accordance  
e sets of tests.

**GALVANOMETERS.** — (See also *Ammeters; Electrodynamometer; Voltmeters.*) The essential parts of a galvanometer are a permanent magnet (electromagnet in Einthoven String Galvanometer, see below) and a coil or wire designed to carry an electric current, the magnet and coil so mounted that the passage of the current through the coil causes a deflection of either the coil or the magnet, as a result of the mechanical action with which the current and magnet act on each other. See *Electricity, Principles of*. Ordinary direct-current ammeters and voltmeters are operated on the same principle, but the term galvanometer is usually reserved for instruments designed for measuring relatively small currents, the deflection being read either by means of a telescope and scale or by means of a mirror and scale. In portable test set galvanometers the deflection of a pointer

**Moving-needle versus Moving-coil Galvanometers.** — Galvanometers in which the moving element is the permanent magnet, in the form of a needle, are called needle galvanometers, whereas those in which the moving element is the coil are called moving-coil galvanometers. The former type of galvanometer is required when extreme sensitiveness is desired, but as a rule is not used in a commercial laboratory, on account of the disturbances of the magnetic fields due to the lighting and power circuits in the laboratory and in neighboring buildings. Railway circuits, even though some distance away, may produce a disturbing field sufficient to render impossible the use of a sensitive needle galvanometer. For ordinary laboratory work, the moving-coil galvanometer can be made sufficiently sensitive, and permanent magnets used to produce the controlling field can be made so strong, the effect of stray fields can be rendered relatively negligible.

**Astatic Galvanometer.** — The disturbing effect of stray magnetic fields on a needle galvanometer can be partially prevented by the use of two stationary coils and two needles, or the equivalent, the two needles being arranged that any external field will produce opposing torques, and so connected that their torques are additive. The Broca galvanometer described below, is a modern type of astatic instrument.

**Damping and Logarithmic Decrement.** — Due to the mechanical resistance to motion and the induced currents set up in the adjacent metal or coil of the instrument as a result of the motion of the moving element, successive swings of the moving element when it is once set in motion decrease in amplitude. This effect is known as damping. Successive swings from the zero or equilibrium position decrease approximately in geometric ratio. Hence the logarithm of one swing to the logarithm of the next swing, to either side of the zero, is approximately a constant. This constant, which is a measure of the damping, is called the logarithmic decrement of the instrument.

**Ballistic Galvanometer.** — A ballistic galvanometer is one in which the moving element has a relatively long period and small damping. It is shown that when a quantity of electricity  $Q$  is discharged through such a galvanometer in an interval of time very short compared with the period of the galvanometer, then the first throw or swing of the moving element is approximately proportional to the quantity of electricity  $Q$ . Such an instrument serves as a very convenient means of measuring the capacity of a condenser (see *Capacity and Charging Current; Condensers, Electric*) as well as for measuring the quantity of electricity discharged through a circuit by transient electromotive forces (see *Magnetic Testing*).

**Effect of External Resistance on Damping.** — Since the damping of a galvanometer is due in part to the currents induced in the coils of the instrument by the motion of the moving element, and since these currents dep-

considerable size are used, they are placed so close together that the system has a very small moment of inertia. A small mirror is located below the coil system and below this an aluminum damping vane that moves in a fluid of the size of which can be varied, thus changing the damping. The vane is suspended by a quartz fiber which serves as a control for the system. The main control is obtained by a movable permanent magnet on the back of the instrument. The stationary coils are made interchangeable and vary in resistance from 10 ohms to 1000 ohms per pair.

Either lamp and scale or telescope and scale can be used to read the deflection of this galvanometer. In the latter case the scale must be brilliantly illuminated owing to the small size of the mirror.

The resistance of this galvanometer can be varied by connecting the coils in parallel or series or by substituting coils of different resistances. To vary the damping two rods on either side of the instrument case are

Fig. 1. Broca Galvanometer System

Fig. 2. D'Arsonval Galvanometer

or pulled out as required, to increase or decrease the size of the damping chamber. The period is changed by changing the position of the control magnet in reference to the system.

In the following table is given the sensitiveness of the instrument for various periods and resistances.

Resistance of coils in series in ohms	Period in seconds	Deflection in mm. at 1 m.	
		For 1 micro-ampere	For 1 micro-volt
10.9	8	218	19.9
107	12	1190	11.1
935	11	2450	2.62

**D'Arsonval Galvanometers.** — For the great majority of electrical measurements requiring galvanometers the D'Arsonval types, of which there are many forms, are the most satisfactory. Fig. 2 shows a typical form of construction suitable either for mounting on the wall or on a tripod. This galvanometer has for its frame an iron casting which also serves as the permanent magnet and to hold the upper suspension tube. In the wall type this magnet is attached to a backboard holding the telescope and scale and the scale.

with copper wire, free from iron and suspended from  
of phosphor bronze, silver or steel, which also serves  
coil. The other terminal is in the form of a spiral of  
strip brought off from the bottom of the coil. The  
or and the entire moving system is visible through a  
al plate that covers the front of the magnet casting,  
movable. The deflection is read by a telescope and  
so that the scale reading will be closely proportional

gives the approximate sensitiveness of galvanometers of  
il resistance and period.

#### METERS PER MICRO-AMPERE

Galvanometer resistance			
Resistance (ohms)	300 ohms	500 ohms	1000 ohms
100	150	200	300
200	300	450	600
300	500	650	800

galvanometers of a slightly different form, having a sensitiveness  
the above, are on the market. Portable galvanometers,  
sensitiveness (0.5 to 10 micro-amperes per smallest scale  
division) are used in connection with thermo-couples and for measuring

**Einthoven string galvanometer.** — The Einthoven string galvanometer,  
which is shown in Fig. 3, is essentially a moving-coil  
galvanometer. The conductor which moves is  
a fine silver wire. The poles of a power-  
ful magnet are the poles of a power-  
ful magnet. The fine conducting "string"  
is suspended in a narrow air gap between the poles  
of the magnet. When a current is passed  
through the string, it deflects at right  
angles to the field of the electromagnet as indicated  
in the diagram. This deflection is observed by  
projecting an enlarged image of the string  
on a screen by means of a projection lantern, or the deflection  
is recorded on a photographic plate.

Fig. 3. Einthoven String Galvanometer

relatively large and the pole faces are so shaped that  
the string is secured in the narrow air gap in which the  
magnetic circuit is always fully saturated so that small  
currents do not affect the flux density in the air gap.  
The string may be an extremely fine silver wire or a silvered quartz  
fiber, which is adjustable by means of a micrometer  
screw. The period depends on the tension on the string and  
may vary from 5 ohms to 10,000 ohms, depending on  
the tension. The period may be increased to 8 or 10 seconds  
by increasing the resistance in sensibility.

gives the characteristics of some Einthoven string gal-  
vanometers. Cambridge Scientific Instrument Company, when used

## CHARACTERISTICS OF EINTHOVEN STRING GALVANOMETER

Material of string	Diameter of string	Resistance in ohms	Period in seconds	Magnifying power of microscope	Deflection in mm.	
					Per micro-amp.	Per micro-amp.
Silver wire.....	0.02 mm.	4.7	.....	500	4.4	
	0.002 mm.	20,000	.....	500	62,500	
Silvered quartz fiber.....	0.003 mm.	6,600	.....	650	333,000	
	0.002 mm.	5,800	0.008	750	30	
	0.002 mm.	3,890	0.005	750	9.7	

\* These are apparent deflections as observed through the microscope. For in the case of the galvanometer having the constants given in the third line, deflection is  $333,000/650 = 512$  mm. per micro-ampere. An apparent deflection  $\frac{1}{8}$  mm. can be detected by the eye, consequently with this particular galvanometer a current of  $10^{-8}/3 \times 333,000 = 10^{-11}$  amperes, approximately, may be detected.

**Vibration Galvanometer.** — The Einthoven galvanometer may also be used as a vibration galvanometer for detecting an alternating current. If an alternating current is sent through the string and the tension on the latter is so that the free period of the string is the same as the period of the current, the string will be set in vibration, the amplitude of the vibration depending on the strength of the current. Consequently when the instrument is thus used it may be used as a detector of extremely minute alternating currents, thus used the instrument is capable of detecting an alternating current of extremely small amperes, effective value.

A moving coil galvanometer may also be used as a vibration galvanometer by providing means for adjusting the free period of the moving element to resonance with the period of the current to be measured. Fig. 4 shows such a galvanometer, the free period being adjusted by moving the movable bridge up or down.

**Marine Galvanometers.** — Any galvanometer that will give deflections that are not affected by the rolling of a ship and consequently can be used on shipboard may be called a marine galvanometer. A common form of marine galvanometer is of the D'Arsonval type with the coil held by suspensions, both above and below, that are stretched under considerable tension.

The moving system of the galvanometer is carefully balanced, so that a 30-degree inclination will not cause a deflection of more than 3 mm. with the scale at 1 meter distance. It has a very stable zero and a sensitivity of 10 to 20 millimeters per micro-ampere with a 3-second period.

Fig. 4. Vibration galvanometer.

**USE AND CALIBRATION OF GALVANOMETERS.** — Galvanometers, other than ballistic, are used in engineering work primarily as detectors in various bridge (q.v.) and potentiometer (q.v.) measurements.

is usually unnecessary. In order to determine such measurements, however, the sensitiveness of the galvanometer is known. This may be determined by connecting a known e.m.f. across a known small fraction of this resistance, and connecting a known or previously measured, the current through the galvanometer can be calculated by Kirchhoff's laws (*see Electricity*), and consequently the millimeters deflection of the galvanometer. If the sensitiveness of the galvanometer is too low for a measurement, it may be reduced by properly shunting the galvanometer.

**Galvanometer.** — The ballistic galvanometer is used for the determination of the magnetic moments of iron or steel (*see Magnetic Testing*). One charges a standard condenser to a known voltage, discharges it through the galvanometer, noting the deflection, and repeating the experiment at various voltages. As the capacity of ordinary standard condensers is small, the time of charging (*see Condensers, Electric*), is long, and the rate of charging is slow.

**Solenoid.** — A better method is to use a standard solenoid. The solenoid should have a length about 50 times its diameter. The solenoid is wound with No. 18 A.W.G. double-cotton-covered copper wire carefully wound upon a cylindrical core of red fiber approximately 1/2 inch in diameter. (A convenient way of winding such a solenoid is to use a small thread in the core of such a pitch that the spaces between the threads will lie up snug.) A second solenoid of No. 36 A.W.G. double-silk-covered wire was wound in a length of 12 inches, at the middle of this coil.

The primary coil of this solenoid in series with an adjustable resistance and a source of constant e.m.f. Connect the secondary coil of the solenoid to the galvanometer. Let

$l$  = length of the primary coil,

$I_1$  = current in amperes in the primary coil,

$I_2$  = current in the secondary coil,

$R$  = resistance of the secondary coil, galvanometer and any other resistance in the secondary circuit,

$A$  = area of the mean cross-section of the primary coil.

When the primary coil is reversed a quantity of electricity

$Q = \frac{4 \times 8 \pi n_1 I_1 A N_2}{10^9 R}$  coulombs

$$Q = \frac{4 \times 8 \pi n_1 I_1 A N_2}{10^9 R} \quad \text{coulombs}$$

$$Q = \frac{638 n_1 I_1 A N_2}{R} \quad \text{microcoulombs}$$

When the primary coil is reversed a quantity of electricity  $Q$  is sent through the galvanometer. Hence, by calculating  $Q$  and noting the deflection of the galvanometer when currents of various strengths are reversed in the primary coil, a curve can be plotted giving the quantity of electricity corresponding to each deflection value; such a curve will be approximately a straight line.

**Broca galvanometer.** — A Broca galvanometer costs from \$40 to \$50. A D'Arsonval galvanometer costs from \$18 to \$25. An Einthoven galvanometer costs from \$100 to \$150.

\$400 to \$500. Vibration galvanometer (type shown in Fig. 4) cost about \$110.

*Combustion Engines; Gas Producers.*) The word means a substance which is capable of indefinite use in a restricted sense to mean any mixture of gas or for fuel. It is in this sense that the word

is given to thousands of cubic feet, at 60° F. and at a pressure of one atmosphere. The term "permanent" or "fixed" gas is used to denote a gas which does not precipitate any of its constituents when cooled.

In addition to natural gas, which exists in limited quantities (in this country, chiefly in western Pennsylvania, Indiana, Kansas, Texas and California), there are several other types of gas. These various types all contain the same elements in different proportions, depending upon the process of production from which they are made. Gas may be made from either solid or liquid fuel, but coal is the fuel usually employed.

Water-gas is given to the mixture of permanent gases resulting from the distillation of retorts of the volatile matter in coal. The heavy hydrocarbons and impurities are extracted by cooling and "washing" with water. The gas is purified by passing through purifiers containing hydrated lime or sesquioxide of iron. The residue left in the retorts is coke; the condensed hydrocarbons and sulphur compounds and cyanogen are absorbed in water. The gas is a valuable by-product of value.

Water-gas is used for illumination, but in this country carburetted water-gas is more extensively employed for this purpose. Coal-gas is not used for illumination on account of its high manufacturing cost as compared with water-gas (see below), which, though unsuitable for illumination, is a very good fuel for gas engines.

Water-gas is given to the mixture of permanent gases resulting from the decomposition of steam which takes place when steam is passed through a body of red-hot iron or iron oxide. The chief reaction is that of the decomposition of the steam by the heated carbon, producing carbon monoxide, the reaction being  $C + H_2O = CO + 2H_2$ . The gas is a valuable by-product of the process, hence the production of water-gas is interdependent upon the production of coal-gas. The chief reactions are: (1) the "blowing up" or heating the fuel bed with air, producing  $CO_2$  by the reaction  $C + 2O = CO_2$ ; (2) the production of water-gas by blowing steam through the fuel bed, the steam being shut off. Water-gas is generally made from iron or iron oxide, not only hydrogen and carbon monoxide, but also contains nitrogen and light hydrocarbons. Pure water-gas is not a good illuminant, since it is deficient in the heavy hydrocarbons which are necessary for illumination. This defect is readily supplied by the addition of coal-gas to the water-gas as it comes from the producer and superheated steam; the naphtha vapor and the superheated steam are added to the permanent gases of the hydrocarbon group. Water-gas is called "carburetted water-gas" and forms an excellent illuminant. The greater proportion of illuminating gas is carburetted water-gas, but carburetted, is seldom used for power purposes,

The same name is given to the mixture of permanent gases resulting from the reactions which take place when air is blown over a bed of coal. At the bottom of the bed, where the air is in contact with the coal, it is reduced on passing through the upper part of

the bed to CO by the reaction  $\text{CO}_2 + \text{C} = 2 \text{CO}$ . The resulting gas also contains hydrogen, resulting from the reaction between the moisture in the coal and hot carbon, this reaction being the same as in the production of water-gas. Nitrogen of the air is also present in the gas, forming more than half of the volume, thereby making a very dilute or "lean" gas. This process has been described by the producer-gas process described below.

**Producer Gas.**— This name is given to the mixture of permanent gases resulting from the chemical reactions which take place when both steam and air are blown through a bed of hot coals. The gas is essentially a mixture of water-gas and Siemens gas. The process is a continuous one, enough air being blown with the steam to maintain the producer bed at the proper temperature, thus eliminating the "blowing up" operation in the water-gas process; and, by the presence of the steam and the reactions which take place between steam and carbon, the proportion of hydrogen is increased and the proportion of carbon monoxide decreased, thus making a gas "richer" than Siemens gas. The exact composition of producer gas depends upon the kind of fuel used and the type of producer of which there are numerous forms (see *Gas Producers*). The gas from a particular form of producer is frequently called by the name or type of producer, for example, "Mond gas," "Dowson gas," etc. Producer gas is used in power plants employing large gas engines; it is also used for firing cement kilns and metallurgical furnaces, and, to a limited extent, for firing steam engines.

The thoroughness with which the gas must be cleaned depends upon the purpose for which it is to be used. For gas-engine work, it is particularly important that no tar should be present. On this account, anthracite coal is used for the production of the gas for this purpose, in spite of the relatively high cost of such coal.

On the basis of the average figures from both the Bureau of Mines and commercial plants, the following gas yield and heating value are expected per ton (2000 pounds) of fuel as fired.

Fuel	Cubic feet of gas per ton of fuel as fired	B.t.u. per cubic foot of gas	B.t.u. per ton of gas
Charcoal.....	160,000	135	21,600,000
Anthracite.....	140,000	135	18,900,000
Bituminous coal.....	135,000	150	20,250,000
Lignite.....	72,000	155	11,160,000
Peat.....	60,000	175	10,500,000

**Other Kinds of Gas.**— "Oil-gas" is a mixture of gases resulting from the vaporization of crude oil and superheating the vapor; it is used to illuminate and for other illuminating qualities of water-gas. "Coke-oven gas" is the gas formed as a by-product in coke ovens. Its properties are intermediate between water-gas, coal-gas and Siemens gas; the composition of the gas, however, varies with the kind of coal and with the time, changing from the beginning to the end of the process. "Oil-water gas" is produced by the chemical reactions between steam and oil heated to a high temperature in closed retorts. The cost of this gas is low where oil is cheap. "Blast-furnace gas" is a waste product of the blast-furnaces, and is a mixture of CO, CO<sub>2</sub> and N<sub>2</sub>, the latter being the largest constituent. The relative proportions of CO and CO<sub>2</sub> vary with the composition of the furnace. An average analysis of blast-furnace gas cooled to at

), 10 per cent  $\text{CO}_2$ , 65 per cent N. Coke-oven gas, producer-gas are all suitable for use in gas engines.

**HEATING VALUE.** — The calorific or heating value (see page 614) of a given quantity of gas is the heat energy developed by its combustion. In this country, the calorific value of a gas is expressed in British thermal units per cubic foot, the volume being measured at  $60^\circ \text{F}$ . and 30 inches of mercury. The total heating value of the gas from a given quantity of coal is less than that of the coal (or other fuel) from which it is made.

In the case of coal-gas, the fixed carbon in the gas contributes nothing to its heating value; therefore, its calorific value contributes nothing to the heating value of water-gas and producer-gas, the carbon in the gas being in the form of carbon monoxide, but the heating value of carbon monoxide is not included in the heating value of the gas, since this carbon is already partially oxidized in the coal, and the heat required to distil the hydrocarbons in the coal is lost due to radiation. The calorific value of producer-gas from a given quantity of coal varies from 55 to 85 per cent of that of the coal from which it is made, depending upon the character of the coal and the manner of operating it.

**HEATING VALUE.** — The discharge from a gas engine is considerably greater than the boiling point of water, and the latent heat of condensation of the water vapor in the discharge is not available for the production of power, whereas the total heating value of a gas includes this latent heat of condensation. The difference between the heating value, as determined by the calorimeter, and the latent heat of condensation of the water vapor in the products of combustion, is called the effective or net heating value. The net (or low) heating value of producer-gas is about 75 per cent of the gross (or high) heating value. The net heating value is generally adopted in this country in reporting the heating value of a gas.

**DIFFERENT KINDS OF GAS.** — The following table shows the average composition (percentage by volume) of the different types of gases used for illumination. It should be noted, however, that the characteristics of the gas vary considerably from the figures given in the table, depending upon the quality of the coal used and the size and type of producer.

## COMPARISONS OF DIFFERENT KINDS OF GASES

Item	Natural gas	Coal-gas	Water-gas	Up-draft producer gas					
				Anthracite	Bituminous	Lignite	Peat	Wood	Oil

**BIBLIOGRAPHY.** — Junge, F. F., *Gas Power*; R. D. Wood & C. *Gas*; Proc. Am. Gas Institute; Proc. Am. Gas Light Assoc.; Kent's *Mechanical Engineers' Pocket-book*; Lange, K. R., *The By-Products of Coal-gas Manufacture*; Hole, W., *The Distribution of Gas*; Fernald and Orrok, *Engineering Plants*.

See also *Gas*; *Gas Producers*; *Illumination*, *Laws of*.)  
It is in terms of "calorific value," expressed in B.t.u.'s  
"radiating power," or the candle-power of a standard  
lamp in its most efficient state, consuming 5 cubic feet of the  
gas. Measurements of volume are reduced to standard condi-  
tions of pressure, viz., 60° F., and a 30-inch barometric height.  
Measurements are stated in atmospheres and in pounds per square  
inch by the inches of water manometer column which the  
atmospheric pressure (*see Units and Conversion Factors*).  
Measurements range from 1.5 to 4 inches in low-pressure systems and from  
10 to 15 inches in high-pressure systems. Most of the gas systems in the United  
States are of the low-pressure type, but high-pressure systems are common in  
certain localities. Commercial varieties of gas and their more important

properties. The gas obtained from the distillation of bituminous coal, consists chiefly of  
hydrocarbons. It varies greatly in quality with  
the stage of distillation. Values of 15 candle-power and  
100 B.t.u. per cubic foot are the usual commercial supply. The use of coal

gas is produced by the reaction of steam and incandescent coal or  
hydrogen and carbon monoxide, and is usually enriched  
with hydrocarbons to increase its calorific and luminous value. The properties of water  
gas range from 18 to 22 candle-power and from 580 to  
600 B.t.u. per cubic foot. Many plants supply a mixture of coal gas and water

gas. The gas obtained from the cracking of rich hydrocarbon gases produced by "cracking"  
of heavy oils. Its candle-power is from 40 to 60 and its calorific value  
is from 100 to 120 B.t.u. per cubic foot. On account of its richness oil gas is often diluted with  
steam for commercial delivery.

Oil gas is usually stored under a pressure of 150 pounds  
per square inch for self-contained and portable systems of light-  
ing. Its calorific value is approximately 900 B.t.u. and 36 candle-power. An essential  
feature of these systems is an automatic reducing valve which supplies the  
lamps with gas at a pressure adapted to flame and mantle illuminants.

Acetylene gas, the product of the reaction of water and calcium carbide, is a simple  
gas with a calorific value of about 1470 B.t.u.'s and 240 candle-power. For use in  
self-contained systems acetylene is dissolved in acetone under a  
pressure of 300 to 400 pounds per square inch. The usual container has a  
volume of 100 cubic feet at this pressure.

A mixture of air with gasoline vapor produced by  
a generator commonly used comprises a blower operated  
by a carburetor and a mixing chamber. In the most  
common type air is forced through sheets of cotton cloth which  
the mixture is produced. In the mixer the gas is diluted  
with air ranging from 2 to 5 gallons of gasoline to 1000 cubic  
feet of air, just below the explosive limit. Self-contained lamps in which the  
gas is heated by heat from the lamp have a wide use in street  
lighting. The calorific value of this gas in flames is very low, but it is well  
adapted to incandescent burners.

Gas obtained chiefly of methane, has a calorific value of about 1000  
B.t.u. per cubic foot. It is excellently adapted to

**PERFORMANCE OF FLAME ILLUMINANTS.** — Light from is due to minute incandescent carbon particles liberated from the gas. The highest efficiency is obtained when the migration of these particles hence the pressure at the flame should not exceed two inches of water. The flame should be set but little above the smoking point. The horizontal distribution from flames is sensibly uniform. The spherical reduction ranges from 85 to 92.5 per cent, depending on the occlusion of light by burner. The batswing and fishtail burners used with ordinary gas should give 90 per cent of the rated illuminating power of the gas when properly adjusted. Acetylene is commonly burned in duplex burners with air holes giving 95 per cent. The usual one-foot acetylene burner gives 40 candle-power.

**INCANDESCENT MANTLES AND BURNERS.** — The incandescent mantle is the ashy residue of a woven structure of vegetable matter such as cotton, ramie or artificial silk, impregnated with oxides of cerium, thorium, with traces of other rare earths. The strength of mantle varies with the material and weave of the fibrous base. Its luminous properties depend on the purity and proportions of the oxides used. Mantles are graded in quality chiefly by strength to resist shock, but the better grades are superior in the maintenance of their candle-power.

The incandescent burner is made in two general types, upright and inverted. Each has a Bunsen tube with adjustable gas cock and air inlet. The operation and flame projection of the upright type is fairly self-regulating over a wide range of gas pressure and consumption. The inverted type admits of a narrow range of adjustment. The conditions required to obtain the best efficiency from mantle burners are: (a) all gas and air ports must be properly adjusted to give the proper air-gas mixture and best projection pressure; (b) the flame should burn at the highest possible temperature; (c) the mantle should be completely immersed in the hottest or outer zone of the flame.

**Performance of Mantle Burners.** — Candle-power and efficiency are based on lamps fitted with new mantles adjusted to the most efficient conditions, this adjustment being, however, of such a character that any one familiar with casual contact with gas lamps is quite competent to make it. The performance of mantle burners in service is always somewhat below the rated values and depends to a marked degree on maintenance conditions. The deterioration is due to (a) the fouling of the burner with dust, (b) the improper adjustment of air and gas ports, (c) the shrinkage of mantles and loss of active materials, and (d) the collection of dirt on glassware. Low-grade mantles show very rapid deterioration, often amounting to 40 per cent in 500 hours. R. F. Pierce (*Trans. Ill. Eng. Soc., Vol. VII, p. 686*) reports from reliable tests under most unfavorable conditions, in an atmosphere charged with industrial dust and so infested with insects that some of the burner tubes became completely clogged the inherent deterioration in candle-power of well-adjusted lamps of the best grade to be as follows: Duration of test, 1000 hours; loss due to mantle alone, 2.5 per cent; loss due to burner alone, 2.5 per cent; loss due to dirt on glassware, 10 per cent; total reduction in candle-power, 15 per cent. Tests of commercial installations receiving skilled maintenance show an average performance from 15 to 25 per cent below the rated candle-power and efficiency. Without skilled maintenance the average performance is generally from 30 to 50 per cent below rated candle-power and efficiency. (*Proc. Nat. Elec. Assn., 1911, Vol. I, p. 800.*)

It is important to note that the principal sources of deterioration in gas lamp candle power, as a general thing, are analogous to those operating in

from dust and varying conditions of energy supply and are substantially of equal weight with the two

and electric lamps under actual service conditions, lamps was found to be within 10 per cent. of laboratory conditions the performance was even somewhat above. On the other hand, some of the electrical installations fell well below laboratory rating, due principally to blackened contacts and drop in the circuits.

In comparing gas and electric installations, to which tend to produce discrepancies in the performance. Too much emphasis on the discrepancies exhibited for practical purposes and under reasonable good service conditions offer the best and most practical methods of comparison. Where good gas service conditions prevail, the performance of gas installations is not likely to be as low as that of low rated candle-power, the figures mentioned above where skilled maintenance is not available.

Lumen-hours per cubic foot varies with the pressure and the volume of gas. At a given pressure the lumen-hours per cubic foot is proportional to the calorific value of the gas. The pressure of the gas systems have little effect on lamp efficiency, as the amount of gas consumption are about equally affected.

**GAS ILLUMINANTS.** — The curves of Figs. 1 and 2 show the variation of the gas illuminants in general use.

**Systems.** — The amount of air entrained in the mantle pressures is insufficient to produce the highest flame efficiency. Three methods of gas supply are designed a, viz., (a) to provide a gas pressure at the lamps of from (b) to provide gas at ordinary pressure and compressed em of piping and (c) to supply both gas and air under roduced by the three systems are approximately on a roduction in Germany of inverted high-pressure lamps as (*Lectures on Illuminating Engineering, Johns Hopkins p. 872*) may be summarized as follows:

Globe life, 2230 hours. Energy for gas compression, 400 cubic feet of gas. Consumption of 3-burner lamp, Costs per lamp-hour of 3-burner inverted lamp: maintenance and renewals, 0.38 cent; gas at 61 cents per ts; total per lamp-hour, 4.87 cents; total per lamp-year \$178.97.

he high-pressure inverted single-mantle lamp is approxi- r hemispherical candle-power for a gas consumption of per hour. The 3-mantle inverted lamp gives approxi- t 70 cubic feet per hour. These efficiencies can be sus- t careful attention to maintenance conditions. Fig. 4 istribution curves of high-pressure lamps.

**Automatic Ignition.** — The automatic ignition of gas lamps the following methods:

suming from 0.05 to 0.10 cubic foot per hour is fitted to ain cock is opened a momentary jet of gas is supplied g the ignition of the main burners. On some remote- g systems a momentary extra pressure is applied as the uce this jet action at the local burners.

ark is produced in the gas issuing at each burner by means he primary circuit contains a battery, ignition switch r. The secondary coil is in series with the several spark f the wire is grounded. Good insulation of the second-

be provided with a small spot of sponge platinum which e by catalytic action due to the rapid absorption of gas. es are apt to be short-lived.

ignition cock is frequently employed with show-window operated during definite time intervals on a flat rate

**LIGHTING (Pre-war figures).** — The following table cost of operation of various gas lamps. The assumed

cost of gas is \$1.00 per thousand cubic feet and the assumed average light as 80 per cent of the nominal ratings with clear glassware. These costs are taken in reference to service conditions, including the effects of dirt.

Type of lamp	Cost per 1000 lamp-hours		
	Renewals and maintenance	Gas	Total
1-Mantle upright.....	\$0.60	\$5.00	\$5.60
1-Mantle miniature.....	0.40	2.00	2.40
1-Mantle inverted.....	0.50	3.30	3.80
4-Mantle upright.....	1.65	18.80	20.45
4-Mantle inverted.....	1.65	13.00	14.65

**Gas vs. Electricity.** — For comparison with the above it may be noted that under initial laboratory performance conditions for given assumed lamp watt ratings the operating costs of 100-watt tungsten lamps with 5 cents and 10 cents per kw-hr. are respectively \$0.75 and \$1.40 per 1000 lumen-hours. Corresponding costs for 250-watt lamps are \$0.61 and \$1.22 respectively. The advantages of electric lighting are chiefly compactness and flexibility in the size and location of illuminants. The chief disadvantages of electric lighting are danger of shock from abnormal voltages, the fire hazard from faulty wiring and the greater likelihood of service interruption. The high-grade incandescent mantle lamp is a closer approach to daylight of the tungsten lamp, but is considered by many as less pleasing.

— (See also *Gas; Internal Combustion Engines; Power*) The name gas producer is usually applied to the apparatus in which the heating of the fuel takes place. The name, however, is applied to the apparatus in which the heating of the fuel takes place to designate the apparatus used in the manufacture of gas. In this article, the name gas producer will be used to designate the apparatus used in making and purifying producer-gas in which the heating of the fuel takes place in a boiler for producing the necessary steam, and various

The simplest form of generator is merely a cylindrical vessel provided with a grate, a roof and an outlet for the gas. A bed of fuel five feet thick is maintained in it and air and steam are passed through it. The oxygen of the air combines with some of the carbon forming carbon monoxide, the steam reacts with the carbon forming hydrogen and carbon monoxide, and the hydrocarbons are formed by the heat. In addition to adding combustible gases to the gas, the steam diminishes the formation of clinker, and the escaping gases and makes a gas lower in nitrogen, and of lower heating value, than would be produced if air alone were used. In the removal of ashes, revolving grates are used, or else the bottom of the producer rests in a shallow pit into which the ashes are removed from time to time. The gas is collected in a hopper set in the roof of the producer, and opening into the atmosphere, but sometimes special forms of rotating hoppers distribute the coal evenly over the bed. To avoid the "caking" of some varieties of soft coal, stirring is provided in the upper part of the producer to break up the

The water-gas producer is essentially a steam boiler, the water being heated by the gases from the generator to circulate around the pipes through which the water flows. The steam thus formed is fed into the generator in proportion of air.

— In order to remove the dust, tar and other harmful impurities from the gas, it is passed through various devices designed to absorb or remove them. The filter consists of some porous material, such as sand, or sawdust, in a suitable retainer. Liquid "scrubbers" are used for removing the gas into intimate contact with water, which removes the various impurities. This is accomplished by causing the gas to come in contact with water, by passing the gas through a chamber into which water is sprayed, or by passing the gas over surfaces continually kept moist. The spray type of scrubber is usually a large cylindrical vessel in which the water is sprayed in a pattern, the latter aiding in absorbing the tar from the gas as it passes through. In other scrubbers are also employed, which may be designed to remove the gas and water, or to drive out the impurities by means of steam. These scrubbers are particularly effective in removing tar, and other impurities present in gas made from bituminous coal.

**CLASSIFICATION.** — The various forms of gas producers, of which there are many, differ chiefly in details of construction and in the arrangement of the parts of the apparatus. Two distinct processes are in use—the up-draft process and the down-draft process. For various purposes these processes are applied by different ways resulting in the following four general types of

- (a) Up-draft suction producers
- (b) Up-draft pressure producers
- (c) Down-draft producers
- (d) Double-zone producers.

In the suction and down-draft types, the pressure in the gas generator is less than that of the atmosphere. This is also true in at least one of the two double-zone producer. In these types, the "suction" or draft through the producer may be produced by an exhaustor or directly by the suction engines which they supply.

In the pressure producer the air and steam are forced through the producer under a slight positive pressure (usually equivalent to from 2 inches to 2 feet of water in the generator space above the fuel-bed).

The double-zone producer is, as its name implies, a combination of up-draft and down-draft principles. Two incandescent zones are maintained in the producer and the gas is withdrawn at the center or waistline of the producer.

**UTILIZATION OF BY-PRODUCTS. MOND PROCESS.** — Ammonia is about the only by-product of producer gas which has enough value to justify the additional expense required to save it. This is accomplished by the Mond process, which is the one in most general use. An excess of steam is injected with the air, lowering the temperature and thus preventing the destruction of the ammonia in the coal. (The proportions of hydrogen and carbon dioxide in the gas is also increased and the proportion of nitrogen decreased.) The gas, after passing through a mechanical separator, is caused to pass through a tower where it is thoroughly washed with sulphuric acid. The ammonia in the gas combines with the sulphuric acid, forming ammonium sulphate. This acid solution of ammonium sulphate trickles through the tower over and over again until it reaches a given degree of saturation; then a certain amount of it is by-passed out of the system and fresh acid is added. In this system, the heat energy lost by the gas is also used to preheat the air which is used in generating the gas, thus giving a considerable increase in the economy of the process. From a gas containing not less than 1.3 per cent nitrogen, it is possible to produce 90 pounds of sulphate of ammonia and from 140,000 to 160,000 B.T.U. gas.

**RATING AND PERFORMANCE.** — A gas producer is usually rated in horse-power, the rating being the number of horse-power which can be developed by gas engines supplied from the producer when the latter is gasified at a maximum rate. Such a rating is, of course, indefinite, as the power developed by the engines depends upon their design and the percentage load which they are carrying, and the rate of gasification depends upon the quality of coal and the care taken in firing. The following data are the results of a series of tests on bituminous coal and lignites made by the U. S. Geological Survey at St. Louis on a 150-horse-power Taylor vertical and a three-cylinder vertical Westinghouse 235-horse-power gas engine. These tests are summarized in a paper by R. H. Fernald in the *J. Soc. Eng.*, 1907, Vol. 12, p. 551. The table on page 625 is derived from the curves there given.

All items in this table affected by load factor are given only for load factors from 90 to 100 per cent of full load (235 brake horse-power). The weight of coal per horse-power-hour does not include the coal required to produce steam which is injected into the fuel bed. The efficiency is based on calorimetric measurements, no deduction being made for the latent heat of condensation of the water vapor in the products of combustion of the gas.

3 to 4 feet for plants ranging from 25 to 200 horse-

**COSTS (Pre-war figures).** — The following approximate forms of producer-plant equipments have been derived from a large number of installations. They include the purchase price of generators, evaporators, the necessary scrubbers and filters, but do not include erection, foundations;  $P$  is the horse-power rating of the producer.

Up to 250 horse-power . . . . .	$\$500 + 10 \times P$
250 to 1000 horse-power . . . . .	$20P - \$2000$

The cost of such plants erected including producer equipment, and foundations averages from \$80 to \$110 per rated horse-power, buildings, for plants up to 250 horsepower. Plants from 1000 to 2000 horsepower average about \$70 per horse-power, including buildings.

Gas holders . . . . .	$\$1000 + \$0.26 \times P$
-----------------------	----------------------------

Detailed manufacturers' estimates of investment cost and cost of operation for twenty-six producer plants are given in the paper by Mr. Fernald in *Soc. Wes. Eng., 1907, Vol. 12, p. 551*.

FIG. — The following terms are commonly em-

A wheel with teeth cut in its periphery, designed similar wheel or with a screw or worm.

**Base and Pitch Diameter.** — Referring to Fig. 1,  $AB$  with their  $bc$  gears, are the center lines of the pitch circle.

Fig. 1, the difference in the width and the circumference called the

Fig. 1. Spur Gear

**Circular pitch** in inches, the pitch circle, between the center lines of two suc-

$$\text{Circular pitch} = \frac{\pi \times (\text{diameter})}{\text{Number of teeth}}$$

distance in inches, measured along the *chord* of the center lines of two successive teeth; let  $N$  be the number of teeth, then

$$\text{Chordal pitch} = D \sin \left( \frac{180^\circ}{N} \right)$$

quotient of the number of teeth by the diameter

of a gearing consisting of two gear wheels meshing together; the gear wheel on the shaft of a railway motor is called the *driving gear*; it is also used for the smaller of two gears mounted

together and driven by a chain.

**Ratio.** — The ratio of the number of teeth in the larger wheel to the number of teeth in the smaller wheel; this is called the "ratio," or the number of revolutions of the smaller wheel to the number of revolutions of the larger wheel.

**External Gearing.** — A gearing in which the external surfaces of the teeth lie in the same planes of the teeth pass through the axis of the gear wheel.

**Internal Gearing.** — A gearing in which the external surfaces of the teeth of one wheel may mesh with another gear having its axis in-

line with the axis of the other gear. Gears of the same pitch and diameter mounted on parallel shafts will act as a single gear. If one gear is keyed on the shaft of the other, but the teeth of the two gears are not in line, but the teeth of one gear mesh with the teeth of the other, the two gears form a stepped gear. If one gear is keyed on a parallel shaft the number of teeth in

contact will be twice as great as in an ordinary gear, which will increase the strength of the gear and its smoothness of action.

**Twisted Teeth.** — If a great number of very thin gears were placed one slightly in advance of the other, they would still act as a step gear. Continuing the subdivision until the thickness of each separate gear is infinitesimal, the faces of the teeth instead of being in steps take the form of a smooth or twisted surface, and we have a twisted gear. The twist may take place in one direction and if it is in one direction for half the width of the gear and in the opposite direction for the other half, we have what is known as the bevel gear with a double helical tooth. This form of tooth is much used in heavy machinery in practice, where great strength and resistance to shocks are necessary. Gears are frequently made of steel castings. The angle of the tooth with a line perpendicular to the axis of the gear is usually 30 degrees.

**Spiral or Helical Gears.** — If a twisted gear has a uniform twist throughout its width, what is commonly called a spiral gear (properly a helical gear). The surface on which the pitch surface intersects the face of the tooth is part of a helix on the pitch surface.

**Pitch Angle.** — The pitch angle of a helical gear is the angle between the center line of the tooth and a line perpendicular to the axis of the gear.

**Screw or Worm.** — A spiral wheel may be made with only one helical tooth wrapped around the cylinder several times, in which it becomes a screw or worm. If it has two or three teeth so wrapped, it is a double- or triple-threaded screw or worm.

**Worm-Gearing.** — When the axes of two spiral gears are at right angles, and a wheel of one, two or three threads works with a larger wheel of many threads, it becomes a worm gear, or endless screw, the smaller wheel being called the worm, and the larger, or driven wheel, the worm wheel. This arrangement a high velocity ratio may be obtained with a single worm and many wheels. For a one-threaded wheel the velocity ratio is equal to the number of teeth in the worm wheel. The worm and wheel are commonly so constructed that the worm will drive the wheel, but the wheel will not drive the worm.

**Differential Gearing.** — Various forms of differential gears are used where the object is to devise a motion such that the velocity ratio is equal to the ratio of the number of teeth in one gear wheel to the difference between the number of teeth in this gear wheel and the number of teeth in the other wheel. One form of differential gearing one wheel meshes with a set of teeth on the circumference of a second wheel. The second wheel is so arranged that it cannot turn on its own axis but its center is caused to move in a circle concentric with the first wheel.

But for the limitation that the difference between the wheels must not be too small, the possible ratio of speed might be increased almost indefinitely by using one pair of differential gears made to do the service of a whole train. If the problem is properly worked out with bevel gears this limitation may be completely set aside, and external and internal bevel gears, differing only in the number of single teeth if need be, made to mesh perfectly with each other.

**DESIGN OF GEARS.** — In order that the teeth of wheels may run together smoothly and with a constant relative velocity, it is necessary that their working faces shall be formed of certain curves called pitch curves. The essential property of these curves is that when two teeth are in contact, the common normal to the tooth curves at their point of contact must pass through the pitch point, or point of contact of the two pitch circles. Two curves are in common use — the cycloid and the involute.

is given in detail in Kent's *Mechanical Engineers' Pocket-Book for Machine Designers*.

**Material.**—Gears are usually made of cast iron or cast steel. For satisfactory results the teeth should be machined. Cast iron pinions, and composite gears, consisting of alternating cast iron and steel or bronze, are also used where smooth running is required. Of this latter form of gearing the cloth is the best, being strong, not liable to damage from cold chills, and vermin proof.

**Phenolic Resin.**—Gears bonded with bakelite, known as "micarta," is used for gears where quietness of running is desirable. The following (p. 368, *Aug., 1916*) give the following as the physical properties: Tensile strength parallel to laminations, 10,000 pounds per square inch; transverse strength, maximum perpendicular to laminations, 17,000 pounds per square inch per degree centigrade, 0.00002 inch perpendicular to laminations; specific gravity, 1.4; water absorption at 21° C.) 0.25 to 2 per cent by weight, depending on the degree exposed.

**Strength of Gearing.**—The strength of gears that may be transmitted by them depend upon so many factors that the formulas and rules given by the various authorities are subject to wide variation. The pitches indicated in the accompanying table \* as representing safely conservative practice for cast iron teeth may afford sufficient strength in some cases, but should not be adhered to with as few exceptions as possible.

Diametrical pitch	Maximum horse-power transmitted	Diametrical pitch
12	10	4
10	15	3
10	20	3
10	25	3
8	50	2½
8	60	2½
6	75	2
6	100	2
5	125	1½
	150	1½

**Efficiency.**—An extensive series of experiments on the efficiency of worm and spiral gearing, is described by the author in *Mechanical Engineering*, Vol. 7, p. 273. The average results are shown in the following table, giving approximate average figures in the table on the

The experiments showed the advantage of spur gearing over all others in both durability and efficiency. The variation from the mean result exceeded 5 per cent in either direction, so long as no cutting occurred. The variation became much greater and very irregular as soon as cutting occurred. The loss of power varies with the speed, the pressure, the temperature and the condition of the surfaces.

The excessive friction of worm and spiral gearing is largely due to the thrust on the collars of the shaft. This may be considerably reduced by roller bearings for the collars. When two worms with opposite spirals run on spiral worm gears that also work with each other, and the pressure of one is opposite that on the other, there is no thrust on the shaft. A loss of power for a worm gear means more than the loss of power, since the power lost reappears as heat and may cause the rapid destruction of the worm.

**ALTERNATING-CURRENT.**— (See also *Alternating Magnetism, Principles of; Generators, Direct-Current; Sales.*) In all dynamo-electric machines of the usual (bipolar) the electromotive force induced in any one coil and alternates in direction. If the terminals of any coil are brought out to an external circuit by means of revolving brushes an alternating current will flow in the circuit. In order to obtain a direct-current it is necessary to add a commutator. The simplest and elementary form of electric generator is an alternator. The direct-current generator is a special form adapted to give a continuous or unidirectional current.

— Alternating-current generators may be classified according to different distinguishing characteristics. The following are the most important characteristics in the order of their prominence.

**Synchronous Type.**— In the synchronous type the action of inducing an electromotive force results from the relative motion of the armature and the magnetic field produced by exciting coils in which a direct current flows. The frequency of the alternating electromotive force depends directly on the number of field poles and the angular velocity of the armature.

**Induction Type.**— In the induction type the magnetic field is of the same frequency as the load current and is produced by polyphase alternating currents which lag with the load current. The mechanical construction is similar to that of an induction motor with a short-circuited polyphase winding. The frequency depends upon the characteristics of the prime mover. In practice the frequency is determined or "set" by a synchronous generator or motor, in the external circuit. This is necessary to supply the exciting current of the induction motor. The frequency setter sets the power factor of the induction motor equal to the inherent power factor of the generator.

**Disadvantages of Induction Type.**— A minority of the units of the induction type with advantage as they will not be damaged in case of a short circuit on the system. Their efficiency is less. A certain number of the units must be used to "set" the frequency and supply the exciting current of the induction machines. Consequently, if there is a large proportion of induction machines the synchronous machines operate at a poor power factor, which has a capacity effect in the load system, such as synchronous machines.

**Revolving-armature Types.**— In the revolving-armature type there are two, or some multiple of two, poles. The field coil for the direct-current excitation, and the flux in the field is constant in value. The relative movement of the armature and the field causes the variation in flux interlinkages between the armature and the field.

— These are constructed with an armature revolving inside a field. As the speed and voltages increased it was found that a more efficient design could be obtained by making the armature the inner member and the insulation of the high-voltage member was kept stationary.

— Generators of large capacity (500 kilowatts and greater) and high voltages (100,000 volts and up) are made of the revolving-field type.

— In the inductor type the direct-current excitation is constant and the field coil is stationary and the variation in magnetic flux is

obtained by revolving a spider with bare projecting poles which a reluctance of the magnetic path. Thus the flux-threading any armature coil is always in the same direction, but varies in intensity of

**Comparison of the Inductor Type with Revolving Field or Rotating Armature Type.** — There are no windings or insulation on the moving part of the inductor type, which is therefore adapted to high speeds. The variation in the reluctance of the main magnetic path and the consequent variation in magnetic densities in the field structure of the inductor causes eddy currents, hence the construction of this type has been abandoned in machines of large power. It is still used for radio work however. See *Communication*.

**Single Phase, Two Phase or Quarter Phase and Three Phase.** The single-phase generator is usually about 30 per cent heavier and more expensive than a polyphase generator of the same rating. By changing the armature connections a polyphase machine may frequently be reconnected to be a three-, two- or single-phase machine.

As transmission by three-phase currents is more economical of copper than by two-phase or single-phase currents, all power transmission lines are three-phase. Consequently unless there is some local condition requiring two phase, the three-phase generator is preferable.

Two-phase and three-phase generators of the same capacity and output strain are of practically the same dimensions, weight and cost.

**Trade Terms.** — It has become almost universally the custom to designate an alternating-current generator as *ASB*, *AQB* and *ATB*; the *A* stands for alternator, *S* for single phase, *Q* for quarter phase, *T* for three phase and *B* for revolving field.

**Separately-excited and Self-excited Types.** — For years it was a common practice to develop a satisfactory and simple self-excited alternator and some were successful but not simple. The object was to obtain a constant voltage at full load by means of automatic self-excitation. However, with the perfecting of the automatic voltage regulator the need for automatic self-regulation has disappeared and there is now very little demand for self-excited alternators.

**METHODS OF RATING.** — All a-c. generators are rated in kilovolt-amperes (kv-a.) and unless otherwise specifically stated are rated at the temperature at which they will give continuously with a rise in temperature not exceeding certain values depending upon the character of the insulating materials used. See *Standardization Rules A.I.E.E.*

Machines, or those parts of machines, insulated with mica, asbestos or other heat resisting material are allowed a rise in temperature of 70° C. as measured by thermometer, or 75° if measured by resistance. This includes most alternators, both armature and field, and the fields of many other alternating-current machines.

Machines, or those parts of machines insulated with varnished cotton or impregnated cotton or linen, are allowed a rise of 50° C. as measured by thermometer, or 55° if measured by resistance. This includes the armatures of most slow and moderate speed machines.

Most machines have their fields designed sufficiently liberally to enable them to give their rated kv-a. at 80 per cent power factor with rated voltage. This is stated in the specifications. It should be noted that the heating of the armature depends upon the kv-a. and not upon the kilowatt load. The heating of the field of the load connected to the alternator, the generator, depends upon the heating of the field coils for the same kv-a. output.

**VOLTAGE.** — Alternators are now built to generate voltages up to 15,000 volts between lines, either single phase or polyphase. All

the insulation and the danger of damage from dis-  
 expensive to install transformers with a lower voltage  
 consider the limit of economical voltage of gener-  
 13,000 volts.

frequency depends upon the speed of rotation and  
 the speed of rotation of the revolving part is given in  
 frequency is

$$\frac{\text{r.p.m.}}{60} \times \frac{\text{number of poles}}{2}$$

it was found much more economical to run at high  
 frequencies such as 133 and 125 cycles per second, were  
 as increased in size and complexity, electrical diffi-  
 these high frequencies and the tendency has been to  
 now we have 60, 50, 40 and 25 cycles per second as  
 25 and 60 are standard in this country. In Europe  
 60. Of late there has been an attempt to have 15  
 or railway work.

is preferable where there is a very long transmission  
 or inductive voltage drop, and where there is much  
 as synchronous motors and rotary converters, as  
 better adapted to parallel operation at low fre-

cycles in U. S. A., and 50 in Europe) is preferable for  
 it is steadier. The higher frequency is also prefer-  
 ers are used, as these are cheaper and more efficient

**VOLTAGES AND CURRENTS.** — For moderate  
 in lines, the method of connection is decided by such  
 a convenient number for the conductors per slot for  
 higher voltages the Y connection is usually chosen  
 on the machine insulation for a given voltage  
 666.

single-phase generator the voltage per phase is the  
 in lines and the current per phase is the same as the  
 fact of voltage and current giving the volt-ampere

**Phase.** — In a properly designed machine of this  
 If the rating, thus the voltage and current per phase  
 vely the same as the voltage and current per phase  
 s equal to  $1000 \times (\text{kv-a.}) + 2 \times$  volts per phase.

nes of this type may be connected either Y or  $\Delta$ .  
 the current per phase is the same as the current in  
 $1000 \times (\text{kv-a.}) + \sqrt{3} \times$  (volts between lines), while the  
 between lines)  $+ \sqrt{3}$ .

the line current is equal to  $1000 \times (\text{kv-a.}) + \sqrt{3} \times$   
 the current per phase is equal to (line current)  $+ \sqrt{3}$ .  
 is equal to the voltage between lines.

**T POLE GENERATORS.** — The procedure in  
 rrent generatr for a given power output, voltage  
 n requirements regarding regulation, efficiency, etc.,  
 tly empirical. The data of four specific-designs are

given below in the section on *Examples of Design and Performance*. The procedure is to lay out a preliminary design from rough calculations, the performance of this design, modify the preliminary design where calculation indicates, recalculate the performances, etc., until a design is obtained which meets the given requirements.

**Definitions.** — The following terminology is used in the discussion of design of generators:

**Pole Arc.** — The arc subtended by one pole face, measured along the periphery of the armature; in the following discussion it will be expressed in inches.

**Pole Pitch.** — The arc measured along the periphery of the armature from the center of one field pole (N-pole, say) to the center of the next pole (S-pole); in the following discussion it will be expressed in inches.

**Ampere Conductors per Inch of Armature Periphery.** — The product of the number of conductors per inch measured along the periphery of the armature by the effective amperes flowing in each conductor.

**Slot Pitch.** — The distance in inches measured along the periphery between the centers of two adjacent slots. The slot pitch is the pole pitch divided by the number of slots per pole.

**Coil Pitch.** — The number of slots spanned by a coil; that is, if the coil has one side in slot number 1, and the other side in slot number 7, the coil pitch is  $7 - 1 = 6$ . A coil which spans a distance exactly equal to the pole pitch is said to have a "full pitch," but if it spans a lesser distance it is said to have a "fractional pitch." For example, if there are six slots per pole, a coil has one side in slot number 1, and the other side in slot number 4, it is said to have a fractional pitch of  $\frac{2}{3}$  or  $\frac{4}{6}$ .

**Leakage Factor.** — The ratio of the flux per pole which enters the armature core to the total flux (including the leakage flux) which would be produced by the field winding.

**Preliminary Calculation of Main Dimensions.** — Let

- $P_0$  = output in kilovolt amperes (kv-a),
- $\rho$  = ratio; pole arc divided by pole pitch,
- $B$  = average magnetic flux density per square inch in air gap,
- $\sigma$  = ampere-conductors per inch of periphery,
- $V$  = peripheral velocity in feet per minute at gap,
- $D$  = diameter of armature in inches,
- $L$  = length of armature along shaft in inches,
- $N$  = revolutions per minute,
- $p$  = number of poles,
- $f$  = frequency in cycles per second,
- $A = D + p$ .

Then the following relation holds for either a single-phase or a polyphase machine, other than turbo-alternators:

$$P_0 = \frac{\rho \sigma B V D L k_2 k_3}{144 \times 10^9}$$

Five of the six design constants in the right-hand member of this equation are subject to choice; the equation then fixes the sixth constant. The choice of the values of the various constants should be based upon modern practice, the idea of which is given below in the following paragraphs. For values of constants  $k_2$  and  $k_3$  see the section below on *Predetermination of Performance*.

For turbo-generators see section below on *Design of Turbo-alternators*.

**Ratio of Pole Arc to Pole Pitch ( $\rho$ )** is governed by two antagonistic phenomena; for the sake of small magnetic leakage and good form factor

desired; for the sake of low reluctance to the main flux a high value is desired. The usual values are

density ( $B$ ) is limited by the current required to produce it, and also by the heating results. Usual values of  $B$  are given in the

Cycles	Lines per sq. in.
25	44,000 to 55,000
60	32,000 to 48,000
125	30,000 to 40,000

per Inch of Periphery. — The ventilation resulting from forced ventilation is good, in-creases are very deep, as in the case of the values of  $\sigma$  may be given for continuous rating at a temperature of 40° C. are:

Number of Poles	500 to 2000 volts	2000 to 7000 volts	Above 7000
25	200	...	...
60	400	300	250
120	700	500	400

of ventilation,  $\sigma$  may be much greater than the normal value, as in the case of turbo-alternators with forced ventilation. The value of  $V$  is altogether a matter of mechanical design and may range from 1000 feet per minute to 10,000. Usual values are

of Armature. — The diameter of armature ( $D$ ) is determined by the number of revolutions per minute ( $N$ ) by the formula

$$D = \frac{12 V}{\pi N}$$

When the diameter  $D$  is fixed when  $V$  is chosen. This then fixes the value of  $\rho$ ,  $B$ ,  $\sigma$  and  $V$  then fixes the value

of  $V$  is not given, reasonable values for  $D$  and  $L$  may be chosen in accordance with normal and economical conditions. The diameter divided by number of poles ( $\lambda$ ) reduces to

$$\frac{VAD}{10^6}$$

Cycles	$\lambda$ = diameter per pole, in.
25	5 to 12
60	2.5 to 5
125	1.75

and  $A$  are chosen. The diameter is adjusted to the frequency of poles (see next paragraph). The diameter per pole are given in the table.

( $\rho$ ) and Revolutions per Minute ( $N$ ). — The

number of field poles is related to revolutions per minute  $N$  and the  $f$  by the formula

$$f = \frac{Np}{120}, \quad \text{or} \quad p = \frac{120f}{N}.$$

Hence when the frequency and speed are both given, the number is fixed. When  $N$  is not given, but  $L$  is assumed approximately equal as above, the number of poles is found, when  $D$  has been determined the relation

$$p = \frac{D}{A}.$$

A value of  $A$  must of course be chosen such that  $p$  is an even number. The speed  $N$  is then obtained from the relation

$$N = \frac{120f}{p}.$$

**Armature Windings.** — While there are many forms of armature which may be used, there are practically only two forms that are in use in this country. These are the "Chain Winding" and the "Lap Winding."

**Chain Winding** (Fig. 1). — This winding is characterized by number of coils equal to half the number of slots; that is, there is only one coil in each slot. The coils may be either lap form wound and insulated, in which case slots with open faces are required; or they may be wound by hand in place, in which case partly or entirely closed slots may be used.

There are at least two kinds of coils in each machine. These are characterized by the shape of their end connections, as these end connections lie some in one plane and some in another. If there is more than one slot per pole per phase, there must be four different shapes of coils, having two different pitches; the coils of any one phase per pole are placed concentrically. The chain winding is most generally used in high-voltage machines, 2000 volts or higher.

Fig. 1. Chain Winding

**Lap Winding** (Fig. 2). — This winding contains a much larger number of coils, all of the same form and size. There may be two, four, six, etc., sides of coils in each slot, the coils being placed side by side two coils deep. This winding is similar to the multiple-drum winding of a direct-current armature. With two coil sides per slot the slots must be open, but with more than two coil sides per slot the slots may be partly closed. This type of winding is satisfactory for low voltages and very convenient if there are a large number of slots per pole.

Fig. 2. Lap Winding

The coils are connected in groups of 2, 3, etc., per pole per phase, depending upon the slots per pole per phase. Successive groups or poles of the same phase are connected in series or multiple by "pole connections."

Each coil may contain from one to many turns in

ed in the slots so that the slots are usually about  
re wide. The size of the slots should be such as  
n over and above the space occupied by the con-  
nering as they may have. The space required for  
ht slots is as follows:

Coil sides per slot	Insulation, inches	
	Vertical	Horizontal
2	0.350	0.150
2	0.430	0.180
2	0.50	0.30
1	0.75	0.375
1	0.835	0.50
1	1.125	0.75

vertical depth of slot may be found in a machine  
a 2 coil sides per slot by multiplying the over-all

diameter of cotton-covered wire, or depth of bar, by the number of conductors in a vertical row and adding 0.43 to the product.

**Slot Factor.** — The ratio of cross section of copper in a slot to cross section of slot is known as the slot factor. Normal values of the slot factor for a 1000-kilowatt machine are given in the accompanying table. For smaller machines the slot factor is slightly less and for larger machines slightly greater.

Voltage	Slot Factor
500	0.85
1,000	0.80
2,000	0.75
4,000	0.70
6,000	0.65
10,000	0.60

**Preliminary Dimensions of Magnetic Circuit.** — The diameter of the armature and the axial length of the pole face for the preliminary design are fixed by the above calculations. There remain to be determined the air gap, the dimensions of the armature teeth, the length and radial depth of the armature iron, the dimensions of the field poles, and the dimensions of the field winding. Preliminary values for these quantities may be arrived at as indicated in the following tables.

**Air Gap.** — The minimum clearance between armature core and field poles in modern generators is given in the accompanying table. The average length of the air gap, due to the chamfer on the poles, is about 25 per cent greater.

Armature Diameter, in.	Min. Air Gap, in.
40	0.10
80	0.12
120	0.15
160	0.18
200	0.22
240	0.25

**Armature Teeth.** — The dimensions of the armature teeth depend upon the number and dimensions of the slots, which in turn must be such as to contain the necessary conductors. Another important limitation to the width of the teeth, however, is the value of the magnetic flux density therein. Let  $s$  = pitch of slots,  $a$  = pole arc,  $g$  = average radial depth of air gap. Then the effective number of conductors under each pole is  $(s + 2g) / s$ . The effective width of the tooth is its average width, or a section one-third the distance from its minimum width towards its maximum width. The effective axial length of the teeth is approximately equal to the axial length of the pole face  $L$  determined above. From these data the effective cross section of the teeth perpendicular to the flux is determined, and this divided into the total flux per pole  $\phi$  gives the average flux density in the teeth. The value of  $\phi$  from the preliminary calculations above is  $\pi \rho L D B + \rho$ , where  $\rho$  = ratio of pole arc to pole pitch,  $D$  = diameter of armature at gap,  $B$  = average magnetic flux density in gap, and  $\rho$  = ratio of pole arc to pole pitch. The average flux density in the teeth in modern alternating-current generators ranges from 90,000 to 110,000 lines per square inch.

**Armature Core.** — The axial length of the armature core is slightly greater than the axial length of the pole face. A fair allowance is to make the axial length twice the radial depth of the air gap. The core is usually built up of steel punchings, 14 mils thick, the punchings having received previously a thin coat of varnish. Ventilating ducts from  $3/8$  to  $1/2$  inch in width (measured along the shaft) are usually provided, these ducts dividing the core into sections from 2.5 to 3 inches thick (measured along the shaft). The axial length of the armature iron is therefore the total length of the core less the space occupied by the air ducts and insulation between punchings. This latter is about 10 per cent of the net length after deducting the space occupied by the air ducts.

One-half the total flux per pole passes through each section of the

the armature core of modern alternating-current machines is about 70,000 lines per square inch. Let  $B_a$  = the flux density in the armature core,  $l$  = effective axial length of armature iron,  $r$  = necessary radial depth of the armature core is

The radial length of the pole face  $f$  is about 0.5 in. less than the pole arc  $a$ . The pole arc  $a$  has already been determined. Let  $c$  = core thickness (see Fig. 3, see below) and the width of the pole face  $w$  have yet to be determined. The width of the pole face is usually 75 per cent of the pole arc (see Fig. 3), and the radial depth of the pole face is 50 to 150 per cent of the width. The necessary radial depth of the pole face will accommodate the field flux  $\phi$  which is determined as follows:

The ampere turns required per pole to force the flux through the pole face  $\phi$  = flux per pole;  $g$  = average radial depth of the pole face. The ampere turns required in the magnetic circuit is about 40 per cent of this for most 25-cycle machines, and 50 per cent of this for most 60-cycle machines. Hence the ampere turns required to produce the flux  $\phi$  is approximately  $0.38 \phi g + af$  for 60-cycle machines. The ampere turns on each field spool at full load, however, will be increased by the armature reaction, by an amount depending on the flux density per pole and the power factor. For preliminary calculations, however, it is sufficient to increase the ampere turns calculated by about 50 per cent, giving as the ampere turns per pole  $F = 0.66 \phi g / aL$  for 25 cycles per second.

The current density of 1000 amperes per square inch in the armature of the copper in the winding is then  $F + 1000$ . The necessary cross section of the copper including the cotton insulation and inter-laminar space is greater than the cross section of the copper when wire is employed. The field pole may be made of cast iron when strip is employed. The field pole may be made of cast steel, which is usually wound on a cast-iron core, and insulated with an insulating collar at each end, and 0.25 inch for the inter-laminar space.

The flux density in the core should not exceed 100,000 lines per square inch in the armature core. Let  $\phi$  = useful flux per pole,  $\nu$  = leakage factor,  $f$  = thickness of core, then the flux density is  $B_c = \nu \phi / f$ . The necessary radial depth of the core ranges from 1.1 to 1.5.

The necessary radial depth of the armature and the radial length of the pole face fixes the internal diameter of the field yoke (see Fig. 3, see below). The radial depth of the pole face is 50 to 150 per cent of the width of the pole face (see Fig. 3). The radial depth of the pole face is determined by the flux density in the yoke. Let  $\phi$  = useful flux per pole,  $\nu$  = leakage factor,  $c$  = axial length of yoke, then the radial depth of the pole face is  $B_y = \nu \phi / c$ . The necessary radial depth of the pole face ranges from 25,000 to 30,000 lines per square inch, and from 70,000 to 80,000 lines per square inch.

It is necessary to attempt an accurate calculation of the ampere turns of the armature and magnetic circuit has been attempted. The method of calculating the number of field ampere turns is given in the

After the excitation in ampere turns per pole required for various power factors desired (according to the specifications or the service required by the generator) has been determined, that condition of operation which requires the greatest number of ampere-turns  $F$  is selected. A field winding is then designed to give this excitation and a margin for safety, with the exciter voltage available. The coil is then designed. Using this value of  $F$  and a current density of 1000 amperes per square inch, the cross section of the field winding is  $1.4 F + 1000$  square inches of insulated wire, or  $1.15 F + 1000$  when made of insulated strip. The length of the coil will be  $c - 0.75$  (see Fig. 3), allowing  $\frac{3}{8}$  inch at each end for end connections and insulation. Therefore the depth of winding will be for wire  $\delta = 1.4 (c - 0.75) +$  thickness of spool on which the wire is wound, or  $\delta = 1.15 (c - 0.75) +$  thickness of spool. The spool is usually 0.25 inch thick.

The radiating surface of the coil is then

$$A = 2c (f + b + 4\delta).$$

#### Resistance and Temperature Rise of Field Winding.

The temperature rise in degrees centigrade per watt radiated per square inch of surface of a field winding depends on the peripheral speed of the revolving field or revolving armature. The accompanying table gives the temperature rise in degrees centigrade per watt radiated per square inch. For other rates of radiation the temperature rise is proportional. Let  $w$  = watts radiated per square inch for the assumed temperature rise (usually 45° C.),  $A$  = area of radiating surface, then the allowable loss per pole is  $wA$ ; and the field current is then  $I_f = wA + v$ , where  $v$  = volts per pole. The volts per pole should be taken as 80 per cent of the exciter voltage divided by the number of poles (all field spools in series), allowing 20 per cent for emergencies (low speed, etc.). The number of field turns per pole is then  $t = F + I_f + 0.5$ , the half turn being added for convenience in connecting up. The proper resistance ( $r$ ) of the field winding is then  $wA + I_f^2$ , and the necessary cross section ( $q$ ) of the conductor in square inches is

$$q = \frac{0.0186 t (f + b + 2\delta)}{12,000 r}.$$

(The resistance of 1000 feet of copper 1 square inch in cross section at 75° C. is 0.0093 ohm and  $2 (f + b + 2\delta)$  is the mean length of turn.) From the table of cross sections the nearest size of wire may be chosen and  $r$ ,  $w$  and volts per pole calculated by reversing the above procedure.

The cross section of the winding should now be recalculated, and the necessary adjustments made to make it fit the winding space available on the field.

**Bearings, Shafts, Bedplates, etc.** — Alternating-current generators may be belt-driven or direct-connected and the latter type may have either horizontal or vertical shaft.

Belt-driven generators are only used in the smaller sizes up to 500 kilowatts. The smallest sizes usually have two bearings and an overhanging pulley. Larger sizes frequently have three bearings and the weight of the pulley and of the belt are taken by two of the bearings.

g on the pitch of the armature coils, which may ch constant."

entering the armature is

$$\phi = \frac{E \times 10^8}{4.44 k_1 k_2 k_3 / S}$$

( $k_1$ ). — This constant is proportional to the form n around the periphery of the armature. In all s are so shaped that this distribution is practically = 1. This is usually done by making the air gap t the center of the pole.

One method of doing this is to make the outline of the pole face a circle of such a radius (less than the radius of the armature in revolving machines) that the gap at the tips is twice the gap at the center.

For very accurate predeterminations the distribution of the flux is calculated. (See S. P. Thompson, *Dynamo Electric Machinery*, Vol. C. A. Adams, *Trans. A.I.E.E.*, Vol. 33.)

**Winding Distribution Constant ( $k_1$ ).** — This constant all fact that if there is more than one slot per pole per phase, the coils of the various slots of one phase under a pole do not generate e.m.f.'s of the same phase. Since the slots pass under the pole consecutively of the conductors reach a maximum consecutively. These e.m.f.'s must therefore be combined vectorially and not merely added together.  $k_1$  is the same in single-phase, two-phase and three-phase machines.

The following table gives the values of  $k_1$  for uniformly distributed windings with equally spaced slots.

Slots per pole	Value of $k_1$		
	1 phase	2 phase	3 phase
1	1.000	.....	.....
2	0.707	1.000	.....
3	0.666	.....	1.000
4	0.65	0.925	.....
6	0.64	0.912	0.966
8	0.64	0.905	.....
9	0.64	.....	.....
12	0.64	0.90	0.960
18	0.64	0.90	0.960
24	0.635	0.90	0.958
$\infty$	0.632	0.90	0.958

These constants apply to a winding uniformly distributed around the armature periphery. This is always the condition in a two- or three-phase machine. A single-phase machine usually has its working winding irregularly distributed, so the above constants are only of theoretical interest. (See *special single-phase machines below*.)

**Pitch Constant ( $k_2$ ).** — It is sometimes desirable to use coils of fractional pitch, particularly in machines of large pole pitch, in order to reduce copper and  $I^2R$  loss, and also in any machine to give a particularly flat air-gap shape. When this is done each turn connects in series two conductors generating e.m.f.'s which are not in phase and their resultant is therefore not as great as their arithmetic sum. The constant  $k_2$  is the ratio of this resultant or vector sum to the arithmetic sum of the two e.m.f.'s. The relation between  $k_2$  and winding pitch expressed as a percentage of the pole pitch is given in the accompanying table.

**Leakage Factor ( $\nu$ ).** — The leakage factor, i.e., the ratio of the total flux produced by the field to the flux which enters the armature,

Arm. teeth.....	$\phi$	See below	.....	.....	$n$
Arm. core.....	$0.5 \phi$	$kl$	.....	.....	$k$

\* The value of  $m$  is found from the  $B-H$  curves in the article on *Magnets* when the flux density has been calculated.

**Field Yoke.** — The field yoke carries only half as much flux a piece, as the flux divides at this point. The material is usually cast steel. Find the magnetic density as indicated and refer to the proper magnetization curve to find the ampere-turns magnetizing force per inch for that density (see Fig. 4). The length of path is one-half the distance from the center of one pole to the center of the adjacent pole and is shown by  $i$  in Fig. 4. The total ampere turns as indicated.

**Field Pole or Magnet Core.** — This carries all the flux. The material is usually sheet steel of high permeability, but sometimes solid steel. The factor 0.95 is used for laminated steel poles; for solid poles this factor is unity. The length of this path is usually taken as  $c$ , the length of space for the field spool. This is not strictly accurate, but the density of the pole shoe ( $c_2$ ) is so low that the excitation required for this part is negligible.

**Air Gap.** — All the flux in the pole piece does not cross the gap, some leaks across the interpolar space. The value of the flux in the gap is the same as the useful flux in the armature. For the area of gap section the mean cross section ( $af$ ) of the pole shoe is taken. The length of the path in the gap is taken as the mean of the gap length. As the maximum length (at the tips) is usually made twice the minimum, and the outline of the pole shoe is made the arc of a circle, the average length is usually 1.25 times the minimum length. The ampere turns per inch are  $0.313 \times$  (density per square inch).

The total ampere turns calculated as above indicated is sometimes multiplied by a constant (0.9 to 1.1), to allow for the spreading of the flux into the air gap.

**Armature Teeth.** — The flux is confined at any one time to a portion of the teeth per pole known as "teeth under one pole." Since the flux spreads somewhat on leaving the pole piece it is logical to assume that the average length of a tooth is equal to the pole arc plus twice the length of the tooth. If, therefore, this length is divided by the pitch of teeth at the periphery of the armature, the quotient is the average number of teeth carrying flux at any given instant. This figure may quite properly contain a fractional number of teeth. The teeth being wedge shaped or sectors of a circle, that cross section (not the mean cross section) which will give the average excitation must be used. Since saturation increases more rapidly than the cross section decreases, an approximate value is found at a point one-third the distance from the minimum width towards the maximum width.

The effective cross section of the teeth is then equal to this width multiplied by the product of the effective length of the core by the number of

ive length of core is the net length of iron in the ce occupied by air ducts and insulation between s usually 10 per cent of the measurable length of  $l = 0.9 \times (\text{total length of armature core less space}$

n series,  
path in inches.

cross section of the copper in the cable is approximately on of the cable, exclusive of insulation. The length of cable is about 7 per cent greater than the length of the

The corresponding reactance is  $2\pi/L$ , where  $f$  is the frequency in second.

There are several paths for this so-called armature leakage flux surrounding one or more slots, namely, the path around each slot around a group of slots of one phase, the path around the end connections. The effect of the flux of one phase on the conductors of another (mutual inductance) must also be considered.

The slots lying under a pole have a path of greater permeance lying opposite the interpolar space or between poles, as the form is completely surrounded by iron.

With the exception of the path around the end connections, the length of each path is readily calculated by the same process as used above in finding the leakage factor. The path around the end connections is so long and the permeance so small compared with that in the core proper, that it is convenient and sufficiently accurate to add a percentage for this flux. This is done by allowing for every inch of the projecting length of the end connections one-tenth as much flux or inductance as for an inch of the embedded portion of the conductors.

In calculating the permeance of the various paths only the length of the path in air is considered, as the reluctance of the path in iron is so small compared to the path in air as to be negligible.

Let  $l$  = effective length of armature core;  $l'$  = length of end connection;  $P_1$  = the total permeance of all the leakage paths for a slot under a pole;  $P_2$  = the total permeance of all the leakage paths for a slot between two poles, and the other quantities as in Fig. 4. Then

$$P_1 = \left( \frac{\pi}{3lw} + \frac{\pi'}{w'} + \frac{p}{q} + \frac{l'}{2g} \right) (l + 0.1 l')$$

$$P_2 = \left( \frac{\pi}{3lw} + \frac{\pi'}{w'} + \frac{p}{q} + \frac{l'}{l+q} \right) (l + 0.1 l')$$

In addition to the above symbols, let  $f$  = frequency in cycles per second;  $s$  = slots per pole per phase;  $s'$  = slots in series per phase;  $c$  = effective conductors per slot =  $2 \times$  (turns per phase)/slots per phase;  $k_2$  = "pitch factor" (see above). Then the effective reactance in ohms per phase corresponding to the permeance  $P_1$  is

$$x_1 = 20.1 f^2 c^2 s' k_2 P_1 \times 10^{-8},$$

and corresponding to the permeance  $P_2$  is

$$x_2 = 20.1 f^2 c^2 s' k_2 P_2 \times 10^{-8}.$$

For reactance of turbo-generators see p. 658.

**Reactance Drop.**— For preliminary or approximate calculations it is better and more conservative to use the value found for the inductance of the slots "under the poles," as this gives a greater reactance and voltage drop, as the poles usually cover about two-thirds of the armature periph-

FIG. 4. Leakage Flux

the armature reactance drop per phase is taken as current per phase.

When both values must be used, and the power component of the current considered separately. Let  $I$  and  $I'$  the armature current per phase. Then the

$$I \sqrt{(x_1 \cos \theta)^2 + (x_2 \sin \theta)^2},$$

is taken for the effective armature reactance

$$\sqrt{(x_1 \cos \theta)^2 + (x_2 \sin \theta)^2}.$$

When current flows through the armature the armature reaction is a magnetomotive force which reacts on the field flux or diminishes the useful flux. If the current lags behind the generated e.m.f. it causes a "cross magnetizing force" passing midway between any pair of poles.

When the current in the armature changes, the direction of the armature m.m.f. shifts, and a component is introduced which is a field magnetizing force (for lagging current) or a demagnetizing force (for leading current). In a polyphase machine the armature m.m.f. for a given armature current lags and has a fixed direction with respect to the field flux depending on the phase of the current.

In machines with interpolar spaces, the direction of the armature reaction force would be such that the angle between this force and the field magnetizing force would be less than 90 degrees between the induced voltage and current.

In machines having interpolar spaces the reluctance of the field iron and armature m.m.f. is intentionally much greater than that of the interpolar spaces. The result of this is that the effect of armature reaction is to distort the field iron, however, changes the field magnetizing forces and renders accurate calculations. However, the approximation resulting from the assumption that the field iron is sufficiently accurate. The error in the calculation is on the safe side, since the armature reaction is less than its actual value.

**Ampere Turns per Pole.** — Let  $S$  = number of poles;  $I$  = effective value of armature current per phase;  $k$  = winding constant of the winding (see above under Magnetomotive force);  $A$  = armature ampere turns per pole effective in pro-

for two-phase machine,

$\frac{I}{2}$ , for three-phase machine.

armature reaction for a given effective value of the current. The armature reaction in single-phase generators is discussed in the following machines below.

The ampere turns of different machines at full rated load and low pole pitch, and is less for high frequencies than for low frequencies. The permissible armature-reaction ampere turns depend on the regulation.

A reasonable value for armature reaction would be between 150 ampere turns per pole for a 25 cycle machine and between 1000 and 60 cycle machine.

**Synchronous Reactance.**—The effect of the armature leakage and armature reaction upon the terminal voltage of a generator at excitation are of like character, since the voltage induced in the armature by each of these causes is in quadrature with the current. The "synchronous reactance" of a generator is the equivalent reactance which would produce the same effect as the armature leakage reactance and armature reaction.

The synchronous reactance may be predetermined by finding the ampere-turns (from magnetization curve) corresponding to a voltage drop due to leakage reactance and adding to these ampere-turns the armature reaction ampere-turns. The voltage from the magnetization curve corresponding to this sum divided by the armature current per phase is the synchronous reactance per phase. In the calculation of regulation by the "magnetomotive force method" (see below), however, it is more convenient to express the synchronous reactance in terms of the excitation ampere-turns which overcome it.

**Regulation.**—The regulation of a generator machine is defined as the difference in terminal voltage at no load and at full load to the terminal voltage at full load, the field excitation being kept constant at its full-load value. As a percentage the regulation is  $100(V_0 - V) / V$  where  $V$  is the terminal voltage and  $V_0$  the no-load terminal voltage at full-load field excitation.

Two different methods have been employed for the calculation of regulation, one known as the "magnetomotive-force" method, and the other as the "electromotive-force" method. Both are approximations, the first giving a value lower than the actual value, and the second a value higher than the actual value. More accurate methods are given in the *Standardization of A.I.E.E.*, which see.

**Magnetomotive-force Method.**—One way in which this method has been applied is the following: Let  $V$  = terminal voltage per phase at full load;  $R$  = alternating-current resistance per phase in ohms (= 1.15 times the direct-current resistance);  $I$  = full load amperes per phase;  $\cos \theta$  = power factor at full load;  $X$  = leakage reactance per phase in ohms. Calculate

$$V' = \sqrt{(V \cos \theta + RI)^2 + (V \sin \theta + XI)^2} \quad \text{and} \quad \theta' = \tan^{-1} \left[ \frac{V \sin \theta + XI}{V \cos \theta + RI} \right]$$

taking  $\theta'$  positive for  $I$  lagging behind  $V'$ . From magnetization curve find the excitation ampere-turns corresponding to  $V'$  and let  $n$  = armature reaction ampere-turns per pole for current  $I$  (see p. 635). The total field ampere-turns

$$F = \sqrt{m^2 + n^2 + 2mn \sin \theta'}$$

Let  $V_0$  = voltage per phase from the magnetization curve corresponding to excitation  $F$ ; then the regulation is

$$100 \frac{V_0 - V}{V}$$

The difference between  $V'$  and  $V$  and between  $\theta'$  and  $\theta$  is usually small, and in preliminary calculations  $m$  may be taken as the excitation ampere-turns corresponding to  $V$ , and  $\theta'$  may be taken equal to  $\theta$ .

**Electromotive-force Method.**—Let  $V$  = terminal voltage at full load;  $R$  = alternating-current resistance per phase in ohms (see preceding paragraph);  $XI$  = volts per phase from magnetization curve

required to send full-load current through armature  
 ent;  $I$  = full-load amperes per phase;  $\cos \theta$  = power  
 per phase  $E$  at no load, corresponding to the full-  
 sum of  $V$ ,  $R I$  and  $X I$ , or

$$V \cos \theta + R I)^2 + (V \sin \theta + X I)^2.$$

oo  $(E - V)/V$ , and the full-load field ampere turns  $P$   
 responding to  $E$  on the magnetization curve.

 ure winding is given above in the section on *Arma-*  
 armature copper loss is equal to the number of  
 rent resistance times the square of the current per

a current flows in the armature conductors a local

flux is set up which will cause eddy currents in these conductors, if they are well subdivided, and in the surrounding iron; as well as a hysteresis loss in the surrounding iron. The loss due to this load flux is called the "load loss."

The load loss is a function of the leakage flux and the subdivision of the conductors. A large number of turns of fine wire will involve a very small load loss. If the conductors must be large, they may be made of stranded cable to shape. It is almost impossible to calculate this loss, and very difficult to measure it. A rough method is to assume the resistance per phase increased 15 per cent, as this loss, like the true copper loss, is proportional to the square of the armature current. The total amount of the loss is less than 1 per cent of the input in well-constructed machines.

**Efficiency.** — Let  $P$  = total output in kilowatts;  $R_a$  = resistance of armature;  $I_a$  = armature amperes per phase;  $R_f$  = resistance of field winding;  $I_f$  = field current;  $q$  = number of phases;  $p$  = number of poles;  $C$  = total core loss in kilowatts; and  $F$  = friction and windage loss in kilowatts. Then the per-cent efficiency is

$$\frac{100 P}{P + C + F + (1.15 R_a q I_a^2 + p R_f I_f^2) \times 10^{-9}}$$

This assumes the load loss equivalent to increasing the armature resistance (as calculated or measured by direct current) by 15 per cent. If the load loss is determined from the short-circuit core loss the formula for efficiency is

$$\frac{100 P}{P + C + F + L + (R_a q I_a^2 + p R_f I_f^2) \times 10^{-9}}$$

where  $L$  is the load loss in kilowatts.

The efficiency is a maximum for that load at which the constant losses are equal to the variable losses.

Customary values for the efficiency at full load and each of the loads are given for various sizes of generators in the following table. These values are merely indications and vary with the frequency, voltage, speed, power factor, etc. A 60-cycle low-voltage machine will be likely to have a higher efficiency than a machine of the same rating for 25 cycles or high voltage.

EFFICIENCY AND LOSSES, USUAL VALUES

Rating, kV-a.	Efficiency, per cent	Friction, per cent	Excitation, per cent	Core, per cent	Armature, per cent

10,000	97.2	0.5	0.35	1.5	

\* Copper and load loss.

**Heating.** — The rise in temperature of the field coils is ascertained as an incidental step in the calculation of the field winding as explained above.

The rise in temperature of the armature is best determined by the method given by Arnold (see *Wechselstromtechnik*, Vol. IV, p. 141). In this method the losses in the projecting portions of the end windings are assumed

ated by the end windings while the core loss and copper loss in that portion of the winding embedded in the slots are radiated by the surface of the armature core. Let  $L$  = length of armature iron in inches;  $\lambda$  = mean length of bare turn in inches (see *Armature Resistance*, below);  $R_a$  = armature resistance per phase in ohms;  $I_a$  = armature amperes per phase;  $D_1$  = outside diameter of armature punchings in inches;  $D$  = inside diameter of armature windings;  $z$  = number of ventilating ducts;  $g$  = number of phases;  $t$  = rise in temperature in degrees centigrade per watt radiated per square inch of surface. Let the watts to be radiated are

$$P = \text{core loss} + \frac{2LgR_aI_a^2}{\lambda}$$

Let the radiating surface, including only one-half the area in the air ducts, as the sides of the air ducts are not as effective as the rest of the surface, is

$$A = \pi L(D_1 + D) + \frac{\pi}{4}(D_1^2 - D^2)(z + s)$$

Let rise in temperature by resistance in degrees centigrade is then

$$T = \frac{Pt}{A}$$

The value of  $t$  for a well-ventilated stationary armature ranges from 30 to 40, depending upon the thickness of coil insulation, and the peripheral speed of the field. For a stationary field and revolving armature the value of  $t$  given here for the rise in a revolving field may be used.

**Checking Calculations.** — Substitution in the following formula gives an excellent check on the above calculations:

$$\frac{DL_f}{Q} = \frac{KA \times 10^9}{fB_g \pi a^2}$$

where  $D$  = diameter of rotor at gap in inches;  $L_f$  = length of pole face parallel to shaft;  $Q$  = total kv-a. of generator;  $f$  = frequency in cycle per second;  $K$  = armature-reaction ampere turns;  $a$  = pole arc in inches;  $A$  = diameter of pole in inches;  $B_g$  = flux density, lines per sq. in. in air gap; and  $K$  = 22.5 for single-phase and 15.9 for two-phase or three-phase generators.

**SINGLE-PHASE GENERATOR.** — Single-phase generators do not make as effective use of the material as do polyphase generators, for the reason that the armature winding can occupy effectively only about one-half of the peripheral surface of the armature; if it occupies more than this there will be voltages generated in the windings which are so out of phase with each other that the resultant voltage is only from 63 to 70 per cent of the sum of all the voltages generated.

Therefore, if a polyphase generator is used as a single-phase machine with the same magnetic densities and the same copper densities, the output will be much less on account of the lesser voltage available. It is, therefore, customary to overload the magnetic elements of the machine somewhat to raise the voltage and thus reduce the overload on the copper which would be necessary to get the desired output. However, if both the iron and copper densities are increased until the machine gives as much output single phase as it is intended to give polyphase, there will be an increased heating. Thus, for the same heating, obtained by a readjustment of the iron and copper losses, a machine of a given first cost will give about 75 per cent as much output single phase as may be obtained polyphase.

In addition to the disadvantage of a single-phase generator that it cannot

make use of all the periphery of the armature, it also labors under the disadvantage that its armature reaction is pulsating instead of constant, and introduces an additional loss in the form of eddy currents.

By using two phases in series of a three-phase machine, or one phase of a two-phase machine, a fairly good single-phase machine is obtained. By winding slightly differently the same number and arrangement of (or coil sides) can be connected up to give a simpler winding requiring less windings of coils, that is, a winding "in one plane."

The formula for the calculation of the e.m.f. of a single-phase generator is  $E = 4.44 k_1 k_2 f S \phi 10^{-8}$ , where the symbols, with the exception of  $k_2$ , have the same significance as in the formula for polyphase machines, p. 629. The value of  $k_2$  depends upon the portion of the armature periphery (including the teeth between slots) occupied by the main winding. Let  $A$  = this fraction of the armature surface, then the corresponding values of  $k_2$  are given in the accompanying table. The value of  $A$  corresponding to a uniformly distributed winding is unity.

$A$	$k_2$
1	1
$\frac{2}{3}$	$\frac{2}{3}$
$\frac{1}{2}$	$\frac{1}{2}$
$\frac{1}{3}$	$\frac{1}{3}$

The average value of the armature-reaction ampere turns per pole of a single-phase machine is  $SI/\phi$ , where  $S$  = the number of turns,  $I$  = the armature current per phase, and  $\phi$  = the number of poles, but this pulsates between 0 and twice the above value. The evil effects of armature reaction may be reduced by employing a short-circuited winding having its axis at 90 degrees to the main field winding. A squirrel cage or "amperage" winding in the pole faces is frequently employed for this purpose.

Due to this pulsating action the load losses are greater and this must be taken into account in calculating the efficiency and regulation by considering the effective armature resistance as 1.15 to 1.5 times the direct-current resistance.

The leakage reactance of a single-phase machine pulsates between a value equal to that obtained by the formula above in the paragraph on *Leakage Reactance*, and a value two-thirds as great. Satisfactory results may be obtained by multiplying the value obtained from the formula by 0.67, which is the effective single-phase value. In this case the whole winding is considered as one phase.

**DESIGN OF TURBO-GENERATORS.** — In turbine-driven generators the steam turbine is usually built by the same company that builds the generator, and the two machines are practically one unit. The steam turbine has been developed to such an extent that for a given capacity in power it weighs less than a reciprocating engine, occupies much less space, costs less and is more economical of steam and fuel. Good economy in steam turbines, however, is obtained only with high angular velocities. This has made it difficult to apply the steam turbine to useful purposes. The electric generator has shown itself to be a suitable device to absorb the power of the turbine and make it available in a compact form and at convenient speeds for general application. It has required many years of experience to develop an electric generator which would operate successfully at the high angular velocities suitable for direct connection to the steam turbine. The principal difficulty was the design of a rotor which would withstand the enormous stresses in the revolving member resulting from the centrifugal force. Thus the design of the machine is largely a question of the type and construction of the rotor, and the field.

speeds. — Most turbo-generators have much more mass on the armature than do slow-speed machines, but the weight of copper is not far different in the two classes. The weight of magnetic iron on account of its high speed. It is of 5000 kv-a. capacity to operate at 3600 r.p.m. and at 1800 r.p.m. To do this involves the use of periphery speeds up to 27,000 feet per minute. At these high speeds the weight of material for each kilowatt is much reduced. Increasing the speed involves a higher cost of construction necessary to withstand centrifugal forces. Most of the machines, even the large sizes, have only two or four poles. This involves the use of a pole pitch of 120 degrees in 25-cycle machines, and 60 to 90 in 25-cycle machines. The flux is concentrated in such small bulk, a great deal of energy is dissipated in a small space. Thus special means are used, such as numerous air ducts, fan blades on the periphery, and a supply of clean, cool air.

— The design of a turbo-generator differs from that of a synchronous motor as described above, because the revolving field of the generator has a large number of groups of coils placed in slots and distributed concentrically on the poles, which resemble large teeth. The pole pitch is about one-third of the pole pitch and has no slots; the field winding gives a peaked shape to the flux wave which is made to approach a sine form as near as practicable as

Fig. 6. Field Distribution

is a developed cross-section of one pole. Thus the pole pitch is small, but the average flux density is approximately the same.

The pole is very large in order to provide a path for the large amount of flux required. On account of the high peripheral speeds the centrifugal force on the pole is high.

The revolving member is from 1000 to 1500 pounds in weight near the periphery. A method for determining the weight of every part is given in *Electric Machine Design*, by Charles F. Weinstock, and in *Electro-magnetic Machinery*, by Hobart and Ellis.

The construction is substantial and rigid, so that the critical stresses are within the normal speed of operation. There are several points of interest among which are:

1. The pole is formed to shape with radial slots containing a distributed winding. The field is in one piece with the field core; see Fig. 5.

2. The pole is consisting of steel discs about three inches thick held

distrib-

5.

hold

-dint

5.

hold

between the two end-plates by through-bolts; the radial or parallel slots milled in the assembled structure.

c. Steel laminations with radial slots, assembled on a forged steel shaft.

d. Laminated pole pieces attached to a spider by keys. (These are being built although there are a large number in service.)

In these revolving fields the length is about the same as the diameter. In large machines the length is greater than the diameter. The air gap is one to two inches. A uniform air gap is necessary to prevent noise and

**Construction of Stator.** — Since the pole pitch is large, a large number of slots per pole is used (12 to 24) and this gives a low armature self inductance and high short-circuit current. Due to the long pole pitch the end coils are long and subjected to considerable mechanical forces, as a result of the leakage flux. They must, therefore, be held securely in place by non-magnetic supports. For armature reaction in ampere-turns per pole values of 5000 to 20,000 are common, and the field winding is usually of a capacity 10 to 20 times the armature ampere-turns. The regulation is poor (20 to 30 per cent). This defect is readily overcome by the use of automatic voltage regulators (*Voltage Regulators*). The current density in the copper (2000 amperes per square inch) is lower than in slow speed machines, while the constant "ampere centimeters per inch periphery" has high values, viz., 600 to 1500.

**Provision for Ventilation.** — The ventilation of these machines is a problem similar to that of air-blast transformers. Thus there must be provided: (a) Sufficient air to carry off the heat generated with a reasonable rise in temperature of the machine and the air; (b) Ample duct capacity to prevent too high a velocity of the air; (c) Proper spacing of the ducts so that there is no part very hot; (d) Proper precautions to prevent the air from carrying dust or moisture into the machine.

One hundred cubic feet of air per minute at 20° C. will carry off 1 kilowatt of heat with a rise in the temperature of the air of 18° C. Velocities of the air of from 1000 to 6000 feet per minute are common in the machine proper. The surface of the stator will give off 4 or 5 watts per square inch with a rise of 35 to 45° C. of the cooling air.

There are two methods of ventilation, the "radial" and the "axial" (see Figs. 7 and 8). In the radial method air enters the air gap at both ends

Fig. 7. Radial Ventilation

Fig. 8. Axial Ventilation

out radially through air ducts  $\frac{1}{4}$  inch wide) at right angles to the shaft. In the radial method air ducts are placed in the stator every two or three inches. In the axial method the stator core contains many holes parallel to the shaft through which air passes, usually entering at both ends and passing out through large radial ducts at the middle of the core. Generally both methods are employed in one machine, and whichever method predominates determines the classification. The larger the outside diameter of the machine, the more appropriate is the axial method because of the depth of core. The machine is totally enclosed in either

air is taken in at a definite entrance and expelled at a definite exit, usually taken from outside the power-house and expelled outside also. An excellent discussion of ventilation is given by Lamme in the *Trans. A.I.E.E.*, Jan., 1913. (Also Knowlton, *G. E. Review*, May, 1916; Newbury, *Trans. A.I.E.E.*, Nov., 1916; Lamme and Newbury, *Trans. A.I.E.E.*, Nov., 1916.)

**Suitable Speed and Number of Poles.** — For 25-cycle machines, 2 poles at 1500 r.p.m. are used for all sizes including 35,000 kv-a. For 60 cycles, 4 poles and 3600 r.p.m. are used up to 6000 kv-a. 4 poles and 1800 up to 30,000 kv-a and 6 poles for larger sizes. Table I gives representative values of occasional constants.

**Preliminary Calculation of Main Dimensions.** — Equation (1), page 634, applies, but customary values of some of the constants are quite different for reasons stated above.

$\rho$  is usually unity with distributed windings.

$B$ , the average density in air gap varies from 25,000 lines per square inch in 60-cycle machines to 32,000 in 25-cycle machines. Maximum density is 1.37 times the average.

$V$ , the peripheral velocity, varies from 15,000 feet per minute in small, low frequency machines to 27,000 in large machines, figured at the surface of the revolving field.

$\sigma$ , the ampere conductors of the armature per inch periphery of the field, must be figured on the same diameter as  $V$  in order for the equation to check.  $\sigma$  has values as in Table I.

$D$  = outer diameter of field, in inches.

$L$  = total length of field parallel to shaft, in inches.

$k_2$  and  $k_1$  the same as on page 634.

Connection of armature winding may be single-phase, two-phase  $Y$ , or three-phase delta. For all three-phase machines for more than 6600 volts, the  $Y$ -connection is usually employed, for the reasons given on page 642.

**Number of Turns in Series per Phase ( $S$ )** is found as on page 642, preliminary value.

**Armature Reaction Ampere Turns ( $\pi$ )** per pole is found as per formula on page 647, and is an important criterion of design in turbo-generators. The values are very close to the values given in Table I.

**Number of Slots and Conductors per Slot** are determined by the number of turns in series by the relation

$$2QS = cs,$$

where  $Q$  is the number of phases,  $S$  the turn in series,  $c$  the conductors per slot and  $s$  the total number of slots. With values of  $2QS$  set, values of 1, 2, 4 and any other even number are tried until the combination which most nearly satisfy the equation is found.  $s$  must be divisible by the number of poles and the number of phases, in order to make a conventional winding. Usual values for  $s$  are given in Table I.

**Size of Armature Conductor.** — For preliminary purposes, a current density of 2000 amp. per square inch may be assumed, which divided into the current per phase gives the cross-section of one "effective" conductor in square inches. By "effective conductor" is meant the conductor which carries the current per phase. On account of the large currents in large machines it is frequently advisable to divide the winding into multiple paths, two or more. For instance, if there are two paths, each conductor carries half the phase current and is called half an effective conductor. To reduce eddy currents and skin effect, the conductors are usually made up of from 4 to 30 strands of angular wire laid parallel and insulated from each other. This makes it easy to build up a conductor of convenient shape, but necessarily reduces the current density factor.

**Size of Armature Slots** is determined, first, by the space necessary for the conductors and insulation, and, second, by the depth which is best suited to the diameter of armature. The slot factor is low for machines of this size for the following reasons: (1) high voltage is customary, (2) a considerable part of the slot is left vacant to serve as a passage for ventilating air, (3) the winding is deep in the slot to give sufficient reactance to limit the instantaneous short-circuit current. A typical slot would be 6 inches deep by 1 inch wide, with winding and wedge occupying only 5 inches of the depth. Customary slot factors are given in Table II, usual depths in Table I and space allowed for insulation and air in Table II. The dimensions given for insulation in Table I are for the insulation on both sides of the coil, that is, an allowance of 0.30 inch on each side. The area of the slot is equal to the cross-section of copper divided by the slot factor and the width of slot is equal to the cross-section divided by a suitable depth as judged from values in Table I.

**The Armature Winding** is usually a double layer barrel with as many slots as poles and one, two or three turns per coil. The coils usually have two-thirds that of a pole in order to shorten the end connections, save space, and reduce the copper loss. It is of the lap winding type shown in Fig. 2. There may be as many circuits in multiple in each phase

FACTOR AND SLOT INSULATION

Slot Factor	Insulation, inches	
	Depth	Width
0.35	1.25	0.17
0.35	1.50	0.25
0.33	1.50	0.32
0.30	2.00	0.46
0.27	2.00	0.55

the amount of current per circuit. Each turn is that it lies near the top of the slot on one side and side.

probable armature resistance is figured at this point the armature does not exceed that which may be figured as on page 645, except that the straight is 1 or 2 inches beyond the core, adding 7 to 8 turn. It is customary to figure the resistance of a temperature the resistance of 1000 feet of copper by ohm. The total  $I^2R$  loss should be from 0.2 per cent for small size machines; less in large machines. See

Armature is found as given on page 641, and has Table I. This is because the output per pole is so uniform quite uniformly from 1.1 to 1.15 and is low and distributed field winding.

adjusted so that the magnetic densities are about stator and rotor teeth and in the air gap the density maximum density (in the center of a field pole) is the density (see *Induction Motors, Polyphase*). For a may be assumed.

MAXIMUM MAGNETIC DENSITIES

	25 cycles	60 cycles
.....	90,000	80,000
.....	100,000	85,000
.....	50,000	45,000
.....	100,000	100,000
.....	90,000	90,000

uction. — The rotor teeth in the final analysis and to determine if there is sufficient material at the equal force due to the masses of the tooth and the the preliminary lay-out a number approximating

those given in Table I is selected, say 36 for a 2-pole machine, and spaced as if there were 54 slots, but two groups of 9 each are omitted at radially placed positions, thus forming the pole centers. This will give 9 coils per pole, in which will be placed 9 coils per pole, each of a different pitch all concentric with the pole center.

For each diameter there is a certain number and depth of slots which is the best proportion between amount of copper and strength of tooth. This may be judged from Table I. The width of a slot is made approximately 0.66 of the pitch on the circle at the bottom of the slots.

**The Length of Air Gap** is much influenced by its function in the machine. For the electrical characteristic of the machine it is found desirable to have the length such that the ampere-turns excitation expended in the air gap at no load and normal voltage are about equal to the armature reaction at rated load.

**No Load Magnetization Curve.**—This is calculated as for induction motors (q.v.) on account of the distributed field winding and the pole pitch of flux. The average densities are figured on a basis of full pitch pole pitch for all stator teeth per pole carrying flux. The maximum density in gap teeth and rotor teeth is obtained by multiplying the average density by 1.5 for a sine wave. With saturation in the teeth (over 110,000) or with wide pole centers, this constant becomes 1.5 or 1.4 respectively.

On account of the long air gap (long compared to slot openings and widths) the effect of slots in contracting the flux in the gap is not material. The density in the air gap may be taken the same as at the surface of the rotor. Investigation shows that the increase in density in the air gap due to the slots is only from 2 to 4 per cent and this is balanced by figure the density at the surface of rotor instead of at the mean gap diameter. The section of rotor teeth is figured at a point one-third the distance from the bottom of the slots and the total section includes the one large cent and several smaller teeth.

The average length of the path of the magnetic flux in the two core sections is considerably less than one-half the pole pitch on account of the distributed flux. It is usually about 100 to 120 magnetic degrees.

The materials used are generally silicon steel for the stator and formica for the rotor. The tendency of the flux to pass through the slots instead of the teeth is not so great in these machines as in other types because, in the rotor, the flux can spread out with saturation, and in the stator, because the densities are not very high. A magnetization curve between no load volts and ampere-turns per pole is usually plotted up to a voltage of 125 per cent of rated voltage.

**Armature Leakage Reactance.**—The formula used for slow-speed generators will not apply because of the large number of slots per pole and the connections and the formula used for induction motors is not suited because of the long air gap.

Arnold (*Vol. IV, p. 8*) gives a formula and proof which has been found to apply very well to present day turbo-generators. Referring to Fig. 4, all dimensions in inches, let  $P_s$  be the effective leakage flux per ampere-conductor in the stator then

$$P_s = 3.2L \left( \frac{n}{3w} + \frac{n'}{w'} + \frac{p}{g} \right),$$

where  $L$  = total length of core in inches.

Let  $P_t$  be the leakage flux per ampere-conductor from tooth tip to tooth tip set up by the belt of  $s_1$  slots per pole per phase, then

$$P_1 = L \left( 2.36 \log_{10} \frac{\pi^2}{2q} + A \right),$$

where  $z$  = pitch of teeth at face and "A" has values as follows:

$z =$	1	2	3	4	5	6	7	8	9	12	15
$A =$	0	.3	.6	1	1.7	2.1	2.7	3.2	3.8	4.8	5.5

Let  $P_c$  be the leakage flux per ampere-conductor around the end connections, cup by and interlinking the whole belt of  $s_1$  coils, then

$$P_c = l_c \left( 1.18 s_1 \log_{10} \frac{2 l_c}{U_c} \right),$$

where  $l_c$  = length of end connection at one end =  $\left( \frac{10 \gamma D}{2 \rho} \right)$  as in the calculation of mean length of turn.

$U_c$  = perimeter of a belt of coils =  $\pi + 2s_1 \pi$  in a double layer winding (see § 4).

Then the total reactance in ohms per phase is

$$x = 2 \pi f \rho s_1 c^2 k_s k_d (P_s + P_1 + P_c) 10^{-9},$$

where  $f$  = frequency;

$\rho$  = number of poles;

$c$  = effective conductors per slot =  $\frac{2 S}{\rho s_1}$ .

The reactance drop in volts is "x" times the current per phase, and this drop divided by the rated voltage is the per cent reactance, or per cent reactance drop, which is usually from 8 to 16 per cent.

**Excitation at Rated Kw-a.** — This is figured as on p. 648, Magnetomotive Force Method, giving conservative values, or as recommended in the Standardization Rules of the A. I. E. E. The excitation required in ampere turns per pole is found for full kw-a. output at 100 per cent and 80 per cent power factor.

**Design of Field Coils.** — These are usually designed to give the excitation required at 80 per cent power factor with about 80 per cent of rated exciter voltage, that is at 200 volts d-c. impressed across the field circuit terminals.

The suitable cross-section (sq. in.) of field conductor is found by the relation

$$a = \frac{0.0115 \times (ml) \times F \times \rho}{E_s \times 12,000},$$

where  $(ml)$  = mean length of field turn (ins.) figured as for the armature turn except as to pitch diameter (at center of slots) and as to pitch of end connections, usually 67 per cent, and

$F$  = required ampere-turns per pole;

$\rho$  = number of poles;

$E_s$  = Assumed voltage across field;

0.0115 = resistance per square inch per 1000 feet of copper at 125° C., the temperature commonly assumed for field copper.

This section,  $a$ , is definite for the conditions assumed and is independent of the number of turns. The number of turns depends upon the allowable heating. The more turns (more copper) the less the loss.

The working field current  $I_f$  is found (a) by assuming 1500 amp. per inch in this section of conductor for the excitation for 100 per cent power or (b) by assuming a definite loss for excitation and dividing this loss by the assumed voltage on the field. The number of field turns per pole  $t = F + I_f$  and these turns are distributed equally in the available slots. It should be noted that each turn lies in two slots. The field slot factor  $k_f$  varies from 0.4 to 0.6, the lower value applying where much space must be allowed for ventilating air. Field coils made up with mica and asbestos insulate successfully with a specific loss of 0.90 watt per square inch of coil surface giving a rise of about 50° C.

**Efficiency and Losses.** — The losses are friction, excitation, core-loss, armature  $I^2R$  and load loss. The last two are usually combined and referred to as the "armature copper loss." The principal friction is that due to the brushes and is a function of the ventilation. The excitation loss is treated above. Core-loss is best calculated on the basis of the loss per cubic inch at the maximum densities as discussed in the article on *Magnetic Properties of Iron*. The material used is usually 14 mils thick, having a hysteresis coefficient  $\eta$  and eddy current coefficient  $\epsilon = 0.00007$ . In turbo-alternators the value by test usually comes out very close to the calculated value, thereby justifying the use of the above formulae. In other machines in which a factor greater than unity must be used for practical results.

The armature copper loss is greater than the true ohmic loss by from 20 to 50 per cent on account of the load losses.

TABLE IV. — USUAL EFFICIENCIES AND LOSSES

Kv-a	Per cent efficiency	Per cent friction	Per cent excitation	Per cent core-loss	Per cent armature loss
3,000	96	1.50	0.70	1.20	1.20
5,000	97	1.30	0.45	1.00	1.00
10,000	97.5	1.00	0.35	0.90	0.90
20,000	98	0.80	0.25	0.77	0.77
30,000	98.2	0.70	0.20	0.75	0.75

**Heating of Armature and Field** may be estimated by means of the formulae given under the section above on *Ventilation*; 100 cubic feet of air per minute is provided for each kilowatt of loss. The rise in the armature coils is about 100° C. per watt per square inch of coil surface and in the field coils about 50° C. per watt per square inch.

**Synchronous Impedance** is very high on these machines and the short-circuit current correspondingly small. It is frequently the case that for rated excitation for rated voltage and no load, the short-circuit current is less than the rated load current. Thus voltage regulation by external means is absolutely necessary, the inherent regulation being from 20 per cent to 30 per cent at unity power factor and rated load.

**TESTS OF ALTERNATING-CURRENT GENERATORS.** — (See *Standardisation Rules of the A.I.E.E.*) The principal tests are

- Magnetization or saturation test;
- Core-loss and friction tests;
- Synchronous-impedance test;
- Load-loss test;
- Resistance measurements;
- Heat runs;
- Insulation tests.

Examples of test results are given below; typical test curves are given in Fig. 9.

Fig. 9. Typical Test Curves

**Magnetization Curve.**—The magnetization curve, popularly known as the "no-load saturation curve," shows the relation between the no-load voltage and the current in the field. Fig. 10 shows the connections for making this test. On account of the existence of the hysteresis loop (see article on *Magnetism of Iron*), it is necessary, in running this test, to increase the field gradually from point to point and never reduce the value at any point until the highest excitation has been obtained. The curve differs from the magnetization curve of a closed sample of iron because the circuit of the alternator contains a considerable air gap, the magnetization curve of which is a straight line. Therefore, if the saturation curve of the machine contains a portion which is very straight, the indications of the air gap is of considerable magnitude. If the machine is operated at very high magnetic densities, this is indicated by the fact that the field current corresponding to rated voltage is found at a point on the curve where it is nearly horizontal.

Some machines obtain good regulation by operating at high saturation. This is a cheaper method than by using a low value of armature reaction and leakage reactance.

The magnetization curve is usually plotted in terms of the volts between terminals. In comparing the observed and calculated magnetization curve it should be noted that the calculations are expressed in terms of the volts per phase.

**Core Loss and Friction.**—The open-circuit, or true core loss curve shows the core loss in watts for each value of the no-load terminal voltage. It is made by driving the generator at rated speed by means of a small motor of known efficiency of which is known, and varying the generator excitation. Fig. 10 shows the connections for this test. The voltage and mechanical power input to motor multiplied by its efficiency) required for each value of excitation are noted. The power  $P_0$  for zero excitation is the friction loss of the machine. The core loss for any excitation is  $P - P_0$ . The no-load saturation curve can be made at the same time as the core-loss test.

**Synchronous Impedance.**—The synchronous-impedance curve shows the relation between various values of field current, or excitation amperes, and the current that flows in the armature on short circuit. It is made by short-circuiting the armature through ammeters and operating at full frequency with various values of field current. Fig. 11 shows the connections for this test. Of course only fractional values of normal excitation are used, or the current in the armature would be so great as to cause damage.

The synchronous-impedance curve gives approximately the ampere turns corresponding to armature reaction and the leakage reactance drop in the armature combined, i.e., the ampere turns corresponding to the synchronous impedance. The approximation arises from the effect of the armature reaction and the low saturation or magnetization of the magnetic circuit under the test circuit conditions.

Fig. 10 Connections for Magnetization Curve, Core Loss and Friction

Fig. 11. Connections for Synchronous Impedance and Load-loss

**Stray Load-losses.** — These include iron losses, and eddy-current losses in copper, due to fluxes varying with load and also to saturation.

The following is quoted from the *Standardization Rules of the A. I. E. E.*: Stray load-losses shall be determined by operating the machine on short circuit and rated-load current. This, after deducting the windage and friction and R loss, gives the stray load-loss for polyphase generators and motors. These losses in single-phase machines are large; but the Institute is not yet prepared to specify a method for measuring them.

**Resistance Measurements** must be made when all parts of the machine are at a known temperature. They are also made after the heat run, when the machine is hot, to check the temperature as measured by thermometers (see note on *Resistance and Conductance*).

**Field Resistance** is measured by the simple voltmeter-ammeter method (see article on *Resistance and Conductance*).

**Armature Resistance.** — The armature resistance between terminals (a) is measured by the simple voltmeter-ammeter method, by connecting two of the terminals to a source of direct current (the other terminal being free), the rotor (field or armature of course being at rest). In the case of a single-phase or two-phase machine the resistance as thus measured is the resistance per phase. In the case of a three-phase machine, let  $R_t$  = the resistance as thus measured and  $R_p$  = the resistance per phase. Then for a Y-connected armature  $R_p = R_t \div 2$ , and for a  $\Delta$ -connected armature  $R_p = 3R_t \div 2$ . If the connection is not known, the calculation of the resistance drop and copper loss may be figured correctly assuming it either Y or  $\Delta$  connected, provided the resistance per phase and current per phase are both calculated on the same assumption regarding the connection. In the case of a two-phase machine the resistance between terminals A and B and between B and C (B being the common terminal) should each be measured, and the average taken. In the case of a three-phase machine the resistance between A and B, B and C, and A and C should be measured and the average taken.

**Calculation of Regulation and Efficiency from Tests.** — From the results of the preceding observations, the regulation and efficiency of the machine at various loads may be calculated by the methods given above, in the discussion of *Predetermination of Performance*, using the test data instead of the calculated quantities. The synchronous-reactance ampere turns may be taken as equal to the synchronous-impedance ampere turns, since the resistance drop in the armature on short circuit and reduced excitation is seldom more than 10 per cent of the synchronous-reactance drop, and as the two are in quadrature the synchronous-impedance drop differs from the synchronous-reactance drop by less than one per cent. In using the magnetization curve and the synchronous-impedance curve one must keep in mind whether they are plotted in terms of voltage and current per phase or in terms of volts between lines and line current.

**Full-load Saturation Curve.** — This curve shows the relation between the terminal voltage and field current with full-load current in the armature. It may be plotted from tests or calculated from the magnetization curve and the synchronous impedance in the same manner as the regulation is calculated.

**Armature Leakage Reactance.** — There are three methods by which the leakage reactance may be determined:

(1) **Synchronous-impedance Method.** — This gives only approximate results but is very generally used as a synchronous-impedance test is made on every generator. Let  $n$  be the field ampere turns per pole required to force full-load current through the short-circuited armature. Let  $a$  be the calculated

armature-reaction ampere turns per pole (see above), with rated current. Then  $n - a$  is the excitation necessary to induce the leakage reactance ( $lX$ ) in the armature. From the open-circuit saturation curve find the current corresponding to  $(n - a)$  ampere turns. Reducing to volts per ampere necessary, and dividing by the current per phase, the result is the leakage reactance  $X$  per phase in ohms.

(2) **Full-load Characteristic Method.**— This method is also used. Let the excitation in ampere turns per pole required to give rated current at full non-inductive load be  $q$ . Let the ampere turns to give rated current without load be  $m$ . Then  $n = \sqrt{q^2 - m^2}$  is taken as the synchronous-current ampere turns, and the leakage reactance is calculated as described in the preceding paragraph.

(3) **Inductance-measurement Method.**— This method gives more accurate values, but is not very often employed. From an external source of constant frequency, full-load current is sent through the armature of the machine tested, with the fields excited to the normal value but not rotating. The voltage drop across the armature terminals is measured for several positions of the coils with respect to the poles, ranging through an arc of one-half the pole pitch. Let  $Z$  = the voltage per phase divided by the current,  $R$  = the resistance per phase corrected for load loss (i.e., the effective resistance as determined from the short-circuit core-loss curve), then the leakage reactance per phase is  $X = \sqrt{Z^2 - R^2}$ . This reactance will vary with the position of the coils and the maximum and minimum may be found by making calculations for the different positions of the coils with respect to the fields.

**Heat runs** are made at rated load and various other specified loads in parts in which the rise in temperature is of interest are:

- Armature core surface;
- Armature core ventilating ducts;
- Armature conductors;
- Collector rings;
- Both pole tips;
- Field winding;
- Bearings;
- Frame;
- Room.

The temperature of the field and armature winding should be measured by thermometers and by the resistance method. In taking the temperature of a hot surface by thermometer a small pad of waste should be placed over the bulb after the thermometer is put in place. The pad should not be too thick or it will prevent the normal radiation from the surface.

With large machines it is inconvenient and expensive to test under full-load conditions. For determining the heating without actually developing full power of the machine there are several methods available.

**Reversed-field Method.**— The field circuit may be tapped to give full-load field current sent through a portion of the field coils in a direction opposed to that for normal operation. For example, in a 24-pole machine the field current in 8 of the field coils may be directed in such a manner that it is reversed with respect to the remaining 16. The armature winding will then generate a voltage due to the 8 poles that are not neutralized and the terminal voltage will be approximately one-third rated value. If the armature is short circuited a current will flow due to this reduced voltage, and this current can be made approximately equal to the full-load value by making a proper division of the field current. If the machine is operated under these conditions the friction, excitation

and armature copper loss will be very nearly equal to their value under normal operating conditions, yet to drive the machine only an amount of power approximately equal to the sum of the losses is required.

**Synchronous-motor Loading.**— If two machines are available they may be connected up as a generator and synchronous motor and the field excitation of the motor adjusted so that a current of full-load value, but having a large reactive component, will flow in the armature, the power factor being nearly zero. The power required to drive the generator at full-load excitation at full-load current will then be small.

**Direct-current Loading.**— Full-load losses may be simulated on a three-phase generator by connecting the three phases in delta and leaving the delta open at one point, to which a direct-current ammeter and a source of direct current may be connected in series. The delta is first closed through an alternating-current ammeter and the triple-frequency current in the delta (see *Alternating Currents*) is measured. The direct-current ammeter and source of direct current are then connected in series with the delta and the direct current increased until the sum of the squares of the local current of triple frequency and the direct current is equal to the square of the rated current per phase.

**Open-circuit Short-circuit Method.**— Another ingenious method, advocated by Hobart, consists in alternating open-circuit and short-circuit tests, each under exaggerated conditions, so that at the end of each hour the total extra hours lost in each part are equal to the watt hours that would be lost in normal operation. For example, let the core and field copper loss be 4 kilowatts, and armature copper loss 1 kilowatt. If, now, the machine is operated for 20 minutes with armature short circuited and the excitation adjusted to give 1 kilowatts copper loss, and for 40 minutes on open circuit with excitation adjusted to give 6 kilowatts core and field copper loss, then the loss per hour in the armature copper is 1 kw.-hr., and in the field winding and core 4 kw.-hr., the same as under normal conditions. For an exact division of the time between the open-circuit and short-circuit conditions, the core and field copper loss during the short-circuit run must be taken into consideration. After several hours of this relaying the machine will have reached a temperature corresponding to full-load operation.

**Insulation Tests.**— The insulation of a machine is usually tested by applying a given voltage between the conductors and the part of the machine from which they are insulated. An insulation resistance test is also made.

**Voltage Tests.**— During manufacture the coils are tested separately, and after the machine is assembled a voltage test between the completed windings and frame is made. After the heat run, while the machine is still warm, a third test of the insulation between windings and frame is made.

For this third test an alternating voltage is applied between armature and frame, according to the *Standardisation Rules of the A.I.E.E.* (q.v.)

The voltage should be increased gradually and the final value should be applied for one minute. In this test the machine acts as a condenser and therefore care should be taken that the frequency is not so high or the inductance of the supply circuit so great as to set up resonance. It is advisable to have considerable resistance in the supply circuit.

To prevent an uneven distribution of voltage, all the terminals of the winding should be connected together by fine wires and one terminal of the high-potential circuit connected to the common connection. The high potential should be measured by a spark gap connected in shunt to the machine.

**Insulation Resistance.**— The insulation resistance is measured by connecting one terminal of a 500-volt direct-current supply to the windings of the ma-

chine through a voltmeter with a 500 scale, and connecting the other terminal to the frame. If the resistance of the voltmeter is  $R_v$ , ohms, and the voltmeter deflection  $x$ , the insulation resistance is  $R = \frac{R_v}{x}(500 - x)$ .

**EXAMPLES OF DESIGN AND PERFORMANCE.** — In the pp. 667 and 668 will be found the essential data both of the mechanical and electrical features of four representative alternators. The list of items will be useful as a guide in collecting data on various machines. Performances are deduced from tests.

**OPERATION.** — In the operation of an alternating-current generator the following factors should be considered:

**Phase Connections and Grounding.** — When a third harmonic is present in the e.m.f. wave of a three-phase generator, the triple frequency e.m.f. in the three phases (or windings) are additive when the three phases are connected in  $\Delta$ , that is, the  $\Delta$  forms a short circuit to the third harmonic e.m.f.'s, and a triple frequency current may therefore be set up in the windings irrespective of the load on the machine. On this account, large three-phase generators are usually  $Y$ -connected, since with this connection the third harmonic e.m.f.'s between any two terminals of the machine neutralize each other. When two or more  $Y$ -connected machines are operated in parallel and their neutrals grounded, a triple frequency cross-current of considerable magnitude may be set up between the machines, unless the wave form of the e.m.f. of the various generators are exactly the same, which is practically never the case. To prevent such cross-currents with  $Y$ -connected machines with grounded neutrals it is the usual practice to ground the neutral of but one generator in a group. Provision must of course be made to shift this ground connection from one machine to any other, so that a ground connection can always be maintained in respect of which machine or group of machines may be running.

The advantages and disadvantages of grounding the neutral are discussed in the article on *Grounding of Electric Circuits*.

**Division of Load between Alternators in Parallel.** — The division of load between two or more alternators operating in parallel cannot be controlled by altering their field excitation, as is the case with direct-current generators. Changes in the load taken by any alternator of a group can be effected by admitting more or less steam to the driving engine or turbine (or water-wheel). In order that the various alternators shall share the load properly, it is therefore necessary that the governors on the several engines or movers give the same speed-load characteristics.

Although the field excitation has no effect on the distribution of the load between the alternators, it does affect the power factor of the load delivered by each machine. The excitation of each alternator should be so adjusted that each delivers its load at the same power factor as the others.

**Starting a Single Generator.** — Before a generator is started up it must be inspected and cleaned and filled with oil if necessary. The speed is then brought up to the proper speed and the bearings again inspected to see if the oil-rings are running properly. The exciter or excitation circuit is then put in readiness and the rheostat in the alternator field circuit adjusted for the desired resistance. Before exciting the field the armature insulation must be thoroughly dry. If it is not the armature is short-circuited through an ammeter for several hours at a partial excitation to give about rated current in the short-circuited armature. When the insulation is thoroughly dry the short-circuit is removed and the excitation adjusted to give rated voltage at the terminals with correct speed. To shut down the machine the load

removed by opening the circuit breaker; then the field rheostat is set at maximum resistance as is also the rheostat in the exciter field if there is an individual exciter. Then the field circuit is opened.

**Paralleling of Generators.**— Before connecting a generator to a bus-bar which one or more other generators are connected, the following conditions must be satisfied:

1. The frequency of the generator must be the same as that of the bus-bar.
2. The frequency of the generator, and therefore its speed, must be constant for an appreciable interval of time.
3. The voltage of the generator must be the same as the voltage of the bus-bar.
4. The generator and bus-bar voltage must be in phase.

If the two machines have not the same frequency or if the frequency is not constant, a condition will occur intermittently in which the two machines are  $180^\circ$  apart or the two machines are in series on a short circuit, and a large current will flow. If the voltages are not equal, a large "wattless" current may flow, and if the two voltages are not in phase, a large current will flow which will cause a mechanical shock. To indicate when these conditions are fulfilled any one of several "synchronizing" devices may be employed, as described in the article on *Synchronizers and Synchronoscopes*.

**Synchronizing with Lamps.**— The simplest method of synchronizing small machines is to use incandescent lamps as shown in Fig. 12. In Fig. 12A the connections are such that the lamps remain dark when the above conditions are satisfied, while in Fig. 12B they will remain bright under these conditions. If the frequencies are wrong the lamps will flicker (the slower the flicker the nearer the two frequencies). If the voltages are wrong the lamps in

s is due to the fact that it takes a finite period of time  
ature reaction to weaken the magnetic field. During  
damage may be done to circuit breakers, etc. This is  
turbo-alternators, as these, due to their construction,  
sient short-circuit current.

l Reactance. — It is therefore frequently the case that  
are connected in circuit with these machines to prevent  
ring in case of sudden short circuit. See *Reactance Coils*.

erators on Short Circuit. — Induction generators are  
e they lose their excitation almost immediately on short  
becoming popular in large central stations.

Thermometers. — In large generators thermocouples or  
s (see *Pyrometers*) are sometimes embedded in the es-  
of the winding, and connected to a suitable indicating  
imes the maximum temperature of the machine. See  
les of the A.I.E.E.

**SPECIFICATION FOR A-C. GENERATOR.**—The following standards are intended to assist in writing specifications. See also article *Specifications*.

**Principal Characteristics and Conditions of Service.**—Service generator is to be used, such as a-c. lighting, single-phase railway operating railway or lighting synchronous converters, etc. Voltage and number of phases. Rated output in kilowatts or kilovolt amperes at standard factor. Frequency and speed.

**Style and Description; Details of Construction.**—Type of revolving field, induction type, etc. Details of speed, governing motor, and how generator is connected to prime mover, e.g., direct driven by steam turbine, reciprocating engine, water wheel, water turbine, engine, oil engine, etc., with vertical or horizontal shaft. Whether rated. Whether exciter is to be supplied; if so, its characteristics. Rheostat is to be supplied, its characteristics, including the effect on generator voltage of each step and of all steps; whether to be controlled by hand or automatically. Restriction of excitation current and voltage requirements respecting carrying capacity of slip rings. Accessibility of slip rings. Whether embedded thermometer coils shall be furnished. Windings to be clamped securely to prevent any vibration of overhanging parts. Method of protection of armature conductors if exposed. If belt driven, special details; whether bed plate is desired.

**Work to be Done by Other Contractors.**—Whether Contractor to furnish and install the following. Main wiring, field wiring, field rheostat, dial plate and chains. Point of division between engine and generator contracts.

**Performance and Tests.**—(See *Standardization Rules of the Institute of Electrical and Electronic Engineers*) Temperature rises upon which ratings are to be based. Details of carrying capacity. Efficiency at 25, 50, 75, 100, and 125 per cent load. High temperature tests of insulation. Requirements regarding effects of moisture on insulation. Requirements for parallel operation, i.e., whether the machine is to operate in parallel with similar machines or different ones. It is recommended to specify that the terminal voltage shall vary according to a sine law. Rating to be at 100 per cent power factor and normal speed; the load may be varied from zero to 150 per cent of rated load without causing more than 5 per cent variation of voltage, the exciter field being kept constant.

**DIMENSIONS, WEIGHT AND COST (1922 prices).**—While generator ratings vary widely in their specific weights and costs, that is weight per kv-a. and cost per kv-a. rating, they may be divided into classes in which their characteristics are fairly definite.

The conditions primarily affecting the specific weight are: method of construction, speed, frequency, voltage and size. In addition there are the peripheral and mechanical construction which cannot be easily classified. The rating is fundamental. For purposes of comparison the rating may be taken as the output in kv-a. which each machine will give continuously without exceeding 50° C. On this basis the specific weight increases with the speed, frequency or capacity increases, and increases with increase in voltage. The cost per pound decreases as the frequency decreases, as the capacity increases. The cost per pound increases as the voltage increases and peripheral speed increases.

Alternating-current generators may be divided into three classes according to their speeds and purposes:

High speed, as turbine-driven generators.

and Suitable Speed for 60-cycle Turbo-generator Sets, Including Turbine.

and Suitable Speed of Water-wheel driven 60-cycle A-C Generator.

Medium speed, as belt-driven and water-wheel-driven.  
 Slow speed, as engine-driven generators.

Approximate weights, costs per kv-a. and suitable speeds are in Fig. 13 for turbo-generators and in Fig. 14 for water-wheel-driven 60-volt, polyphase machines. The weight and cost of 25-cycle generators from 10 to 20 per cent greater than for 60-cycle generators. Turbo-generators for less than 2300 volts is practically the same as for 2300-volts. Two-phase generators weigh and cost practically the same as single-phase. Single-phase generators weigh and cost from 25 to 30 per cent more. These data are of course suitable only for preliminary estimates; particularly, are subject to large variations due to changes in conditions from year to year. For final estimates exact dimensions and weights should be obtained from the manufacturers.

**DC-CURRENT.** — (See also *Alternating Current, Principles of; Generators, Alternating-Current; Standardization Rules.*)

Direct-current, or, as it is sometimes called, continuous-current, was in general use before the alternating-current type. For the distance to which energy is to be transmitted there is no doubt that the direct-current system is to be preferred. For energy is to be transmitted over long distances the direct-current system with its transformer has unequivocal advantages. The compromise is that a compromise is adopted. The major advantage is that provide alternating currents and many of the disadvantages are provided by rotary converters. Thus the direct-current system is of less relative importance while the direct-current system occupies an important position.

A fundamental principle involved in the construction of a dynamo-electric machine is the production of an induced current in more conductors by the relative motion of these conductors. Such a machine may, as a rule, be used either as a generator or as a motor.

A shunt machine, either generator or motor, is one in which the field current is derived from a circuit of many turns and high resistance. The voltage regulation is poor or multiple with the armature circuit. The voltage regulation is poor; that is, the voltage of a shunt machine falls as the load increases. This is so marked that some shunt machines, when heavily loaded, their terminal voltage dropping to zero.

A series machine, generator or motor, is one in which the field current flows through the field winding. Series generators are used to supply constant current to an external circuit irrespective of the voltage of that circuit.

A compound machine. — This type of machine is sometimes used in which the field current is readily obtained from separately excited field regulator is used.

A long-shunt machine. — This type of machine has on each field pole a few turns of thick wire which carry the load current. This winding causes the excitation to be constant and tends to keep the terminal voltage constant. The field windings are proportioned to cause the terminal voltage at no load the machine is said to be "flat compounded" machine has the same voltage at no load; an "under compounded" machine has a lower terminal voltage at no load.

Connections. — A compound-wound machine may be connected as in Fig. 1 or long shunt as in Fig. 2. The convenience of station wiring.

Fig. 2. Long-shunt Connections

**Commutating Pole or Interpole Machines.**—These machines have small auxiliary poles alternately placed with respect to the main poles and excited by a few turns in series with the load. The effect of these poles is to improve the operation of the machine in the matter of commutation.

**Bi-polar Machines.**—Small continuous-current machines are of the bi-polar or two-pole type with a more or less inclosed frame of cylindrical shape.

**Multi-polar Machines.**—Large direct-current machines are of the multi-polar type, that is, have a large number of radial pole pieces.

**Belt-driven and Direct-connected Types.**—Direct-current machines may be of either the "belt-driven" or the "direct-connected" type, determined by the method of connecting to the driving unit. Belt-driven machines are characterized by a higher angular velocity than direct-connected machines.

**RATINGS.**—It has been common practice (up to 1914) to rate direct-current machines on the basis of the output in kilowatts which they will give continuously with a maximum rise in temperature by thermometer of  $50^{\circ}$  above the surrounding air at  $25^{\circ}$  C. See however the recent recommendations of the A.I.E.E. in the article on *Standardisation Rules*.

**VOLTAGE.**—The standard voltages for which continuous-current machines are built are:

80 volts for use on shipboard.

110-125 volts for lighting purposes and incidental small power motors, cooking utensils.

220 volts for three-wire systems with lighting and power combined.

500-600 volts for power alone and particularly for railway service.

1200-2400 volts for special railway service and heavy traction.

2000-6000 volts for series-arc-light circuits fed by series machines.

### ELECTROMOTIVE FORCE INDUCED IN ARMATURE

$Z$  = total number of armature conductors

$p$  = number of field poles.

$m$  = number of parallel conducting paths between the positive and negative brush sets; that is  $\frac{Z}{m}$  is the number of armature conductors

in series between positive and negative brush sets. (See *Armature Windings*.)

$\phi$  = total useful magnetic flux per pole.

$N$  = revolutions of armature per minute.

$f$  = frequency in cycles per second.

If a coil of wire be revolved about an axis in a magnetic field as shown in Fig. 3, each length of conductor, or side of the coil, will pass under

the armature in  $\frac{60}{N}$  seconds. The time taken for a conductor to pass through the magnetic field under each

pole, or from  $a$  to  $b$ , is  $\frac{60}{Np}$ . Hence the average value of the electromotive force induced in each armature

conductor as it passes under each pole is  $\frac{Np\phi}{60 \times 10^8}$  volts,

since a cutting of  $10^8$  lines per second gives one volt. Since in an actual machine the conductors are uniformly distributed around the surface of the armature, this is also the average voltage induced in each of the conductors between  $a$  and  $b$  at any instant.

Fig. 3.   
 Gen

ries between the positive and negative brush sets,  
 and electromotive force between the brushes, when a  
 (w) is provided, is

$$E = \frac{p\phi ZN}{60 \times 10^8 m} \text{ volts.}$$

each conductor alternates (i.e., passes through a  
 and negative values) with a frequency of  $f = \frac{pN}{120}$   
 the formula for the average e.m.f. between brushes is

$$E = \frac{2 f \phi Z}{10^8 m} \text{ volts.}$$

series between the positive and negative brushes is  
 expressed as

$$E = 4 f \phi S \times 10^{-8} \text{ volts.}$$

ous electromotive force can be obtained from the  
 for reversing the connection from each conductor  
 same time that the direction of e.m.f. induced in  
 this is accomplished by the commutator. Taps  
 connections of the armature windings are connected  
 nutator, so that as the segments come alternately  
 brushes the current delivered to the circuit is always

**WINDING.** — Though there are a large variety of types of  
 ical man and even the designing engineer seldom  
 the multiple-drum or lap winding and (2) the two-  
 winding. The other types may be used in a few  
 lines but a designer may work for many years with-  
 using them.

**Winding.** — This type of winding is very common  
 otary converters, induction motors and is somewhat  
 generators. Its chief advantage is that it affords a  
 ber of coils and slots, and is very simple to lay  
 disadvantage is that it is not easily adapted to cir-  
 characteristic is that there are always as many cir-

Fig. 5. Wave Winding

ny studs of brushes as there are poles. The dis-  
 tance is the direction of bending of the end con-  
 fig. 4. The characteristic form of the coils is shown

**Winding.** — The customary simplex multiple-  
 addition expressed by the formula

$$C = pz = \dots$$

where

$C$  = total number of coil-sides or bars,

$p$  = number of poles,

$z$  = average pitch\* =  $\frac{\text{front pitch} + \text{back pitch}}{2}$ ,

$s$  = total number of slots,

$b$  = number of coil-sides or bars per slot.

The total number of sides ( $C$ ) is double the number of coils, has two sides.  $C$  must be a multiple of the number of slots ( $s$ ) number of poles ( $p$ ).

The average pitch ( $z$ ) must be an even number so that the front pitches may be different and odd ( $z - 1$ ) and ( $z + 1$ ), respectively always two layers of coil-sides, top and bottom. One side of each coil is in the top layer in one slot and in the bottom layer in another slot. The front and back pitches of a coil are always odd because they are made from the top layer (odd numbers) to one in the lower layer (even number). Fig. 6. Here the pitch is  $14 - 1 = 13$ .

Fig. 6. Pitch of Connection

Fig. 7. Lap Winding

In order that the winding should progress continuously the front pitch of commutator connections, must differ by one coil (or two coils) from the back pitch, or actual pitch of coils. The actual spread of a coil (Fig. 7) is the same front and back and is equal to the "back pitch".

The total number of coils  $Q = C/2$  is equal to the number of segments and must be a multiple of the number of slots. In general a common multiple of the number of poles and the number of slots drum winding is possible. It is sometimes desirable that the number of coils should not be a multiple of the number of poles. In order to grow in poly-coils  $z$  should be a multiple of the coil-sides per slot.

**Series-drum or Wave Windings, Simplex.** — This type of winding is used in direct-current armatures where the ordinary multiple drum winding would give too low a voltage or require too many turns of fine wire in each coil. Its advantage is that it gives an armature that is better balanced magnetically and that only two brush studs are necessary. A greater number of studs may, however, be used. There are always two circuits in multiple, regardless of the number of poles. The characteristic reverse bends of its face conductors are shown in Fig. 5. The characteristic form of the coils is represented in Fig. 8.

Fig. 8. Wave Winding

**Conditions for Wave Winding.** — The conditions to be observed in laying out a series-drum winding are expressed in the formula

$$C = pz = 2 = sb,$$

\* Let the coil-sides be numbered consecutively from slot to slot, and travel through the conductors in the order in which they are connected starting at conductor No. 1, say, passes through the point or commutator to conductor No. 8 and thus through the back connection to No. 3, the front pitch is  $8 - 1 = 7$  and the back pitch is  $8 - 3 = 5$ , and the average pitch

coil-sides or bars,  
 end connections,  
 slots,  
 sides or bars per slot.

l-sides ( $C$ ) is double the number of coils and must also be even. In the formula  $+2$  is preferable to  $-2$ , to allow for shorter end connections.

$p$  may be odd or even. If it is odd the front and back pitches must be odd. If it is even the front and back pitches must be even. In a wire winding the back pitch must be one greater than the front pitch in order to fit the coils into the slots.

$s$  is very much restricted and is intimately connected with the number of poles unless the expedient of using a dead coil is used.

$b$  must be even and cannot be 4 or 8 in a four-pole machine, 6 or 12 in a six-pole machine, unless a dead coil is used.

$s$ . — By leaving one of the coils dead or out of circuit, a dead coil, and conductors is available. Four coil-sides per slot may then be employed. In general  $s$  must be divisible by the number of poles. The formula is then

$$C = ps - 2 = sb - 2.$$

not connected in at all and the number of commutator segments is the number of active coils or one less than the total coils. The number of coils is  $C/2$ .

Examples for 4- and 6-pole machines with no dead coil are: For 4 poles, then  $s$  may be 25, 31, 37, etc., and usual values for  $b$  are 17, 21, 25, etc. For  $b = 10$ , then  $s$  may be 47, 57, 67, 23, 27, 31, etc. For 6 poles, then  $s$  may be 17, 21, 25, etc., and  $b$  may be 26, 32, 38, etc.

Drum Windings. — It sometimes becomes desirable to provide a multiplex winding rather than two circuits in multiple but not as many as the number of poles. In a case a multiplex wave winding would be selected. In a series drum winding each the circuit passes completely around the armature. In a series drum winding this we use two entirely separate electric circuits we use a series drum winding, denoted by the symbol  $\circ \circ$ . If, on the other hand, the circuit crosses on itself after passing twice around the armature we use a series drum winding, denoted by the symbol  $\odot$ . Series drum windings are sometimes used when it is desired to have a number of circuits different from the number of poles. Thus we may use a series drum winding with four circuits in multiple which with a given voltage would give a greater voltage than a multiple-drum winding with four circuits in multiple. This would be a duplex winding.

Multiplex Winding. — The conditions are imposed by

$$c = ps \pm 2m = sb,$$

where  $c$  has the same meaning as before and  $m$  is the number of

multiple windings and  $z = m$  the number of circuits in multiple. If  $m$  prime to each other we have a singly reentrant winding. The greatest factor of  $m$  and  $z$  gives the number of times the winding reenters or words the number of independent windings.

The multiplicity and complexity may be carried to a very extent (See under *Armature Windings in any standard text-book.*) These windings are hardly ever used in the United States and England occasionally in Germany and France.

### ARMATURE REACTION (OR ARMATURE INTERFERENCE)

The armature reaction of a d-c. machine has a very important influence on commutation and regulation of both generators and motors. It is of the magnetomotive force of the current in the armature conductors and the magnetic field set up by the field coils.

**Separate Fluxes by Field and Armature Currents.** — When current flows in the field coils and no current flows in the armature, a flux is set up which follows a path directly across the armature from pole to pole as in Fig. 9. On the other hand when current flows in the armature and there is no current in the field coils, a flux is set up in the armature across the axis of the poles, as in Fig.

Fig. 9. Field Flux

Fig. 10. Armature Flux

Fig. 11. Displacement of Flux

**Resultant Flux.** — As a result of this action the flux is shifted around one tip of each pole has its density increased and one tip has the density decreased as in Fig. 11. If the brushes are at the geometrical neutral axis, they are no longer on an axis at right angles to the flux; that is, they are no longer on the neutral point with respect to the resultant flux. With the brush position the coil underneath a brush is cutting flux and generating an e.m.f. which is short-circuited by the brush and causes sparking. The brushes therefore, be moved a small angle in the direction of rotation in a generator (the opposite direction in a motor) until they are on the neutral axis. The armature reaction of the brushes aggravates the conditions, but nevertheless, unless the armature reaction is too great, a position can be found in which a brush short-circuits a coil that is in the real neutral position and is inactive.

**Relations Shown Vectorially.** — In Fig. 12  $F_1$  and  $A_1$  are the magnetomotive forces of the field and armature with the brushes on the geometrical or apparent neutral axis.

Fig. 12. Vector Relations of M.M.F.'s

Fig. 13. Demagnetizing and Magnetizing Turns

$R_1$  is the resultant of these. The brushes which are in line with  $A_1$  are at right angles to  $R_1$ . If the brushes are moved to an axis at right angles to  $A_2$ , then the resultant becomes  $R_2$  and the desired conditions have

brushes still further to  $A_2$  giving the resultant  $R_0$  and  $A_2$  at right angles to each other. The stronger the field the greater will be the angle through which the brushes are moved.

Moved through an angle  $\alpha$  to the position  $A_1$  there is an induced e.m.f.,  $A \sin \alpha$ , directly opposed to the field e.m.f.,  $A \cos \alpha$ , is at right angles to the field m.m.f. This is referred to in Fig. 13.

**Demagnetizing and Cross-magnetizing Action.** — Let the movement of the brushes to  $A_2$  be represented in Fig. 13 by the movement from  $A_1$  to  $A_2$  through an angle  $\alpha$ . Then the conductors in the angle  $2\alpha$ , between  $A_1$  and  $A_2$ , carry currents whose m.m.f. directly opposes the field m.m.f.; these are known as back or demagnetizing conductors. The conductors in the sections  $A-C$  and  $B-D$ , carry currents whose m.m.f. is at right angles to the field and cause a disturbance known as cross-magnetizing conductors. While all the conductors in the sections  $A-B$  and  $C-D$  constitute back ampere-turns, these are opposed to the field m.m.f. When we come to our quantitative treatment in which we make use of the turns of  $2\alpha$  as the back ampere-

**Armature Reaction.\*** — The demagnetizing effect is almost entirely overcome by placing the brushes

To prevent sparking under these conditions interference with the main poles does not in itself prevent armature reaction. The sparkless commutation when the brushes are set to neutralize the armature demagnetization to a minimum.

**Induced Voltage.** — Each coil of the armature carries a current as it travels from a positive brush to a negative brush. In the direction as the coil travels from a negative to a positive brush the direction of the current in each coil reverses during its passage. The brushes to which the coil is connected pass under the main poles. The current in any circuit it is necessary to take out the induced voltage of magnetic flux linked with the circuit, and put it in the opposite direction. In doing this the induced voltage of self-inductance which is proportional to the time of reversal and which opposes any change in the value of the induced voltage of self-inductance of the coil.

**Self-Inductance.** — To minimize the voltage of self-inductance we keep the number of ampere-turns in each coil as constant as possible during the reversal to take place as slowly as possible. It is the induced voltage of self-inductance by introducing an opposing current. This is accomplished in practical machines by giving the brushes a lead.

**Brushes.** — The brushes are moved in the direction (opposite direction in a motor) away from the true neutral position. The brush leading is moving in a flux coming from an interpole of greater density that it induces by rotation in that particular direction and neutralizes the voltage of self-inductance.

**Interpoles on Commutation.** — Interpoles or commutating poles are placed between the main poles over the neutral space. These poles

\* See *Motors, Direct-current.*

are excited by the load current until they give a flux of the proper direction to induce the desired neutralizing voltage. (See also above under *Armature Reaction*.)

**Increasing Resistance in Path of Short-circuit Current** commutation. This changes the time constant of this circuit, that is the stored energy of the magnetism is dissipated in  $I^2R$  loss in this instead of in sparking at the brush. The usual method of accomplishing this is to use carbon brushes which have a higher resistance of contact than iron brushes. Another method is to introduce a high resistance in the circuit between the winding and the commutator segment.

**DESIGN.**—The steps in the systematic procedure in the design of a machine of given voltage and power rating are given below. Simple cases are assumed.

1. Statement of problem.
2. Suitable speed.
3. Number of poles.
4. Diameter and length of armature.
5. Length of air gap.
6. Number and size of slots.
7. Total flux, preliminary.
8. Number of turns on armature, preliminary.
9. Armature reaction, ampere-turns.
10. Number of conductors per slot.
11. Form of armature winding.
12. Size of armature conductors.
13. Exact size of slots.
14. Armature resistance and heating.
15. Design of commutator and brushes.
16. Reactance voltage.
17. Exact value of flux.
18. Cross-section of magnetic path; usual flux densities.
19. Excitation; calculation of magnetic circuit.
20. Stability factor.
21. Armature reaction or interference.
22. Field winding, series, shunt.
23. Interpoles or commutating poles.

The performance of the machine should then be calculated from the preliminary design to determine whether the design meets the imposed conditions and such modifications as are necessary should then be made. The calculations for determining the performance are the calculations of:

24. Core-loss.
25. Friction.
26. Excitation loss.
27. Armature circuit loss.
28. Efficiency.
29. Regulation.
30. Heating.

**Symbols.**—The following notation is employed uniformly throughout this article; other symbols, and the same symbols with primes or subscripts, are defined in the paragraphs in which they are used.

- (A.R.) = armature reaction ampere-turns per pole.  
 $B$  = flux density in air gap, lines per sq. inch.  
 $\delta$  = number of coil sides per slot.

re-turns per pole.

ductors per slot.

radius of armature, in inches.

terminal voltage.

resistance of short-circuited coil.

EMF of voltage induced in armature.

armature current, in amperes.

radius, in inches.

number of parallel paths between brushes.

rotation per minute.

output in kilowatts in case of generator; input in case of motor.

length of magnetic path of short-circuited coil.

area of one armature conductor, in square inches.

resistance of armature between brushes, in ohms.

number of turns in series between brushes.

number of slots.

peripheral velocity of armature in feet per minute.

peripheral velocity of commutator in feet per minute.

width of coil-sides.

average pitch of end connections.

pitch.

average pitch is the arc from pole center to center of adjacent pole, measured at air gap; pole arc is the arc

covered by the pole face.

number of conductors per inch of armature periphery.

conductors per pole.

Example. — The rating in kilowatts or horse-power and

terminal voltage. The current and speed may or may not be given.

The current is found as follows:

$$I = \frac{1000 P}{E}$$

$$I = \frac{746 \times (\text{Horse-power})}{E \times (\text{Efficiency})}$$

Efficiency may be taken from the table of usual values

(p). — Machines are classified in commercial practice

into high speed and low speed. The proper speed for a machine

is given in the curves in the section below on *Cost*,

(p) depends upon the size, speed and character of the

machine, much variation depending upon specific conditions.

Values are indicated in the first table on page 682.

Length of Armature are related by the following for-

$$D^2 L = \frac{610 P \times 10^9}{\sigma_p B N}$$

Kw. rating	Number of poles		
	High speed	Moderate speed	Low speed
0-10	2	4	4
10-50	4	4	4
50-100	4	4-6	6
100-300	6	6	8
300-500	6	8	10
500 and greater	..	..	12 and more

Usual Values of the Constants in the formula at bottom are:

*Magnetic Density in Air Gap (B)* has values from 40,000 lines per sq. in. in small machines, 55,000 in medium and 70,000 in large machines. The density in the air gap is taken the same as the density at the pole.

*Ampere-Conductors per Inch of Periphery, or the Specific Loading* is the product of the total conductors around the armature times the current, divided by the periphery of the armature. The usual values for  $\sigma$  are in the accompanying table.

*Ratio of Pole Arc to Pole Pitch ( $\rho$ )* varies from 0.6 to 0.85 with an average value of 0.7.

**Determination of D and L.**  
— Having found  $D^2L$  the two factors may be separated by two methods. Assuming a square pole face (a desirable proportion for economy of armature and field copper), then

$$L = \frac{\pi \rho D}{p}$$

and substituting in  $D^2L$  we can solve for  $D$ .

Another method of determining separate values for  $D$  and  $L$  is by a relation of the peripheral speed. The peripheral speed is fairly uniform in machines, having values of from 3000 to 5000 feet per minute. An average value near 4000. The diameter of armature is given by the

$$D = \frac{(\text{Peripheral speed}) \times 12}{\pi N}$$

5. **Length of Air Gap** in inches for a given diameter has a value approximately by the table in the next paragraph. This gives a starting point for preliminary work but it may be found advisable to change it later in design.

6. **Number and Size of Armature Slots.** — A rough approximate practice gives the number of slots as four times the diameter in inches. General practice is shown in the following table.

Kw. rating	$\sigma$ -amp.-co. inch of p.
0-150	250-400
150-400	400-600
400 and greater	600-900

Air gap, in.	No. of slots	Depth of slots, in.
0.08	25-40	0.6
0.10	30-60	0.75
0.12	40-80	1.00
0.125	60-100	1.25
0.15	80-150	1.50
0.19	100-200	1.75
0.25	150-300	2.50
0.35	200-400	3.25

Armature ( $\phi$ ) is fixed by the assumed gap density  $B$  and diameter  $D$  of the armature:

$$\phi = \frac{\pi p L D B}{p}$$

in Series ( $S$ ) between brushes is

$$S = \frac{E \times 10^8}{4f\phi}$$

Amper-Turns per Pole are

$$(AR) = \frac{IS}{p}$$

Amper-turns per pole ( $AR$ ) should not exceed certain values as explained in the accompanying table. If the value is higher than advisable it can be reduced by increasing the value of the flux by

conductors per Slot ( $c$ ). — If the number of slots on the armature, the number of conductors per slot ( $c$ ) must be chosen. There are sometimes antagonistic considerations. The solution is a compromise.

$$c = \frac{2pS}{s}$$

Kw. rating	Armature reactive amper-turns per pole ( $AR$ )
0-100	1500-3500
100-300	3500-6000
300-500	6000-8000

$$c = \frac{2 \pi v D}{I_s} \quad \text{and} \quad c = \frac{4S}{s}$$

and give a number of conductors which can be placed in a slot having a depth of from 3 to 4 times its width. For a multiple winding we then choose a series winding.

Winding (for general discussion of forms of windings). — If the number of conductors per slot ( $c$ ) is chosen for a multiple-drum winding, we choose an arrangement of coil sides per slot and assume the conductors per slot

at a value the nearest multiple of the coil sides per slot, thus grouping conductors into coils.

**Series-drum Winding.** — If a series-drum winding is indicated

For a four-pole machine choose a number of conductors per slot ( $c$ ) by 6 and a number of slots ( $s$ ) in the series 29, 33, 37, etc., endeavoring that value of  $\frac{sc}{4}$  that comes nearest to our preliminary value of  $S$ , the

of turns in series between brushes. Or for a four-pole machine choose a number of conductors divisible by 10 and a number of slots in the series 27, 31, 35, etc., that gives a value of  $\frac{sc}{4}$  the nearest the preliminary value of  $S$ .

For a six-pole machine choose a value of  $c$  divisible by 4 and a number of slots ( $s$ ) in the series 26, 32, 38, that gives a value of  $\frac{sc}{4}$  nearest the preliminary value of  $S$ .

The preceding values of  $s$  give the best winding arrangement but other combinations giving unequal front and back pitches and longer coils are possible.

**Revised Value of Turns in Series ( $S$ ).** — Having chosen values for  $s$  and  $c$  to fit the form of winding desired we must revise our preliminary assumption for the turns in series,  $S$ , to accord with the actual winding. For a multiple drum  $S = \frac{sc}{2p}$ , and for a series drum  $S = \frac{sc}{4}$ .

**12. Size of Armature Conductors.** — The current in each conductor is the line current  $I$  divided by the number of poles in a multiple-drum winding and to  $I/2$  in a series-drum winding of the simple type. The cross-section of each conductor is equal to the current per conductor divided by the number of amperes per square inch, which varies from 3000 in small machines and 2000 in intermediate size machines to 1500 in large machines.

**13. Exact Size of Slots, Slot Factor.** — The total number of slots is definitely set by the style of winding. The maximum allowable depth depends upon the diameter of the armature. The width of each slot should be from 0.4 to 0.6 of the pitch of the slots, which is the quotient of the periphery of the armature divided by the number of slots. The ratio of the total cross-section of copper in a slot to the cross-section of the slot is known as the slot factor and has more or less consistent values.

Kw. rating	Slot factor
	For 125 volts
0-10	0.28
10-50	0.35
50-100	0.40
100-400	0.50
400-1000	0.60

Type of slot	No. of bars or coil-sides per slot	Allowance for coil and slot insulation, in.	
		Width	Depth.
Open	2	0.09	0.30
Open	4	0.14	0.35
Open	6	0.15	0.35
Partly closed	4	0.15	0.40

of the slots are found by adding to the width and  
 red conductors, suitably arranged, an allowance for  
 on. The allowances in the preceding table are for

nce and Heating. — The mean length of turn is  
 is roughly estimated as

$$l = 2L + \frac{10D}{p}$$

at 60° C. of the armature from brush to brush is

$$R_a = \frac{0.0003 Sl}{12,000 qms}$$

armature is  $R_a I$ .

per is  $R_a I^2$ .

$$T_c = \frac{100 R_a I^2}{(a + b) Is}$$

width of coils in slot, in inches.

depth of coils in slot, in inches.

Commutator and Brushes. — The diameter of the com-  
 the diameter of the armature. The peripheral speed  
 per minute and should not exceed 4000 unless a special  
 number of segments should be such that the average  
 than 15.

$$\text{bar} = \frac{(\text{Rated voltage}) \times (\text{Poles})}{\text{Number of segments}}$$

ction the pitch of segments should not be less than  
 about 30 mils is occupied by insulation.

Brushes. — The width of the brushes is limited by the  
 segments which it is permissible to cover and the width  
 number of segments covered is limited by the reactance  
 y. In general, the width of the brushes is from 2 to  
 ts. The area of the brush surface is such as to allow  
 r square inch of brush contact surface at full load.  
 equally over a number of studs equal to one-half the  
 multiple-wound armature and may be all on one stud  
 a series-wound armature.

Commutator. — The total length of brushes per stud  
 commutator is

$$\frac{\text{Total surface of positive brushes}}{\text{width of brushes} \times (\text{No. of studs})}$$

Commutator is greater than this by about 0.5 inch to  
 n brushes and at the ends. It is also customary to  
 e end of the commutator for insulation to prevent  
 n general have a gross superficial area of from 0.67 to  
 of total current.

**Resistance of Brushes and Brush Contact** is a variable. Some designers allow 2 volts total drop in positive and negative brushes under all conditions of load.

Another method is to use the values for the resistance per square inch of brush and brush contact as given in the accompanying table.

Kind of brush	Resistance of each brush, ohm			
	20 amp. per sq. in.	40 amp. per sq. in.	60 amp. per sq. in.	80 amp. per sq. in.
Hard.....	0.051	0.03	0.023	0.018
Medium.....	0.037	0.021	0.015	0.012
Soft.....	0.024	0.014	0.011	0.009

**Friction of Brushes on Commutator.** — The value of this

$$\text{Friction in watts} = \frac{(\text{No. of brushes}) \times (\text{Pressure per brush}) \times V_c}{45}$$

where

$V_c$  = peripheral speed of commutator, feet per minute.

$k$  = coefficient of friction = 0.2 to 0.3.

The usual value of pressure on the brushes is from 1.5 to 2 pound per inch of contact surface.

**Rise in Temperature of Commutator** is

$$T = t \times \frac{(\text{Brush } I^2R) + (\text{Brush friction})}{\text{Surface of commutator}}$$

where  $t$  has the value indicated in the accompanying table:  $t$  is the temperature rise in °C. for a total commutator loss of 1 watt per sq. in.

Peripheral speed of commutator, ft. per min.	Value of $t$ .
2000	15
3000	12
4000	10

Fig. 14. Slot Diagram

**16. Reactance Voltage.** — The armature leakage flux per ampere may be resolved into three parts for convenience in analysis. The fluxes are:  $P_s$  flux inside the slot itself,  $P_t$  flux from tooth tip to tooth tip about the end connections.

Referring to the dimensions in Fig. 14 these fluxes are given by the following equations:

$$P_s = 3.2 I \left( \frac{A}{3F} + \frac{B}{E} \right)$$

$$P_s = 2.35 I \log_{10} \left( \frac{rm}{2g} \right)$$

$$P_c = 1.17 l_c \left( \log_{10} \frac{2 l_c}{U_c} \right),$$

5	1.18 - 1.4
10	1.16 - 1.35
25	1.15 - 1.30
50	1.14 - 1.28
100	1.12 - 1.20
500	1.08 - 1.15

a of Magnetic Path. — Usual Flux Densities. —  
 ies for determining the proportions of the magnetic circuit  
 anpanying table.

Part	Material	Lines per sq. in.
Field yoke	Steel	70,000-100,000
Field yoke	Cast iron	35,000-70,000
Pole core	Steel	70,000-100,000
Air gap	Air	40,000-70,000
Armature teeth	Steel laminations	90,000-125,000
Armature core	Steel laminations	60,000-90,000

The proper cross-section of each part is found by dividing the flux in by an assumed density. (See also following paragraph.) In most dimension, as the length along the shaft, is known and the other is the

19. **Excitation.** — Calculation of Magnetic Circuit. — It is to calculate the densities and excitation for a value of flux corresponding to at the speed at full load, as this is the most important condition. It is practice to assume a loss of voltage of 5 per cent at full load instead of predetermining the value.

**Values of Flux in Different Parts of Magnetic Circuit.** — In the armature teeth and air gap the total flux is equal to the calculated value of useful flux. In the armature core the flux divides and we have one-half flux in each branch. The field flux or flux in pole cores is greater than useful flux and is equal to the useful flux multiplied by the leakage ( $\nu$ ). (See section 17.) In the yoke the flux divides and each branch carries one-half as much as the pole core.

**Ampere-Turns.** — The number of ampere-turns required for excitation is best calculated by the assistance of a tabulation like the following. The symbols refer to the dimensions shown in Fig. 15.

1	2	3	4	5	6
Part	Flux	Cross-Section	Flux density	Amp.-turns per in.	Length of path
Field yoke....	$\frac{\nu\phi}{2}$	$dc$	.....	.....	$l$
Pole core.....	$\nu\phi$	$0.785 f^2$ or $fb$	.....	.....	$c$
Air gap.....	$\phi$	$aL_p$	.....	$0.313 B$	$g$
Arm. teeth....	$\phi$	$T_0 l_t$	.....	.....	$m$
Arm. core.....	$\frac{\phi}{2}$	$M_t$	.....	.....	$k$

Net ampere-turns for flux: . . . . .

The dimensions in column 3 can be taken directly from a sketch of the pole as shown in Fig. 16. If the pole is circular its area is  $0.785 f^2$  and if it is square

of pole shoe  $L_p$  is usually about 0.5 inch less than core.

of the armature teeth is found as follows: At any of the teeth are carrying flux. These are known as

Fig. 15. Dimensions of Magnetic Circuit

$T$ , and are slightly greater than those actually under the tendency of the flux to spread,

$$T = \frac{a + 3g}{\mu_1}$$

face.

ent cross-section of the teeth is not that which gives that which gives the mean excitation required and in

$$\frac{(h_1 + 2t_1)}{3} l_1 = k_1 l_1$$

to give the effective length of iron, excluding that between laminations.

$0.9 \times (L - \text{space of air ducts})$ .

section of armature teeth =  $T k_1 l_1$ .

column 2) divided by the cross-section (column 3).

ampere-turns per inch which are to be taken from respective materials as given in the article on *Magnetic* magnetizing force for a one-inch gap is always

paths of the respective paths as shown on Fig. 15.

ampere-turns required for each part of the path and the values in column 5 by the respective lengths in the values in column 7 is the excitation in ampere-turns the field to establish the necessary flux in the machine. in the armature this would give a voltage about 5 per cent voltage of the machine. See section 21 below for reaction.

**20. Stability Factor.** — It is necessary at this point in the design the relations to see if the machine is liable to be unstable or require a shift of the brushes. If interpoles are to be used this is not important. If interpoles are not to be used certain conditions must be fulfilled. The most important of these conditions is the "stability factor" which is the quotient of the ampere-turns required for gap and teeth divided by the armature ampere-turns beneath the pole.

The ampere-turns beneath the pole are equal to

$$\frac{(\text{Armature reaction ampere-turns}) \times (\text{Pole arc})}{\text{Pole pitch}}$$

The conditions to be filled are that at maximum current in the armature the ampere-turns beneath the pole shall not exceed the field ampere-turns required for gap and teeth. This is covered by the custom of making the stability factor at full load have a value of from 1.3 to 1.5 in generators and 1.5 to 2.0 in motors.

**21. Armature Reaction or Interference.** — The current in the armature conductors sets up a magnetomotive force which reacts on the magnetomotive force of the field coils and prevents them from setting up as much flux as there is no current in the armature. It is, therefore, necessary to have a reserve strength at any load greater than at no load by an amount sufficient to overcome or neutralize the armature reaction, or to provide special auxiliary means for the purpose. There are four methods of estimating the effect of armature reaction and overcoming it.

(a) It is common practice in the manufacture of d-c. machines to provide a field coil of such ample capacity that it is sure to be more than sufficient to overcome armature interference and set up the flux desired. This is usually adjusted in practice by putting an adjustable resistance in series with the field and a suitable resistance in multiple with the series field. For this purpose it is usual to provide a total number of field ampere-turns per pole ( $F$ ) at no load equal to the net ampere-turns per pole at full load required for flux, as calculated under item No. 19, plus a number of field ampere-turns equal to 40 per cent of the armature reaction ampere-turns as calculated under item No. 9.

(b) The effect of armature reaction is divided into back ampere-turns and cross ampere-turns. The excitation ampere-turns per pole to overcome the back ampere-turns (caused by shifting the brushes) is

$$A' = \frac{(\text{Armature reaction}) \times (\text{Brush shift in segments}) \times 2}{\text{Total commutator segments}}$$
