If signs of disturbance are present for more than a month but less than six months, the diagnosis of schizophreniform disorder is applied. Psychotic symptoms lasting less than a month may be diagnosed as brief psychotic disorder, and various conditions may be classed as psychotic disorder not otherwise specified, while schizoaffective disorder is diagnosed if symptoms of mood disorder are substantially present alongside psychotic symptoms. If the psychotic symptoms are the direct physiological result of a general medical condition or a substance, then the diagnosis is one of a psychosis secondary to that condition.[93] Schizophrenia is not diagnosed if symptoms of pervasive developmental disorder are present unless prominent delusions or hallucinations are also present.[93]

## Subtypes

With the publication of DSM-5, the APA removed all sub-classifications of schizophrenia.[98] The five sub-classifications included in DSM-IV-TR were:[99][100]

- Paranoid type: Delusions or auditory hallucinations are present, but thought disorder, disorganized behavior, or affective flattening are not. Delusions are persecutory and/or grandiose, but in addition to these, other themes such as jealousy, religiosity, or somatization may also be present. (DSM code 295.3/ICD code F20.0)
- Disorganized type: Named *hebephrenic schizophrenia* in the ICD. Where thought disorder and flat affect are present together. (DSM code 295.1/ICD code F20.1)
- Catatonic type: The subject may be almost immobile or exhibit agitated, purposeless movement. Symptoms can include catatonic stupor and waxy flexibility. (DSM code 295.2/ICD code F20.2)
- Undifferentiated type: Psychotic symptoms are present but the criteria for paranoid, disorganized, or catatonic types have not been met. (DSM code 295.9/ICD code F20.3)
- Residual type: Where positive symptoms are present at a low intensity only. (DSM code 295.6/ICD code F20.5)

The ICD-10 defines two additional subtypes:[99]

- Post-schizophrenic depression: A depressive episode arising in the aftermath of a schizophrenic illness where some low-level schizophrenic symptoms may still be present. (ICD code F20.4)
- Simple schizophrenia: Insidious and progressive development of prominent negative symptoms with no history of psychotic episodes. (ICD code F20.6)

Latent schizophrenia (F21.1), schizophrenic reaction (F21.2), pseudoneurotic schizophrenia (F21.3), pseudopsychopathic schizophrenia (F21.4), "symptom-depleted" schizophrenia (F21.5) are in the Russian version of the ICD-10. They are in the category of "schizotypal" disorder in section F21 of chapter V.[101]

## Differential diagnosis

*See also: Dual diagnosis and Comparison of bipolar disorder and schizophrenia*

Psychotic symptoms may be present in several other mental disorders, including bipolar disorder,[102] borderline personality disorder,[103] drug intoxication and drug-induced psychosis. Delusions ("non-bizarre") are also present in delusional disorder, and social withdrawal in social anxiety disorder, avoidant personality disorder and schizotypal personality disorder. Schizotypal personality disorder has symptoms that are similar but less severe than those of schizophrenia.[5] Schizophrenia occurs along with obsessive-compulsive disorder (OCD) considerably more often than could be explained by chance, although it can be difficult to distinguish obsessions that occur in OCD from the delusions of schizophrenia.[104] A few people withdrawing from benzodiazepines experience a severe withdrawal syndrome which may last a long time. It can resemble schizophrenia and be misdiagnosed as such.[105]

A more general medical and neurological examination may be needed to rule out medical illnesses which may rarely produce psychotic schizophrenia-like symptoms, such as metabolic disturbance, systemic infection, syphilis, AIDS dementia complex, epilepsy, limbic encephalitis, and brain lesions. Stroke, multiple sclerosis, hyperthyroidism, hypothyroidism and dementias such as Alzheimer's disease, Huntington's disease, frontotemporal dementia and Lewy Body dementia may also be associated with schizophrenia-like psychotic symptoms.[106] It may be necessary to rule out a delirium, which can be distinguished by visual hallucinations, acute onset and fluctuating level of consciousness, and indicates an underlying medical illness. Investigations are not generally repeated for relapse unless there is a specific *medical* indication or possible adverse effects from antipsychotic medication. In children hallucinations must be separated from typical childhood fantasies.[5]

# Prevention

Prevention of schizophrenia is difficult as there are no reliable markers for the later development of the

disorder.[107] There is tentative evidence for the effectiveness of early interventions to prevent schizophrenia.[108] While there is some evidence that early intervention in those with a psychotic episode may improve short-term outcomes, there is little benefit from these measures after five years.[12] Attempting to prevent schizophrenia in the prodrome phase is of uncertain benefit and therefore as of 2009 is not recommended.[109] Cognitive behavioral therapy may reduce the risk of psychosis in those at high risk after a year[110] and is recommended in this group, by the National Institute for Health and Care Excellence (NICE).[111] Another preventative measure is to avoid drugs that have been associated with development of the disorder, including cannabis, cocaine, and amphetamines.[9]

# Management

*Main article: Management of schizophrenia*

The primary treatment of schizophrenia is antipsychotic medications, often in combination with psychological and social supports.[12] Hospitalization may occur for severe episodes either voluntarily or (if mental health legislation allows it) involuntarily. Long-term hospitalization is uncommon since deinstitutionalization beginning in the 1950s, although it still occurs.[11] Community support services including drop-in centers, visits by members of a community mental health team, supported employment[112] and support groups are common. Some evidence indicates that regular exercise has a positive effect on the physical and mental health of those with schizophrenia.[113]

## Medication

Risperidone (trade name Risperdal) is a common atypical antipsychotic medication.

The first-line psychiatric treatment for schizophrenia is antipsychotic medication,[114] which can reduce the positive symptoms of psychosis in about 7 to 14 days. Antipsychotics, however, fail to significantly improve the negative symptoms and cognitive dysfunction.[32][115] In those on antipsychotics, continued use decreases the risk of relapse.[116][117] There is little evidence regarding effects from their use beyond two or three years.[117]

The choice of which antipsychotic to use is based on benefits, risks, and costs.[12] It is debatable whether, as a class, typical or atypical antipsychotics are better.[10][118] Amisulpride, olanzapine, risperidone and clozapine may be more effective but are associated with greater side effects.[119] Typical antipsychotics have equal drop-out and symptom relapse rates to atypicals when used at low to moderate dosages.[120] There is a good response in 40–50%, a partial response in 30–40%, and treatment resistance (failure of symptoms to respond satisfactorily after six weeks to two or three different antipsychotics) in 20% of people.[32] Clozapine is an effective treatment for those who respond poorly to other drugs ("treatment-resistant" or "refractory" schizophrenia),[121] but it has the potentially serious side effect of agranulocytosis (lowered white blood cell count) in less than 4% of people.[9][12][122]

Most people on antipsychotics have side effects. People on typical antipsychotics tend to have a higher rate of extrapyramidal side effects while some atypicals are associated with considerable weight gain, diabetes and risk of metabolic syndrome; this is most pronounced with olanzapine, while risperidone and quetiapine are also associated with weight gain.[119] Risperidone has a similar rate of extrapyramidal symptoms to haloperidol.[119] It remains unclear whether the newer antipsychotics reduce the chances of developing neuroleptic malignant syndrome or tardive dyskinesia, a rare but serious neurological disorder.[123]

For people who are unwilling or unable to take medication regularly, long-acting depot preparations of antipsychotics may be used to achieve control.[124] They reduce the risk of relapse to a greater degree than [116]

oral medications. When used in combination with psychosocial interventions they may improve long-term adherence to treatment.[124] The American Psychiatric Association suggests considering stopping antipsychotics in some people if there are no symptoms for more than a year.[117]

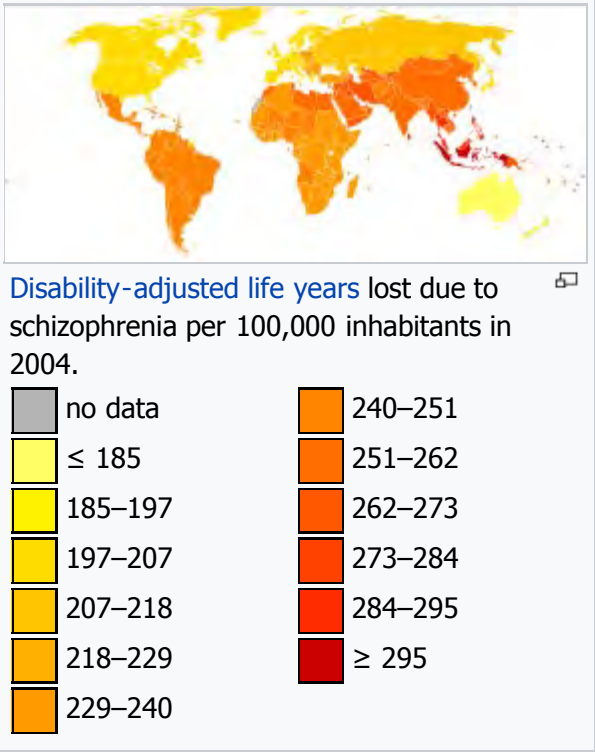
### Psychosocial

A number of psychosocial interventions may be useful in the treatment of schizophrenia including: family therapy,[125] assertive community treatment, supported employment, cognitive remediation,[126] skills training, token economic interventions, and psychosocial interventions for substance use and weight management.[127] Family therapy or education, which addresses the whole family system of an individual, may reduce relapses and hospitalizations.[125] Evidence for the effectiveness of cognitive-behavioral therapy (CBT) in either reducing symptoms or preventing relapse is minimal.[128][129] Art or drama therapy have not been well-researched.[130][131] Music therapy has been shown to improve mental state and social functioning when paired with regular care.[132]

## Prognosis

*Main article: Prognosis of schizophrenia*

Schizophrenia has great human and economic costs.[12] It results in a decreased life expectancy by 10–25 years.[15] This is primarily because of its association with obesity, poor diet, sedentary lifestyles, and smoking, with an increased rate of suicide playing a lesser role.[12][15][133] Antipsychotic medications may also increase the risk.[15] These differences in life expectancy increased between the 1970s and 1990s.[134]



Disability-adjusted life years lost due to schizophrenia per 100,000 inhabitants in 2004.

Schizophrenia is a major cause of disability, with active psychosis ranked as the third-most-disabling condition after quadriplegia and dementia and ahead of paraplegia and blindness.[135] Approximately three-fourths of people with schizophrenia have ongoing disability with relapses[32] and 16.7 million people globally are deemed to have moderate or severe disability from the condition.[136] Some people do recover completely and others function well in society.[137] Most people with schizophrenia live independently with community support.[12] About 85% are unemployed.[6] In people with a first episode of psychosis a good long-term outcome occurs in 42%, an intermediate outcome in 35% and a poor outcome in 27%.[138] Outcomes for schizophrenia appear better in the developing than the developed world.[139] These conclusions, however, have been questioned.[140][141]

There is a higher than average suicide rate associated with schizophrenia. This has been cited at 10%, but a more recent analysis revises the estimate to 4.9%, most often occurring in the period following onset or first hospital admission.[16][142] Several times more (20 to 40%) attempt suicide at least once.[5][143] There are a variety of risk factors, including male gender, depression, and a high intelligence quotient.[143]

Schizophrenia and smoking have shown a strong association in studies worldwide.[144][145] Use of cigarettes is especially high in individuals diagnosed with schizophrenia, with estimates ranging from 80 to 90% being regular smokers, as compared to 20% of the general population.[145] Those who smoke tend to smoke heavily, and additionally smoke cigarettes with high nicotine content.[146] Some evidence suggests

that paranoid schizophrenia may have a better prospect than other types of schizophrenia for independent living and occupational functioning.[147] Among people with schizophrenia use of cannabis is also common.[61]

# Epidemiology

*Main article: Epidemiology of schizophrenia*

Schizophrenia affects around 0.3–0.7% of people at some point in their life,[12] or 24 million people worldwide as of 2011.[148] It occurs 1.4 times more frequently in males than females and typically appears earlier in men[9]—the peak ages of onset are 25 years for males and 27 years for females.[149] Onset in childhood is much rarer,[150] as is onset in middle or old age.[151]

Deaths per million persons due to schizophrenia in 2012.

0-0 2-2 4-6
1-1 3-3 7-20

Despite the prior belief that schizophrenia occurs at similar rates worldwide, its frequency varies across the world,[5][152] within countries,[153] and at the local and neighborhood level.[154] This variation has been estimated to be fivefold.[6] It causes approximately one percent of worldwide disability adjusted life years[9] and resulted in 20,000 deaths in 2010.[155] The rate of schizophrenia varies up to threefold depending on how it is defined.[12]

In 2000, the World Health Organization found the percentage of people affected and the number of new cases that develop each year is roughly similar around the world, with age-standardized prevalence per 100,000 ranging from 343 in Africa to 544 in Japan and Oceania for men, and from 378 in Africa to 527 in Southeastern Europe for women.[156] About 1.1% of adults have schizophrenia in the United States.[157]

# History

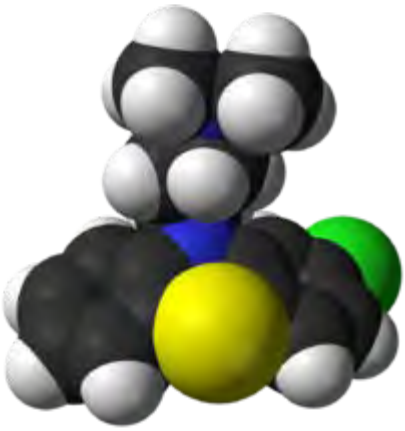
*Main article: History of schizophrenia*

In the early 20th century, the psychiatrist Kurt Schneider listed the forms of psychotic symptoms that he thought distinguished schizophrenia from other psychotic disorders. These are called *first-rank symptoms* or Schneider's first-rank symptoms. They include delusions of being controlled by an external force, the belief that thoughts are being inserted into or withdrawn from one's conscious mind, the belief that one's thoughts are being broadcast to other people, and hearing hallucinatory voices that comment on one's thoughts or actions or that have a conversation with other hallucinated voices.[158] Although they have significantly contributed to the current diagnostic criteria, the specificity of first-rank symptoms has been questioned. A review of the diagnostic studies conducted between 1970 and 2005 found that they allow neither a reconfirmation nor a rejection of Schneider's claims, and suggested that first-rank symptoms should be de-emphasized in future revisions of diagnostic systems.[159] The absence of first-rank symptoms should raise suspicion of a medical disorder, however.[19]

The term "schizophrenia" was coined by Eugen Bleuler.

The history of schizophrenia is complex and does not lend itself easily to a linear narrative.[160] Accounts of a schizophrenia-like syndrome are thought to be rare in historical records before the 19th century, although reports of irrational, unintelligible, or uncontrolled behavior were common. A detailed case

report in 1797 concerning James Tilly Matthews, and accounts by Philippe Pinel published in 1809, are often regarded as the earliest cases of the illness in the medical and psychiatric literature.[161] The Latinized term *dementia praecox* was first used by German alienist Heinrich Schule in 1886 and then in 1891 by Arnold Pick in a case report of a psychotic disorder (hebephrenia). In 1893 Emil Kraepelin borrowed the term from Schule and Pick and in 1899 introduced a broad new distinction in the classification of mental disorders between *dementia praecox* and mood disorder (termed manic depression and including both unipolar and bipolar depression).[162] Kraepelin believed that *dementia praecox* was probably caused by a long-term, smouldering systemic or "whole body" disease process that affected many organs and peripheral nerves in the body but which affected the brain after puberty in a final decisive cascade.[163] His use of the term "praecox" distinguished it from other forms of dementia such as Alzheimer's disease which typically occur later in life.[164] It is sometimes argued that the use of the term *démence précoce* in 1852 by the French physician Bénédict Morel constitutes the medical discovery of schizophrenia. However, this account ignores the fact that there is little to connect Morel's descriptive use of the term and the independent development of the *dementia praecox* disease concept at the end of the nineteenth century.[165]



Molecule of chlorpromazine (trade name Thorazine), which revolutionized treatment of schizophrenia in the 1950s

The word *schizophrenia*—which translates roughly as "splitting of the mind" and comes from the Greek roots *schizein* (σχίζειν, "to split") and *phrēn*, *phren-* (φρήν, φρεν-, "mind")[166]—was coined by Eugen Bleuler in 1908 and was intended to describe the separation of function between personality, thinking, memory, and perception. American and British interpretations of Bleuler led to the claim that he described its main symptoms as four *A*'s: flattened *affect*, *autism*, impaired *association* of ideas, and *ambivalence*.[167][168] Bleuler realized that the illness was *not* a dementia, as some of his patients improved rather than deteriorated, and thus proposed the term schizophrenia instead. Treatment was revolutionized in the mid-1950s with the development and introduction of chlorpromazine.[169]

In the early 1970s, the diagnostic criteria for schizophrenia were the subject of a number of controversies which eventually led to the operational criteria used today. It became clear after the 1971 US–UK Diagnostic Study that schizophrenia was diagnosed to a far greater extent in America than in Europe.[170] This was partly due to looser diagnostic criteria in the US, which used the DSM-II manual, contrasting with Europe and its ICD-9. David Rosenhan's 1972 study, published in the journal *Science* under the title "On being sane in insane places", concluded that the diagnosis of schizophrenia in the US was often subjective and unreliable.[171] These were some of the factors leading to the revision not only of the diagnosis of schizophrenia, but the revision of the whole DSM manual, resulting in the publication of the DSM-III in 1980.[172]

The term schizophrenia is commonly misunderstood to mean that affected persons have a "split personality". Although some people diagnosed with schizophrenia may hear voices and may experience the voices as distinct personalities, schizophrenia does not involve a person changing among distinct, multiple personalities; the confusion arises in part due to the literal interpretation of Bleuler's term "schizophrenia" (Bleuler originally associated schizophrenia with dissociation, and included split personality in his category of schizophrenia).[173][174] Dissociative identity disorder (having a "split personality") was also often misdiagnosed as schizophrenia based on the loose criteria in the DSM-II.[174][175] The first known misuse of the term to mean "split personality" was in an article by the poet T. S. Eliot in 1933.[176] Other scholars have traced earlier roots.[177] Rather, the term means a "splitting of mental functions", reflecting the presentation of the illness.[178]

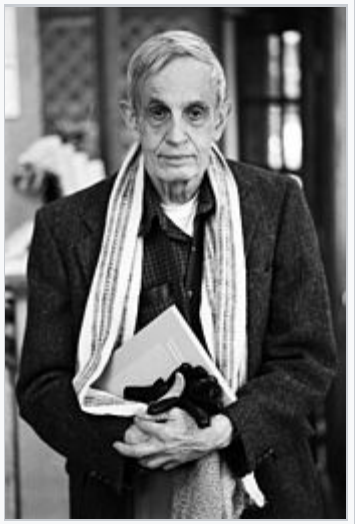
*schizophrenia*

In 2002, the term for schizophrenia in Japan was changed from *seishin-bunretsu-byō* (精神分裂病?, lit. "mind-split disease") to *tōgō-shitchō-shō* (統合失調症?, lit. "integration disorder") to reduce stigma.[179] The new name was inspired by the biopsychosocial model; it increased the percentage of people who were informed of the diagnosis from 37 to 70% over three years.[180] A similar change was made in South Korea in 2012.[181] A professor of psychiatry, Jim van Os, has proposed changing the English term to "psychosis spectrum syndrome".[182]

In the United States, the cost of schizophrenia—including direct costs (outpatient, inpatient, drugs, and long-term care) and non-health care costs (law enforcement, reduced workplace productivity, and unemployment)—was estimated to be $62.7 billion in 2002.[183] The book and film *A Beautiful Mind* chronicles the life of John Forbes Nash, a Nobel Prize–winning mathematician who was diagnosed with schizophrenia.



John Nash, an American mathematician and joint recipient of the 1994 Nobel Prize for Economics, who had schizophrenia. His life was the subject of the 2001 Academy Award-winning film *A Beautiful Mind*.

## Violence

Individuals with severe mental illness, including schizophrenia, are at a significantly greater risk of being *victims* of both violent and non-violent crime.[184] Schizophrenia has been associated with a higher rate of violent acts, although this is primarily due to higher rates of drug use.[185] Rates of homicide linked to psychosis are similar to those linked to substance misuse, and parallel the overall rate in a region.[186] What role schizophrenia has on violence independent of drug misuse is controversial, but certain aspects of individual histories or mental states may be factors.[187] About 11% of people in prison for homicide have schizophrenia while 21% have mood disorders.[188] Another study found about 8-10% of people with schizophrenia had committed a violent act in the past year compared to 2% of the general population.[188]

Media coverage relating to violent acts by individuals with schizophrenia reinforces public perception of an association between schizophrenia and violence.[185] In a large, representative sample from a 1999 study, 12.8% of Americans believed that individuals with schizophrenia were "very likely" to do something violent against others, and 48.1% said that they were "somewhat likely" to. Over 74% said that people with schizophrenia were either "not very able" or "not able at all" to make decisions concerning their treatment, and 70.2% said the same of money-management decisions.[189] The perception of individuals with psychosis as violent has more than doubled in prevalence since the 1950s, according to one meta-analysis.[190]

Research has found a tentative benefit in using minocycline to treat schizophrenia.[191] Nidotherapy or efforts to change the environment of people with schizophrenia to improve their ability to function, is also being studied; however, there is not enough evidence yet to make conclusions about its effectiveness.[192] Negative symptoms have proven a challenge to treat, as they are generally not made better by medication. Various agents have been explored for possible benefits in this area.[193] There have been trials on drugs with anti-inflammatory activity, based on the premise that inflammation might play a role in the pathology of schizophrenia.[194]

*For other uses, see Suicide (disambiguation).*

**Suicide** is the act of intentionally causing one's own death.[1] Risk factors include mental disorders such as depression, bipolar disorder, schizophrenia, personality disorders, alcoholism, or substance misuse.[2][3] Others are impulsive acts due to stress such as from financial difficulties, troubles with relationships, or from bullying.[3][4] Those who have previously attempted suicide are at higher risk for future attempts.[3] Suicide prevention efforts include limiting access to method of suicide, such as firearms and poisons, treating mental disorders and substance misuse, proper media reporting of suicide, and improving economic conditions.[3] Although crisis hotlines are common, there is little evidence for their effectiveness.[5]

The most commonly used method of suicide varies between countries, and is partly related to the availability of effective means.[6] Common methods include hanging, pesticide poisoning, and firearms.[3][7] Suicide resulted in 842,000 deaths globally in 2013 (up from 712,000 deaths in 1990).[8] This makes it the 10th leading cause of death worldwide.[2][9] Approximately 0.5% to 1.4% of people die by suicide, about 12 per 100,000 persons per year.[9][10] Three quarters of suicides globally occur in the developing world.[3] Rates of completed suicides are generally higher in men than in women, ranging from 1.5 times as much in the developing world to 3.5 times in the developed world.[11] Suicide is generally most common among those over the age of 70; however, in certain countries those aged between 15 and 30 are at highest risk.[11] There are an estimated 10 to 20 million non-fatal attempted suicides every year.[12] Non-fatal suicide attempts may lead to injury and long-term disabilities. In the Western world, attempts are more common in young people and females.[10]

Views on suicide have been influenced by broad existential themes such as religion, honor, and the meaning of life.[13][14] The Abrahamic religions traditionally consider suicide an offense towards God due to the belief in the sanctity of life.[15] During the samurai era in Japan, a form of suicide known as seppuku was respected as a means of making up for failure or as a form of protest.[16] Sati, a practice outlawed by

the British Raj, expected the Indian widow to kill herself on her husband's funeral fire, either willingly or under pressure from the family and society.[17] Suicide and attempted suicide, while previously illegal, are no longer in most Western countries.[18] It remains a criminal offense in many countries.[19] In the 20th and 21st centuries, suicide has been used on rare occasions as a form of protest, and kamikaze and suicide bombings have been used as a military or terrorist tactic.[20] The word is from the Latin *suicidium*, which means "the killing of oneself".[21]

# Definitions

*Main article: Suicide terminology*

Suicide, also known as completed suicide, is the "act of taking one's own life".[1] Attempted suicide or non-fatal suicidal behavior is self-injury with the desire to end one's life that does not result in death.[22] Assisted suicide is when one individual helps another bring about their own death indirectly via providing either advice or the means to the end.[23] This is in contrast to euthanasia, where another person takes a more active role in bringing about a person's death.[23] Suicidal ideation is thoughts of ending one's life but not taking any active efforts to do so.[22]

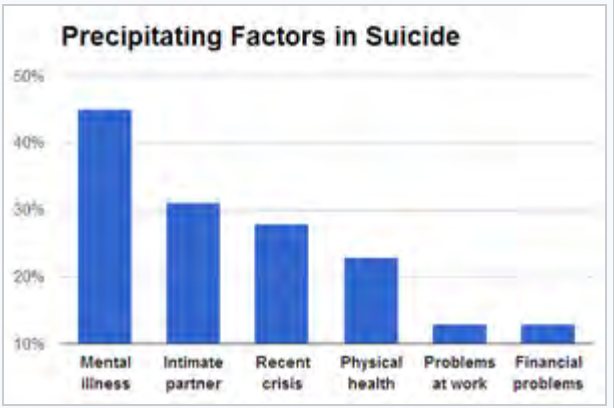
There is discussion about the appropriateness of the term *"commit"*, and its use to describe suicide. Those who object to the use of *commit* argue

A picture of a woman with depression who was suicidal

that it carries with it implications that suicide is a criminal, sinful or morally wrong act.[24] There is growing consensus that it is more appropriate to use "completed suicide," "died by suicide" or simply "killed him/herself" to describe the act of suicide, and this is reflected in mental health organisations' media guidance.[25][26][27][28] Despite these efforts, "committed suicide" and similar descriptions remain common in both scholarly research and journalism.[29][30]

## Risk factors for humans

Factors that affect the risk of suicide include mental disorders, drug misuse, psychological states, cultural, family and social situations, and genetics.[32] Mental disorders and substance misuse frequently co-exist.[33] Other risk factors include having previously attempted suicide,[10] the ready availability of a means to take one's life, a family history of suicide, or the presence of traumatic brain injury.[34] For example, suicide rates have been found to be greater in households with firearms than those without them.[35]



The precipitating circumstances for suicide from 16 American states in 2008[31]

Socio-economic problems such as unemployment, poverty, homelessness, and discrimination may trigger suicidal thoughts.[36][37] About 15–40% of people leave a suicide note.[38] Genetics appears to account for between 38% and 55% of suicidal behaviors.[39] War veterans have a higher risk of suicide due in part to higher rates of mental illness such as post traumatic stress disorder and physical health problems related to war.[40]

### Mental disorders

Mental disorders are often present at the time of suicide with estimates ranging from 27%[41] to more than 90%.[10] In Asia, rates of mental disorders appear to be lower than in Western countries.[11] Of those who have been admitted to a psychiatric unit, their lifetime risk of completed suicide is about 8.6%.[10] Half of all people who die by suicide may have major depressive disorder; having this or one of the other mood disorders such as bipolar disorder increases the risk of suicide 20-fold.[42] Other conditions implicated include schizophrenia (14%), personality disorders (8%),[43][44] bipolar disorder,[42] and posttraumatic stress disorder.[10] Others estimate that about half of people who complete suicide could be diagnosed with a personality disorder with borderline personality disorder being the most common.[45] About 5% of people with schizophrenia die of suicide.[46] Eating disorders are another high risk condition.[47]

In approximately 80% of completed suicides, the individual has seen a physician within the year before their death,[48] including 45% within the prior month.[49] Approximately 25–40% of those who completed

suicide had contact with mental health services in the prior year.[41][48] Antidepressants of the SSRI type appear to increase the risk of suicide in children but do not change the risk in adults.[50]

## Previous attempts and self-harm

A previous history of suicide attempts is the most accurate predictor of completed suicide.[10] Approximately 20% of suicides have had a previous attempt, and of those who have attempted suicide, 1% complete suicide within a year[10] and more than 5% die by suicide within 10 years.[47] Acts of self-harm are not usually suicide attempts and most who self-harm are not at high risk of suicide.[51] Some who self-harm, however, do still end their life by suicide, and risk for self-harm and suicide may overlap.[51]

## Substance use

"The Drunkard's Progress", 1846 demonstrating how alcoholism can lead to poverty, crime, and eventually suicide

Substance abuse is the second most common risk factor for suicide after major depression and bipolar disorder.[52] Both chronic substance misuse as well as acute intoxication are associated.[33][53] When combined with personal grief, such as bereavement, the risk is further increased.[53] Substance misuse is also associated with mental health disorders.[33]

Most people are under the influence of sedative-hypnotic drugs (such as alcohol or benzodiazepines) when they die by suicide[54] with alcoholism present in between 15% and 61% of cases.[33] Countries that have higher rates of alcohol use and a greater density of bars generally also have higher rates of suicide.[55] About 2.2–3.4% of those who have been treated for alcoholism at some point in their life die by suicide.[55] Alcoholics who attempt suicide are usually male, older, and have tried to take their own lives in the past.[33] Between 3 and 35% of deaths among those who use heroin are due to suicide (approximately 14 fold greater than those who do not use).[56] In adolescents who misuse alcohol, neurological and psychological dysfunctions may contribute to the increased risk of suicide.[57]

The misuse of cocaine and methamphetamine has a high correlation with suicide.[33][58] In those who use cocaine the risk is greatest during the withdrawal phase.[59] Those who used inhalants are also at significant risk with around 20% attempting suicide at some point and more than 65% considering it.[33] Smoking cigarettes is associated with the risk of suicide.[60] There is little evidence as to why this association exists; however it has been hypothesized that those who are predisposed to smoking are also predisposed to suicide, that smoking causes health problems which subsequently make people want to end their life, and that smoking affects brain chemistry causing a propensity for suicide.[60] Cannabis however does not appear to independently increase the risk.[33]

## Problem gambling

Problem gambling is associated with increased suicidal ideation and attempts compared to the general population.[61] Between 12 and 24% pathological gamblers attempt suicide.[62] The rate of suicide among their spouses is three times greater than that of the general population.[62] Other factors that increase the risk in problem gamblers include mental illness, alcohol and drug misuse.[63]

## Medical conditions

There is an association between suicidality and physical health problems such as[47] chronic pain,[64]

traumatic brain injury,[65] cancer,[66] kidney failure (requiring hemodialysis), HIV, and systemic lupus erythematosus.[47] The diagnosis of cancer approximately doubles the subsequent risk of suicide.[66] The prevalence of increased suicidality persisted after adjusting for depressive illness and alcohol abuse. In people with more than one medical condition the risk was particularly high. In Japan, health problems are listed as the primary justification for suicide.[67]

Sleep disturbances such as insomnia[68] and sleep apnea are risk factors for depression and suicide. In some instances the sleep disturbances may be a risk factor independent of depression.[69] A number of other medical conditions may present with symptoms similar to mood disorders, including hypothyroidism, Alzheimer's, brain tumors, systemic lupus erythematosus, and adverse effects from a number of medications (such as beta blockers and steroids).[10]

## Psychosocial states

A number of psychological states increase the risk of suicide including: hopelessness, loss of pleasure in life, depression and anxiousness.[42] A poor ability to solve problems, the loss of abilities one used to have, and poor impulse control also play a role.[42][70] In older adults the perception of being a burden to others is important.[71] Suicide in which the reason is that the person feels that they are not part of society is known as egoistic suicide.[72] Rates of suicide appear to decrease around Christmas.[73] One study however found the risk may be greater for males on their birthday.[74]

Recent life stresses such as a loss of a family member or friend, loss of a job, or social isolation (such as living alone) increase the risk.[42] Those who have never married are also at greater risk.[10] Being religious may reduce one's risk of suicide.[75] This has been attributed to the negative stance many religions take against suicide and to the greater connectedness religion may give.[75] Muslims, among religious people, appear to have a lower rate of suicide; however the data supporting this is not strong.[19] There does not appear to be a difference in rates of attempted suicide rates.[19] Young women in the Middle East may have higher rates.[76]

Some may take their own lives to escape bullying or prejudice.[77] A history of childhood sexual abuse[78] and time spent in foster care are also risk factors.[79] Sexual abuse is believed to contribute to about 20% of the overall risk.[39]

An evolutionary explanation for suicide is that it may improve inclusive fitness. This may occur if the person dying by suicide cannot have more children and takes resources away from relatives by staying alive. An objection is that deaths by healthy adolescents likely does not increase inclusive fitness. Adaptation to a very different ancestral environment may be maladaptive in the current one.[70][80]

Poverty is associated with the risk of suicide.[81] Increasing relative poverty compared to those around a person increases suicide risk.[82] Over 200,000 farmers in India have died by suicide since 1997, partly due to issues of debt.[83] In China suicide is three times as likely in rural regions as urban ones, partly, it is believed, due to financial difficulties in this area of the country.[84]

## Media

The media, which includes the Internet, plays an important role.[32] How it depicts suicide may have a negative effect, with high-volume, prominent, repetitive coverage glorifying or romanticizing suicide having the most impact.[85] When detailed descriptions of how to kill oneself by a specific means are portrayed, this method of suicide may increase in the population as a whole.[6]

This trigger of suicide contagion or copycat suicide is known as the *Werther effect*, named after the protagonist in

In Goethe's *The Sorrows of Young Werther*, the title character kills himself due to a love triangle involving Charlotte (pictured at his grave). Some admirers of the story were triggered into copycat suicide, known as the Werther effect.

Goethe's *The Sorrows of Young Werther* who killed himself and then was emulated by many admirers of the book.[86] This risk is greater in adolescents who may romanticize death.[87] It appears that while news media has a significant effect; that of the entertainment media is equivocal.[88][89] The opposite of the Werther effect is the proposed *Papageno effect*, in which coverage of effective coping mechanisms may have a protective effect. The term is based upon a character in Mozart's opera *The Magic Flute*, who (fearing the loss of a loved one) had planned to kill himself until his friends helped him out.[86] When media follows recommended reporting guidelines the risk of suicides can be decreased.[85] Getting buy-in from industry, however, can be difficult, especially in the long term.[85]

### Rational

Rational suicide is the reasoned taking of one's own life,[90] although others consider suicide as never rational.[90] The act of taking one's life for the benefit of others is known as altruistic suicide.[91] An example of this is an elder ending his or her life to leave greater amounts of food for the younger people in the community.[91] Suicide in some Inuit cultures has been seen as an act of respect, courage, or wisdom.[92]

A suicide attack is a political action where an attacker carries out violence against others which they understand will result in their own death.[93] Some suicide bombers are motivated by a desire to obtain martyrdoms.[40] Kamikaze missions were carried out as a duty to a higher cause or moral obligation.[92] Murder–suicide is an act of homicide followed within a week by suicide of the person who carried out the act.[94]

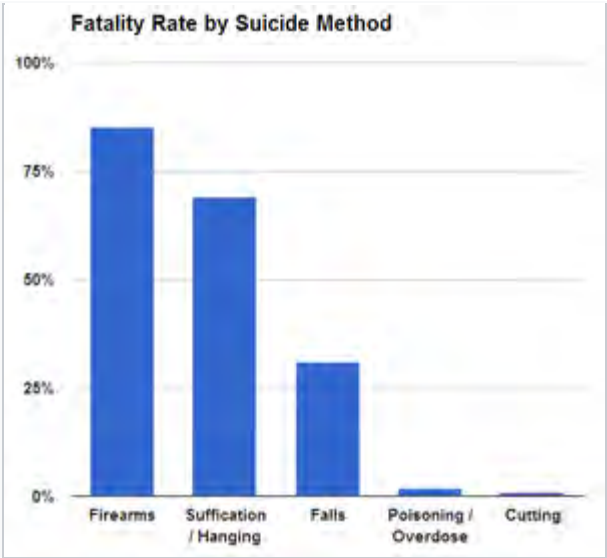
Mass suicides are often performed under social pressure where members give up autonomy to a leader.[95] Mass suicides can take place with as few as two people, often referred to as a suicide pact.[96]

In extenuating situations where continuing to live would be intolerable, some people use suicide as a means of escape.[97] Some inmates in Nazi concentration camps are known to have killed themselves by deliberately touching the electrified fences.[98]

## Methods

*Main article: Suicide methods*

The leading method of suicide varies among countries. The leading methods in different regions include hanging, pesticide poisoning, and firearms.[7] These differences are believed to be in part due to availability of the different methods.[6] A review of 56 countries found that hanging was [99]



Case fatality rate by suicide method in the United States[35]

the most common method in most of the countries, accounting for 53% of the male suicides and 39% of the female suicides.[100]

Worldwide, 30% of suicides are estimated to occur from pesticide poisoning, most of which occur in the developing world.[3] The use of this method varies markedly from 4% in Europe to more than 50% in the Pacific region.[101] It is also common in Latin America due to easy access within the farming populations.[6] In many countries, drug overdoses account for approximately 60% of suicides among women and 30% among men.[102] Many are unplanned and occur during an acute period of ambivalence.[6] The death rate varies by method: firearms 80-90%, drowning 65-80%, hanging 60-85%, car exhaust 40-60%, jumping 35-60%, charcoal burning 40-50%, pesticides 6-75%, and medication overdose 1.5-4%.[6] The most common attempted methods of suicide differ from the most common successful methods; up to 85% of attempts are via drug overdose in the developed world.[47]

In China, the consumption of pesticides is the most common method.[103] In Japan, self-disembowelment known as seppuku (or hara-kiri) still occurs;[103] however, hanging and jumping are the most common.[104] Jumping to one's death is common in both Hong Kong and Singapore at 50% and 80% respectively.[6] In Switzerland, firearms are the most frequent suicides method in young males, however this method has decreased relatively since guns have become less common.[105][106] In the United States, 57% of suicides involve the use of firearms, with this method being somewhat more common in men than women.[10] The next most common cause was hanging in males and self-poisoning in females.[10] Together these methods comprised about 40% of U.S. suicides.[107]

## Pathophysiology

There is no known unifying underlying pathophysiology for either suicide or depression.[10] It is however believed to result from an interplay of behavioral, socio-environmental and psychiatric factors.[6]

Low levels of brain-derived neurotrophic factor (BDNF) are both directly associated with suicide[108] and indirectly associated through its role in major depression, posttraumatic stress disorder, schizophrenia and obsessive–compulsive disorder.[109] Post-mortem studies have found reduced levels of BDNF in the hippocampus and prefrontal cortex, in those with and without psychiatric conditions.[110] Serotonin, a brain neurotransmitter, is believed to be low in those who die by suicide. This is partly based on evidence of increased levels of 5-HT2A receptors found after death.[111] Other evidence includes reduced levels of a breakdown product of serotonin, 5-Hydroxyindoleacetic acid, in the cerebral spinal fluid.[112] Direct evidence is however hard to gather.[111] Epigenetics, the study of changes in genetic expression in response to environmental factors which do not alter the underlying DNA, is also believed to play a role in determining suicide risk.[113]

## Prevention

*Main article: Suicide prevention*

Suicide prevention is a term used for the collective efforts to reduce the incidence of suicide through preventative measures. Reducing access to certain methods, such as firearms or toxins can reduce risk.[6][114] Other measures include reducing access to charcoal and barriers on bridges and subway platforms.[6][115] Treatment of drug and alcohol addiction, depression, and those who have attempted suicide in the past may also be effective.[114] Some have proposed reducing access to alcohol as a preventative strategy (such as reducing the number of bars).[33] Although crisis hotlines are common there is little evidence to support or refute their effectiveness.[5][116] In young adults who have recently thought about suicide, cognitive behavioral therapy appears to improve outcomes.[117] Economic development through its ability to reduce poverty may be able to decrease suicide rates.[81] Efforts to increase social connection, especially in elderly males, may be effective.[118] The World Suicide Prevention Day is observed annually on September 10 with the support of the International Association for Suicide Prevention and the World Health Organization.[119]

As a suicide prevention initiative, this sign promotes a special telephone available on the Golden Gate Bridge that connects to a crisis hotline.

## Screening

There is little data on the effects of screening the general population on the ultimate rate of suicide.[120][121] Screening those who come to the emergency departments with injuries from self harm have been shown to help identify suicide ideation and suicide intention. Psychometric tests such as the Beck Depression Inventory or the Geriatric Depression Scale for older people are being used.[122] As there is a high rate of people who test positive via these tools that are not at risk of suicide, there are concerns that screening may significantly increase mental health care resource utilization.[123] Assessing those at high risk however is recommended.[10] Asking about suicidality does not appear to increase the risk.[10]

## Mental illness

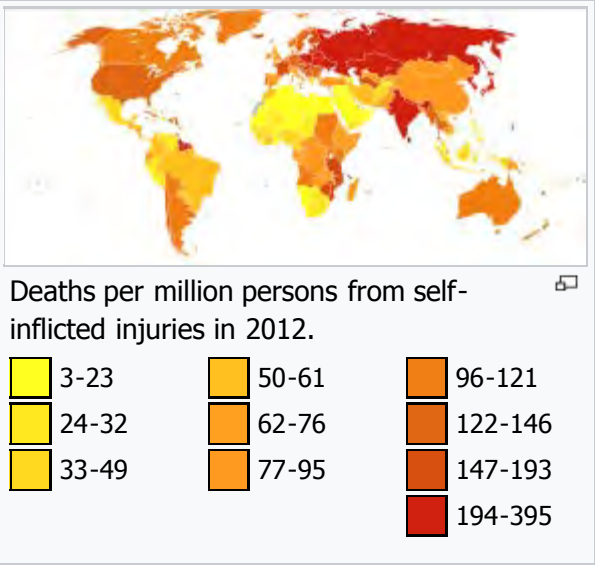
In those with mental health problems a number of treatments may reduce the risk of suicide. Those who are actively suicidal may be admitted to psychiatric care either voluntarily or involuntarily.[10] Possessions that may be used to harm oneself are typically removed.[47] Some clinicians get patients to sign suicide prevention contracts where they agree to not harm themselves if released.[10] Evidence however does not support a significant effect from this practice.[10] If a person is at low risk, outpatient mental health treatment may be arranged.[47] Short-term hospitalization has not been found to be more effective than community care for improving outcomes in those with borderline personality disorder who are chronically suicidal.[124][125]

There is tentative evidence that psychotherapy, specifically, dialectical behaviour therapy reduces suicidality in adolescents[126] as well as in those with borderline personality disorder.[127] It may also be useful in decreasing suicide attempts in adults at high risk.[128] Evidence however has not found a decrease in completed suicides.[126]

There is controversy around the benefit-versus-harm of antidepressants.[32] In young persons, the newer antidepressants such as SSRIs appear to increase the risk of suicidality from 25 per 1000 to 40 per 1000.[129] In older persons however they might decrease the risk.[10] Lithium appears effective at lowering the risk in those with bipolar disorder and unipolar depression to nearly the same levels as the general population.[130][131] Clozapine may decrease the thoughts of suicide in some people with schizophrenia.[132]

# Epidemiology

*Main article: Epidemiology of suicide*

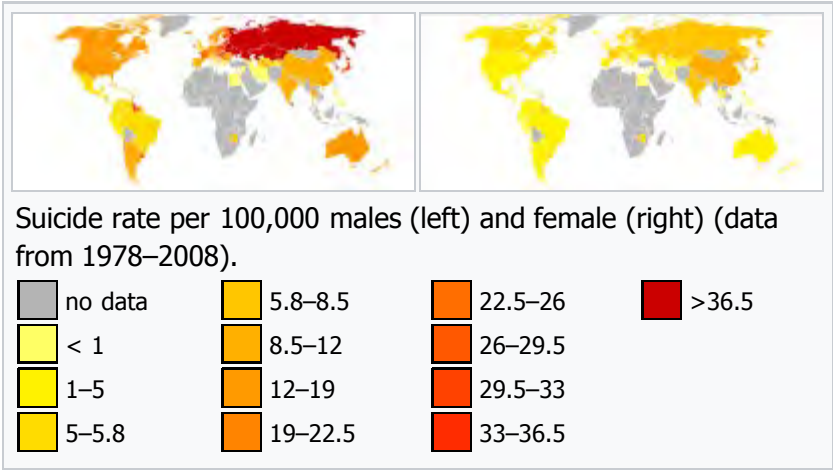


Approximately 0.5% to 1.4% of people die by suicide, a mortality rate of 11.6 per 100,000 persons per year.[9][10] Suicide resulted in 842,000 deaths in 2013 up from 712,000 deaths in 1990.[8] Rates of suicide have increased by 60% from the 1960s to 2012,[114] with these increases seen primarily in the developing world.[2] Globally, as of 2008/2009, suicide is the tenth leading cause of death.[2] For every suicide that results in death there are between 10 and 40 attempted suicides.[10]

Suicide rates differ significantly between countries and over time.[9] As a percentage of deaths in 2008 it was: Africa 0.5%, South-East Asia 1.9%, Americas 1.2% and Europe 1.4%.[9] Rates per 100,000 were: Australia 8.6, Canada 11.1, China 12.7, India 23.2, United Kingdom 7.6, United States 11.4 and South Korea 28.9.[133][134] It was ranked as the 10th leading cause of death in the United States in 2009 at about 36,000 cases a year,[135] with about 650,000 people seen in emergency departments yearly due to attempting suicide.[10] The country's rate among men in their 50s rose by nearly half in the decade 1999–2010.[136] Lithuania, Japan and Hungary have the highest rates.[9] Around 75% of suicides occur in the developing world.[3] The countries with the greatest absolute numbers of suicides are China and India, accounting for over half the total.[9] In China, suicide is the 5th leading cause of death.[137]

## Sex

*Main article: Gender differences in suicide*



Globally as of 2012 death by suicide occur about 1.8 times more often in males than female.[9][138]

In the Western world, males die three to four times more often by means of suicide than do females.[9] This difference is even more pronounced in those over the age of 65, with tenfold more males than females dying by suicide.[139] Suicide attempts and self-harm are between two and four times more frequent in females.[10][140][141] Some researchers have attributed this to males using more lethal means to end their lives.[139] However, separating intentional suicide attempts, from non-suicidal self-harm, is not currently done in the United States, when gathering statistics at the national level.[142]

China has one of the highest female suicide rates in the world and is the only country where it is higher than that of men (ratio of 0.9).[9][137] In the Eastern Mediterranean, suicide rates are nearly equivalent between males and females.[9] The highest rate of female suicide is found in South Korea at 22 per 100,000, with high rates in South-East Asia and the Western Pacific generally.[9]

Due in part to social stigmatisation and the resulting depression, people whose gender identity does not align with their assigned sex are at a high risk of suicide.[143]

In Sweden, same-sex married men have a suicide risk nearly three times higher than their heterosexual counterparts and same-sex married women have a tentatively elevated suicide risk.[144]

### Age

In many countries the rate of suicide is highest in the middle-aged[145] or elderly.[6] The absolute number of suicides however is greatest in those between 15 and 29 years old due to the number of people in this age group.[9] In the United States it is greatest in Caucasian men older than 80 years, even though younger people more frequently attempt suicide.[10] It is the second most common cause of death in adolescents[32] and in young males is second only to accidental death.[145] In young males in the developed world it is the cause of nearly 30% of mortality.[145] In the developing world rates are similar, but it makes up a smaller proportion of overall deaths due to higher rates of death from other types of trauma.[145] In South-East Asia in contrast to other areas of the world, deaths from suicide occur at a greater rate in young females than elderly females.[9]

## History

*Main article: History of suicide*

In ancient Athens, a person who committed suicide without the approval of the state was denied the honors of a normal burial. The person would be buried alone, on the outskirts of the city, without a headstone or marker.[146] However, it was deemed to be an acceptable method to deal with military defeat.[147] In Ancient Rome, while suicide was initially permitted, it was later deemed a crime against the state due to its economic costs.[148]

*The Death of Seneca* (1684), painting by Luca Giordano, depicting the suicide of Seneca the Younger in Ancient Rome

Suicide came to be regarded as a sin in Christian Europe and was condemned at the Council of Arles in 452 as the work of the Devil. In the Middle Ages, the Church had drawn-out discussions as to when the desire for martyrdom was suicidal, as in the case of martyrs of Córdoba. Despite these disputes and occasional official rulings, Catholic doctrine was not entirely settled on the subject of suicide until the later 17th century. A criminal ordinance issued by Louis XIV of France in 1670 was extremely severe, even for the times: the dead person's body was drawn through the streets, face down, and then hung or thrown on a garbage heap. Additionally, all of the person's property was confiscated.[149][150]

Attitudes towards suicide slowly began to shift during the Renaissance. John Donne's work *Biathanatos*, contained one of the first modern defences of suicide, bringing proof from the conduct of Biblical figures, such as Jesus, Samson and Saul, and presenting arguments on grounds of reason and nature to sanction suicide in certain circumstances.[151]

The secularization of society that began during The Enlightenment questioned traditional religious attitudes toward suicide and brought a more modern perspective to the issue. David Hume denied that suicide was a crime as it affected no one and was potentially to the advantage of the individual. In his 1777 *Essays on Suicide and the Immortality of the Soul* he rhetorically asked, "Why should I prolong a miserable existence, because of some frivolous advantage which the public may perhaps receive from me?"[151] A shift in public opinion at large can also be discerned; *The Times* in 1786 initiated a spirited debate on the motion "Is suicide an act of courage?".[152]

By the 19th-century, the act of suicide had shifted from being viewed as caused by sin to being caused by insanity in Europe.[150] Although suicide remained illegal during this period, it increasingly became the target of satirical comments, such as the Gilbert and Sullivan musical *The Mikado* that satirized the idea of executing someone who had already killed himself.

By 1879, English law began to distinguish between suicide and homicide, although suicide still resulted in forfeiture of estate.[153] In 1882, the deceased were permitted daylight burial in England[154] and by the middle of the 20th century, suicide had become legal in much of the western world.

## Legislation

*Main article: Suicide legislation*

In most Western countries, suicide is no longer a crime.[18] It was, however, in most Western European countries from the Middle Ages until at least the 1800s.[153] It remains a criminal offense in most Muslim-majority nations.[19]

A *tantō* knife prepared for *seppuku* (abdomen-cutting)

In Australia suicide is not a crime.[155] It however is a crime to counsel, incite, or aid and abet another in attempting to die by suicide, and the law explicitly allows any person to use "such force as may reasonably be necessary" to prevent another from taking their own life.[156] The Northern Territory of Australia briefly had legal physician-assisted suicide from 1996 to 1997.[157]

No country in Europe currently considers suicide or attempted suicide to be a crime.[158] England and Wales decriminalized suicide via the Suicide Act 1961 and the Republic of Ireland in 1993.[158] The word "commit" was used in reference to it being illegal, however many organisations have stopped it because of the negative connotation.[159][160]

In India, suicide used to be illegal and surviving family could face legal difficulties.[161] The government of India decided to repeal the law in 2014.[162] In Germany, active euthanasia is illegal and anyone present during suicide may be prosecuted for failure to render aid in an emergency.[163] Switzerland has recently taken steps to legalize assisted suicide for the chronically mentally ill. The high court in Lausanne, in a 2006 ruling, granted an anonymous individual with longstanding psychiatric difficulties the right to end his own life.[164]

In the United States, suicide is not illegal but may be associated with penalties for those who attempt it.[158] Physician-assisted suicide is legal in the state of Washington for people with terminal diseases.[165] In Oregon, people with terminal diseases may request medications to help end their life.[166]

Canadians who have attempted suicide may be barred from entering the US. US laws allow border guards to deny access to people who have a mental illness, including those with previous suicide attempts.[167][168]

## Religious views

*Main article: Religious views on suicide*

In most forms of Christianity, suicide is considered a sin, based mainly on the writings of influential Christian thinkers of the Middle Ages, such as St. Augustine and St. Thomas Aquinas, but suicide was not considered a sin under the Byzantine Christian code of Justinian, for

A Hindu widow burning herself with the corpse of her husband, 1820s

instance.[169][170] In Catholic doctrine, the argument is based on the commandment "Thou shalt not kill" (made applicable under the New Covenant by Jesus in Matthew 19:18), as well as the idea that life is a gift given by God which should not be spurned, and that suicide is against the "natural order" and thus interferes with God's master plan for the world.[171] Traditionally suiciders were buried in the forest without ceremonies, like horses or cows.[*citation needed*]

However, it is believed that mental illness or grave fear of suffering diminishes the responsibility of the one completing suicide.[172] Counter-arguments include the following: that the sixth commandment is more accurately translated as "thou shalt not murder" (not necessarily applying to the self), that God has given free will to humans, that taking one's own life no more violates God's Law than does curing a disease and that a number of suicides by followers of God are recorded in the Bible with no dire condemnation.[173]

Judaism focuses on the importance of valuing this life, and as such, suicide is tantamount to denying God's goodness in the world. Despite this, under extreme circumstances when there has seemed no choice but to either be killed or forced to betray their religion, Jews have committed individual suicide or mass suicide (see Masada, First French persecution of the Jews, and York Castle for examples) and as a grim reminder there is even a prayer in the Jewish liturgy for "when the knife is at the throat", for those dying "to sanctify God's Name" (see Martyrdom). These acts have received mixed responses by Jewish authorities, regarded by some as examples of heroic martyrdom, while others state that it was wrong for them to take their own lives in anticipation of martyrdom.[174]

Islamic religious views are against suicide.[19] The Qu'ran forbids it by stating "do not kill or destroy yourself".[175] The hadiths also state individual suicide to be unlawful and a sin.[19] Stigma is often associated with suicide in Islamic countries.[175]

In Hinduism, suicide is generally frowned upon and is considered equally sinful as murdering another in contemporary Hindu society. Hindu Scriptures state that one who dies by suicide will become part of the spirit world, wandering earth until the time one would have otherwise died, had one not taken one's own life.[176] However, Hinduism accepts a man's right to end one's life through the non-violent practice of fasting to death, termed *Prayopavesa*.[177] But Prayopavesa is strictly restricted to people who have no desire or ambition left, and no responsibilities remaining in this life.[177] Jainism has a similar practice named *Santhara*. Sati, or self-immolation by widows, was prevalent in Hindu society during the Middle Ages.[178]

## Philosophy

*Main article: Philosophy of suicide*

A number of questions are raised within the philosophy of suicide, included what constitutes suicide, whether or not suicide can be a rational choice, and the moral permissibility of suicide.[179] Arguments as to acceptability of suicide in moral or social terms range from the position that the act is inherently immoral and unacceptable under any circumstances to a regard for suicide as a sacrosanct right of anyone who believes they have rationally and conscientiously come to the decision to end their own lives, even if they are young and healthy.

Opponents to suicide include Christian philosophers such as Augustine of Hippo, Thomas Aquinas,[179] Immanuel Kant[180] and, arguably, John Stuart Mill – Mill's focus on the importance of liberty and autonomy meant that he rejected choices which would prevent a person from making future autonomous decisions.[181] Others view suicide as a legitimate matter of personal choice. Supporters of this position maintain that no one should be forced to suffer against their will, particularly from conditions such as incurable disease, mental illness, and old age, with no possibility of improvement. They reject the belief that

suicide is always irrational, arguing instead that it can be a valid last resort for those enduring major pain or trauma.[182] A stronger stance would argue that people should be allowed to autonomously choose to die regardless of whether they are suffering. Notable supporters of this school of thought include Scottish empiricist David Hume[179] and American bioethicist Jacob Appel.[164][183]

## Advocacy

*See also: Advocacy of suicide*

Advocacy of suicide has occurred in many cultures and subcultures. The Japanese military during World War II encouraged and glorified kamikaze attacks, which were suicide attacks by military aviators from the Empire of Japan against Allied naval vessels in the closing stages of the Pacific theater of World War II. Japanese society as a whole has been described as "suicide tolerant"[185] (see Suicide in Japan).

Internet searches for information on suicide return webpages that 10-30% of the time encourage or facilitate suicide attempts. There is some concern that such sites may push those predisposed over the edge. Some people form suicide pacts online, either with pre-existing friends or people they have recently encountered in chat rooms or message boards. The Internet, however, may also help prevent suicide by providing a social group for those who are isolated.[186]

In this painting by Alexandre-Gabriel Decamps, the palette, pistol, and note lying on the floor suggest that the event has just taken place; an artist has taken his own life.[184]

## Locations

*See also: List of suicide sites*

Some landmarks have become known for high levels of suicide attempts.[187] These include San Francisco's Golden Gate Bridge, Japan's Aokigahara Forest,[188] England's Beachy Head[187] and Toronto's Bloor Street Viaduct.[189]

As of 2010, the Golden Gate Bridge has had more than 1,300 die by suicide by jumping since its construction in 1937.[190] Many locations where suicide is common have constructed barriers to prevent it;[191] this includes the Luminous Veil in Toronto,[189] the Eiffel Tower in Paris and Empire State Building in New York City.[191] As of 2011, a barrier is being constructed for the Golden Gate Bridge.[192] They appear to be generally effective.[192]

## Notable cases

*Main article: List of suicides*

An example of mass suicide is the 1978 Jonestown killings/suicide in which 909 members of the Peoples Temple, an American religious group led by Jim Jones, ended their lives by drinking grape Flavor Aid laced with cyanide.[193][194][195] Thousands of Japanese civilians took their own lives in the last days of the Battle of Saipan in 1944, some jumping from "Suicide Cliff" and "Banzai Cliff".[196]

The 1981 hunger strikes, led by Bobby Sands, resulted in 10 deaths. The cause of death was recorded by the coroner as "starvation, self-imposed" rather than suicide; this was modified to simply "starvation" on the death certificates after protest from the dead strikers' families.[197] During World War II, Erwin Rommel was found to have foreknowledge of the July 20 Plot on Hitler's life; he was threatened with public trial, execution and reprisals on his family unless he took his own life.[198]

# Other species

*Main article: Animal suicide*

As suicide requires a willful attempt to die, some feel it therefore cannot be said to occur in non-human animals.[147] Suicidal behavior has been observed in salmonella seeking to overcome competing bacteria by triggering an immune system response against them.[199] Suicidal defenses by workers are also noted in the Brazilian ant *Forelius pusillus*, where a small group of ants leaves the security of the nest after sealing the entrance from the outside each evening.[200]

Pea aphids, when threatened by a ladybug, can explode themselves, scattering and protecting their brethren and sometimes even killing the ladybug.[201] Some species of termites have soldiers that explode, covering their enemies with sticky goo.[202][203]

There have been anecdotal reports of dogs, horses and dolphins killing themselves, though with little conclusive evidence.[204] There has been little scientific study of animal suicide.[205]

# Carpal tunnel syndrome

From Wikipedia, the free encyclopedia

**Carpal tunnel syndrome** (**CTS**) is a medical condition due to compression of the median nerve as it travels through the wrist at the carpal tunnel.[1] The main symptoms are pain, numbness, and tingling, in the thumb, index finger, middle finger, and the thumb side of the ring fingers.[1] Symptoms typically start gradually and during the night.[2] Pain may extend up the arm.[2] Weak grip strength may occur and after a long period of time the muscles at the base of the thumb may waste away.[2] In more than half of cases both sides are affected.[1]

Risk factors include obesity, repetitive wrist work, pregnancy, and rheumatoid arthritis.[3][4] There is tentative evidence that hypothyroidism increases the risk.[5] It is unclear if diabetes plays a role. The use of birth control pills does not affect the risk. Types of work that are associated include computer work, work with vibrating tools, and work that requires a strong grip.[3] Diagnosis is suspected based on signs, symptoms, and specific physical tests and may be confirmed with electrodiagnostic tests.[2] If muscle wasting at the base of the thumb is present, the diagnosis is likely.[3]

Being physically active can decrease the risk of developing CTS. Symptoms can be improved by wearing a wrist splint or with corticosteroid injections. Taking NSAIDs or gabapentin does not appear to be useful. Surgery to cut the transverse carpal ligament is effective with better results at a year compared to non surgical options. Further splinting after surgery is not needed. Evidence does not support magnet therapy.[3]

About 5% of people in the United States have carpal tunnel syndrome.[6] It usually begins in adulthood and women are more commonly affected than men.[2] Up to 33% of people may improve without specific treatment over approximately a year.[1] Carpal tunnel syndrome was first fully described after World War II.[7]

## Signs and symptoms [edit]

People with CTS experience numbness, tingling, or burning sensations in the thumb and fingers, in particular the index and middle fingers and radial half of the ring finger, because these receive their sensory and motor function (muscle control) from the median nerve. Ache and discomfort can possibly be felt more proximally in the forearm or even the upper arm.[8] Less-specific symptoms may include pain in the wrists or hands, loss of grip strength,[9] and loss of manual dexterity.[10]

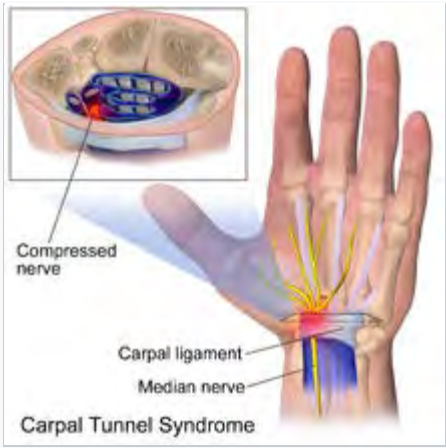
Untreated carpal tunnel syndrome, showing how the muscles at the base of the thumb have wasted away.

Some suggest that median nerve symptoms can arise from compression at the level of the thoracic outlet or the area where the median nerve passes between the two heads of the pronator teres in the forearm,[11] although this is debated.

Numbness and paresthesias in the median nerve distribution are the hallmark neuropathic symptoms (NS) of carpal tunnel entrapment syndrome. Weakness and atrophy of the thumb muscles may occur if the condition remains untreated, because the muscles are not receiving sufficient nerve stimulation.[12] Discomfort is usually worse at night and in the morning.[13]

## Causes [edit]

Most cases of CTS are of unknown cause.[14] Carpal tunnel syndrome can be associated with any condition that causes pressure on the median nerve at the wrist. Some common conditions that can lead to CTS include obesity, hypothyroidism, arthritis, diabetes, prediabetes (impaired glucose tolerance), and trauma.[15] Genetics play a role.[16] The use of birth control pills does not affect the risk.[3] Carpal tunnel is



Anatomy of the carpal tunnel showing the median nerve passing through the tight space it shares with the finger tendons.

a feature of a form of Charcot-Marie-Tooth syndrome type 1 called hereditary neuropathy with liability to pressure palsies.

Other causes of this condition include intrinsic factors that exert pressure within the tunnel, and extrinsic factors (pressure exerted from outside the tunnel), which include benign tumors such as lipomas, ganglion, and vascular malformation.[17] Carpal tunnel syndrome often is a symptom of transthyretin amyloidosis-associated polyneuropathy and prior carpal tunnel syndrome surgery is very common in individuals who later present with transthyretin amyloid-associated cardiomyopathy, suggesting that transthyretin amyloid deposition may cause carpal tunnel syndrome.[18][19][20][21][22][23][24]

The median nerve can usually move up to 9.6 mm to allow the wrist to flex, and to a lesser extent during extension.[25] Long-term compression of the median nerve can inhibit nerve gliding, which may lead to injury and scarring. When scarring occurs, the nerve will adhere to the tissue around it and become locked into a fixed position, so that less movement is apparent.[26]

Normal pressure of the carpal tunnel has been defined as a range of 2–10 mm, and wrist flexion increases this pressure 8-fold, while extension increases it 10-fold.[25] Repetitive flexion and extension in the wrist significantly increase the fluid pressure in the tunnel through thickening of the synovial tissue that lines the tendons within the carpal tunnel.[27]

## Work related [edit]

The international debate regarding the relationship between CTS and repetitive motion in work is ongoing. The Occupational Safety and Health Administration (OSHA) has adopted rules and regulations regarding cumulative trauma disorders. Occupational risk factors of repetitive tasks, force, posture, and vibration have been cited. The relationship between work and CTS is controversial; in many locations, workers diagnosed with carpal tunnel syndrome are entitled to time off and compensation.[28][29]

Some speculate that carpal tunnel syndrome is provoked by repetitive movement and manipulating activities and that the exposure can be cumulative. It has also been stated that symptoms are commonly exacerbated by forceful and repetitive use of the hand and wrists in industrial occupations,[30] but it is unclear as to whether this refers to pain (which may not be due to carpal tunnel syndrome) or the more typical numbness symptoms.[31]

A review of available scientific data by the National Institute for Occupational Safety and Health (NIOSH) indicated that job tasks that involve highly repetitive manual acts or specific wrist postures were associated with incidents of CTS, but causation was not established, and the distinction from work-related arm pains that are not carpal tunnel syndrome was not clear. It has been proposed that repetitive use of the arm can affect the biomechanics of the upper limb or cause damage to tissues. It has also been proposed that postural and spinal assessment along with ergonomic assessments should be included in the overall determination of the condition. Addressing these factors has been found to improve comfort in some studies.[32] A 2010 survey by NIOSH showed that 2/3 of the 5 million carpal tunnel cases in the US that year were related to work.[33] Women have more work-related carpal tunnel syndrome than men.[34]

Speculation that CTS is work-related is based on claims such as CTS being found mostly in the working adult population, though evidence is lacking for this. For instance, in one recent representative series of a consecutive experience, most patients were older and not working.[35] Based on the claimed increased incidence in the workplace, arm use is implicated, but the weight of evidence suggests that this is an

inherent, genetic, slowly but inevitably progressive idiopathic peripheral mononeuropathy.[36]

### Associated conditions [edit]

A variety of patient factors can lead to CTS, including heredity, size of the carpal tunnel, associated local and systematic diseases, and certain habits.[37] Non-traumatic causes generally happen over a period of time, and are not triggered by one certain event. Many of these factors are manifestations of physiologic aging.[38]

Examples include:

- Rheumatoid arthritis and other diseases that cause inflammation of the flexor tendons.
- With hypothyroidism, generalized myxedema causes deposition of mucopolysaccharides within both the perineurium of the median nerve, as well as the tendons passing through the carpal tunnel.
- During pregnancy women experience CTS due to hormonal changes (high progesterone levels) and water retention (which swells the synovium), which are common during pregnancy.
- Previous injuries including fractures of the wrist.
- Medical disorders that lead to fluid retention or are associated with inflammation such as: inflammatory arthritis, Colles' fracture, amyloidosis, hypothyroidism, diabetes mellitus, acromegaly, and use of corticosteroids and estrogens.
- Carpal tunnel syndrome is also associated with repetitive activities of the hand and wrist, in particular with a combination of forceful and repetitive activities[15]
- Acromegaly causes excessive growth hormones. This causes the soft tissues and bones around the carpel tunnel to grow and compress the median nerve.[39]
- Tumors (usually benign), such as a ganglion or a lipoma, can protrude into the carpal tunnel, reducing the amount of space. This is exceedingly rare (less than 1%).
- Obesity also increases the risk of CTS: individuals classified as obese (BMI > 29) are 2.5 times more likely than slender individuals (BMI < 20) to be diagnosed with CTS.[40]
- *Double-crush syndrome* is a debated hypothesis that compression or irritation of nerve branches contributing to the median nerve in the neck, or anywhere above the wrist, increases sensitivity of the nerve to compression in the wrist. There is little evidence, however, that this syndrome really exists.[41]
- Heterozygous mutations in the gene SH3TC2, associated with Charcot-Marie-Tooth, confer susceptibility to neuropathy, including the carpal tunnel syndrome.[42]

## Pathophysiology [edit]

*Main article: Carpal tunnel*

The carpal tunnel is an anatomical compartment located at the base of the palm. Nine flexor tendons and the median nerve pass through the carpal tunnel that is surrounded on three sides by the carpal bones that form an arch. The median nerve provides feeling or sensation to the thumb, index finger, long finger, and half of the ring finger. At the level of the wrist, the median nerve supplies the muscles at the base of the thumb that allow it to abduct, move away from the other four fingers, as well as move out of the plane of the palm. The carpal tunnel is located at the middle third of the base of the palm, bounded by the bony prominence of the scaphoid tubercle and trapezium at the base of the thumb, and the hamate hook that can be palpated along the axis of the ring finger. From the anatomical position, the carpal tunnel is bordered on the anterior surface by the transverse carpal ligament, also known as the flexor retinaculum. The flexor retinaculum is a strong, fibrous band that attaches to the pisiform and the hamulus of the hamate. The proximal boundary is the distal wrist skin crease, and the distal boundary is approximated by a line known as Kaplan's cardinal line.[43] This line uses surface landmarks, and is drawn between the apex of the skin fold between the thumb and index finger to the palpated hamate hook.[44] The median nerve can be compressed by a decrease in the size of the canal, an increase in the size of the contents (such as the swelling of lubrication tissue around the flexor tendons), or both.[45] Since the carpal tunnel is bordered by carpal bones on one side and a ligament on the other, when the pressure builds up inside the tunnel, there is nowhere for it to escape and thus it ends up pressing up against and damaging the median nerve.

Simply flexing the wrist to 90 degrees will decrease the size of the canal.

Compression of the median nerve as it runs deep to the transverse carpal ligament (TCL) causes atrophy of the thenar eminence, weakness of the flexor pollicis brevis, opponens pollicis, abductor pollicis brevis, as well as sensory loss in the digits supplied by the median nerve. The superficial sensory branch of the median nerve, which provides sensation to the base of the palm, branches proximal to the TCL and travels superficial to it. Thus, this branch spared in carpal tunnel syndrome, and there is no loss of palmar sensation.[46]

## Diagnosis [edit]

There is no consensus reference standard for the diagnosis of carpal tunnel syndrome. A combination of described symptoms, clinical findings, and electrophysiological testing may be used. CTS work up is the most common referral to the electrodiagnostic lab. Historically, diagnosis has been made with the combination of a thorough history and physical examination in conjunction with the use of electrodiagnostic (EDX) testing for confirmation. Additionally, evolving technology has included the use of ultrasonography in the diagnosis of CTS. However, it is well established that physical exam provocative maneuvers lack both sensitivity and specificity. Furthermore, EDX cannot fully exclude the diagnosis of CTS due to the lack of sensitivity. A Joint report published by the American Association of Neuromuscular and Electrodiagostic Medicine (AANEM), the American Academy of Physical Medicine and Rehabilitation (AAPM&R) and the American Academy of Neurology defines practice parameters, standards and guidelines for EDX studies of CTS based on an extensive critical literature review. This joint review concluded median and sensory nerve conduction studies are valid and reproducible in a clinical laboratory setting and a clinical diagnosis of CTS can be made with a sensitivity greater than 85% and specificity greater than 95%. Given the key role of electrodiagnostic testing in the diagnosis of CTS, The American Association of Neuromuscular & Electrodiagnostic Medicine has issued evidence-based practice guidelines, both for the diagnosis of carpal tunnel syndrome.

Numbness in the distribution of the median nerve, nocturnal symptoms, thenar muscle weakness/atrophy, positive Tinel's sign at the carpal tunnel, and abnormal sensory testing such as two-point discrimination have been standardized as clinical diagnostic criteria by consensus panels of experts.[47][48] Pain may also be a presenting symptom, although less common than sensory disturbances.

Electrodiagnostic testing (electromyography and nerve conduction velocity) can objectively verify the median nerve dysfunction. Normal nerve conduction studies, however, do not exclude the diagnosis of CTS. Clinical assessment by history taking and physical examination can support a diagnosis of CTS. If clinical suspicion of CTS is high, treatment should be initiated despite normal electrodiagnostic testing.

### Physical exam [edit]

The use of Phalen test, Tinel sign, Flick sign, or upper limb nerve test alone is not sufficient for diagnosis.[3]

- Phalen's maneuver is performed by flexing the wrist gently as far as possible, then holding this position and awaiting symptoms.[49] A positive test is one that results in numbness in the median nerve distribution when holding the wrist in acute flexion position within 60 seconds. The quicker the numbness starts, the more advanced the condition. Phalen's sign is defined as pain and/or paresthesias in the median-innervated fingers with one minute of wrist flexion. Only this test has been shown to correlate with CTS severity when studied prospectively.[37]
- Tinel's sign, a classic — though less sensitive - test is a way to detect irritated nerves. Tinel's is performed by lightly tapping the skin over the flexor retinaculum to elicit a sensation of tingling or "pins and needles" in the nerve distribution. Tinel's sign (pain and/or paresthesias of the median-innervated fingers with percussion over the median nerve) is less sensitive, but slightly more specific than Phalen's sign.[37]
- Durkan test, *carpal compression test*, or applying firm pressure to the palm over the nerve for up to 30 seconds to elicit symptoms has also been proposed.[50][51]
- Hand elevation test The hand elevation test has higher sensitivity and specificity than Tinel's test,

Phalen's test, and carpal compression test. Chi-square statistical analysis confirms the hand elevation test is not ineffective compared with Tinel's test, Phalen's test, and carpal compression test.[52]

As a note, a patient with true carpal tunnel syndrome (entrapment of the median nerve within the carpal tunnel) will not have any sensory loss over the thenar eminence (bulge of muscles in the palm of hand and at the base of the thumb). This is because the palmar branch of the median nerve, which innervates that area of the palm, branches off of the median nerve and passes over the carpal tunnel.[53] This feature of the median nerve can help separate carpal tunnel syndrome from thoracic outlet syndrome, or pronator teres syndrome.

Other conditions may also be misdiagnosed as carpal tunnel syndrome. Thus, if history and physical examination suggest CTS, patients will sometimes be tested electrodiagnostically with nerve conduction studies and electromyography. The goal of electrodiagnostic testing is to compare the speed of conduction in the median nerve with conduction in other nerves supplying the hand. When the median nerve is compressed, as in CTS, it will conduct more slowly than normal and more slowly than other nerves. There are many electrodiagnostic tests used to make a diagnosis of CTS, but the most sensitive, specific, and reliable test is the Combined Sensory Index (also known as Robinson index).[54] Electrodiagnosis rests upon demonstrating impaired median nerve conduction across the carpal tunnel in context of normal conduction elsewhere. Compression results in damage to the myelin sheath and manifests as delayed latencies and slowed conduction velocities [37] However, normal electrodiagnostic studies do not preclude the presence of carpal tunnel syndrome, as a threshold of nerve injury must be reached before study results become abnormal and cut-off values for abnormality are variable.[48] Carpal tunnel syndrome with normal electrodiagnostic tests is very, very mild at worst.

The role of MRI or ultrasound imaging in the diagnosis of carpal tunnel syndrome is unclear.[55][56][57] Their routine use is not recommended.[3]

### Differential diagnosis [edit]

Carpal tunnel syndrome is sometimes applied as a label to anyone with pain, numbness, swelling, and/or burning in the radial side of the hands and/or wrists. When pain is the primary symptom, carpal tunnel syndrome is unlikely to be the source of the symptoms.[31] As a whole, the medical community is not currently embracing or accepting trigger point theories due to lack of scientific evidence supporting their effectiveness.

## Prevention [edit]

Suggested healthy habits such as avoiding repetitive stress, work modification through use of ergonomic equipment (wrist rest, mouse pad), taking proper breaks, using keyboard alternatives (digital pen, voice recognition, and dictation), and have been proposed as methods to help prevent carpal tunnel syndrome. The potential role of B-vitamins in preventing or treating carpal tunnel syndrome has not been proven.[58][59][*unreliable medical source?*] There is little or no data to support the concept that activity adjustment prevents carpal tunnel syndrome.[60]

Carpal tunnel prevention

Stretches and isometric exercises will aid in prevention for persons at risk. Stretching before the activity and during breaks will aid in alleviating tension at the wrist.[61] Place the hand firmly on a flat surface and gently press for a few seconds to stretch the wrist and fingers. An example for an isometric exercise of the wrist is done by clenching the fist tightly, releasing and fanning out fingers.[61] None of these stretches or exercises should cause pain or discomfort.

Biological factors such as genetic predisposition and anthropometric features had significantly stronger causal association with carpal tunnel

syndrome than occupational/environmental factors such as repetitive hand use and stressful manual work.[60] This suggests that carpal tunnel syndrome might not be preventable simply by avoiding certain activities or types of work/activities.

stretch[*citation needed*]

# Treatment [edit]

Generally accepted treatments include: physiotherapy, steroids either orally or injected locally, splinting, and surgical release of the transverse carpal ligament.[62] There is insufficient evidence for ultrasound, yoga, lasers, vitamin B6, and exercise.[62] Change in activity may include avoiding activities that worsen symptoms.[16]

The American Academy of Orthopedic Surgeons recommends proceeding conservatively with a course of nonsurgical therapies tried before release surgery is considered.[63] A different treatment should be tried if the current treatment fails to resolve the symptoms within 2 to 7 weeks. Early surgery with carpal tunnel release is indicated where there is evidence of median nerve denervation or a person elects to proceed directly to surgical treatment.[63] Recommendations may differ when carpal tunnel syndrome is found in association with the following conditions: diabetes mellitus, coexistent cervical radiculopathy, hypothyroidism, polyneuropathy, pregnancy, rheumatoid arthritis, and carpal tunnel syndrome in the workplace.[63]

## Splints [edit]

The importance of wrist braces and splints in the carpal tunnel syndrome therapy is known, but many people are unwilling to use braces. In 1993, The American Academy of Neurology recommend a non-invasive treatment for the CTS at the beginning (except for sensitive or motor deficit or grave report at EMG/ENG): a therapy using splints was indicated for light and moderate pathology.[64] Current recommendations generally don't suggest immobilizing braces, but instead activity modification and non-steroidal anti-inflammatory drugs as initial therapy, followed by more aggressive options or specialist referral if symptoms do not improve.[65][66]

A rigid splint can keep the wrist straight

Many health professionals suggest that, for the best results, one should wear braces at night and, if possible, during the activity primarily causing stress on the wrists.[67][68]

A different type of rigid splint used in carpal tunnel syndrome.

## Corticosteroids [edit]

Corticosteroid injections can be effective for temporary relief from symptoms while a person develops a long-term strategy that fits their lifestyle.[69] The injections are done under local anæsthesia.[70][71] This treatment is not appropriate for extended periods, however. In general, local steroid injections are only used until other treatment options can be identified.

## Surgery [edit]

*Main article: Carpal tunnel surgery*

Release of the transverse carpal ligament is known as "carpal tunnel release" surgery. It is recommended when there is static (constant, not just intermittent) numbness, muscle weakness, or atrophy, and when night-splinting or other conservative interventions no longer control [72]

Carpal Tunnel Syndrome Operation

intermittent symptoms. The surgery may be done with local[73][74][75] or regional anesthesia[76][77] with[78] or without[74] sedation, or under general anesthesia.[75][77][79] In general, milder cases can be controlled for months to years, but severe cases are unrelenting symptomatically and are likely to result in surgical treatment.[80]

Surgery is more beneficial in the short term to alleviate symptoms (up to six months) than wearing an orthosis for a minimum of 6 weeks. However, surgery and wearing a brace resulted in similar symptom relief in the long term (12-18 month outcomes).[81]

### Physical therapy [edit]

A recent evidence based guideline produced by the American Academy of Orthopedic Surgeons assigned various grades of recommendation to physiotherapy (also called physical therapy) and other nonsurgical treatments.[82] One of the primary issues with physiotherapy is that it attempts to reverse (often) years of pathology inside the carpal tunnel. Practitioners caution that any physiotherapy such as myofascial release may take weeks of persistent application to effectively manage carpal tunnel syndrome.[83]

Again, some claim that pro-active ways to reduce stress on the wrists, which alleviates wrist pain and strain, involve adopting a more ergonomic work and life environment. For example, some have claimed that switching from a QWERTY computer keyboard layout to a more optimised ergonomic layout such as Dvorak was commonly cited as beneficial in early CTS studies, however some meta-analyses of these studies claim that the evidence that they present is limited.[84][85]

## Prognosis [edit]

Scars from carpal tunnel release surgery. Two different techniques were used. The left scar is 6 weeks old, the right scar is 2 weeks old. Also note the muscular atrophy of the thenar eminence in the left hand, a common sign of advanced CTS

Most people relieved of their carpal tunnel symptoms with conservative or surgical management find minimal residual or "nerve damage".[86] Long-term chronic carpal tunnel syndrome (typically seen in the elderly) can result in permanent "nerve damage", i.e. irreversible numbness, muscle wasting, and weakness. Those that undergo a carpal tunnel release are nearly twice as likely as those not having surgery to develop trigger thumb in the months following the procedure.[87]

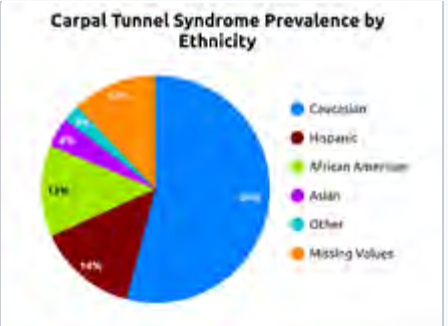
While outcomes are generally good, certain factors can contribute to poorer results that have little to do with nerves, anatomy, or surgery type. One study showed that mental status parameters or alcohol use yields much poorer overall results of treatment.[88]

Recurrence of carpal tunnel syndrome after successful surgery is rare.[89] If a person has hand pain after surgery, it is most likely not caused by carpal tunnel syndrome. It may be the case that the illness of a person with hand pain after carpal tunnel release was diagnosed incorrectly, such that the carpal tunnel release has had no positive effect upon the patient's symptoms.[*citation needed*]

## Epidemiology [edit]

Carpal tunnel syndrome can affect anyone. It accounts for about 90% of [90]

all nerve compression syndromes. In the U.S., 5% of people have the effects of carpal tunnel syndrome. Caucasians have the highest risk of CTS compared with other races such as non-white South Africans.[91] Women suffer more from CTS than men with a ratio of 3:1 between the ages of 45–60 years. Only 10% of reported cases of CTS are younger than 30 years.[91] Increasing age is a risk factor. CTS is also common in pregnancy.



Rates of carpal tunnel syndrome by ethnicity. CTS is much more common in Caucasians.

## Occupational [edit]

As of 2010, 8% of U.S. workers reported ever having carpal tunnel syndrome and 4% reported carpal tunnel syndrome in the past 12 months. Prevalence rates for carpal tunnel syndrome in the past 12 months were higher among females than among males; among workers aged 45–64 than among those aged 18–44. Overall, 67% of current carpal tunnel syndrome cases among current/recent workers were reportedly attributed to work by health professionals, indicating that the prevalence rate of work-related carpal tunnel syndrome among workers was 2%, and that there were approximately 3.1 million cases of work-related carpal tunnel syndrome among U.S. workers in 2010. Among current carpal tunnel syndrome cases attributed to specific jobs, 24% were attributed to jobs in the manufacturing industry, a proportion 2.5 times higher than the proportion of current/recent workers employed in the manufacturing industry, suggesting that jobs in this industry are associated with an increased risk of work-related carpal tunnel syndrome.[92]

# History [edit]

The condition known as carpal tunnel syndrome had major appearances throughout the years but it was most commonly heard of in the years following World War II.[7] Individuals who had suffered from this condition have been depicted in surgical literature for the mid-19th century.[7] In 1854, Sir James Paget was the first to report median nerve compression at the wrist in a distal radius fracture.[93] Following the early 20th century there were various cases of median nerve compression underneath the transverse carpal ligament.[93] Carpal Tunnel Syndrome was most commonly noted in medical literature in the early 20th century but the first use of the term was noted 1939. Physician Dr. George S. Phalen of the Cleveland Clinic identified the pathology after working with a group of patients in the 1950s and 1960s.

# Notable cases [edit]

- HRH Prince Philip, husband of Queen Elizabeth II[94]
- Mike Dirnt, bassist with the band Green Day[95]

# Fibromyalgia

From Wikipedia, the free encyclopedia

**Fibromyalgia** (**FM**) is a medical condition characterised by chronic widespread pain and a heightened pain response to pressure.[2] Other symptoms include feeling tired to a degree that normal activities are affected, sleep problems, and troubles with memory.[3] Some people also report restless legs syndrome, bowel or bladder problems, numbness and tingling, and sensitivity to noise, lights or temperature.[4] Fibromyalgia is frequently associated with depression, anxiety, and posttraumatic stress disorder. Other types of chronic pain are also frequently present.[3]

The cause of fibromyalgia is unknown but believed to involve a combination of genetic and environmental factors with half the risk attributed to each.[3][4] The condition runs in families and many genes are believed to be involved.[5] Environmental factors may include psychological stress, trauma, and certain infections.[3] The pain appears to result from processes in the central nervous system and the condition is referred to as a "central sensitization syndrome".[2][3] Fibromyalgia is recognized as a disorder by the US National Institutes of Health and the American College of Rheumatology.[4][6] There is no specific diagnostic test.[4] Diagnosis involves first ruling out other potential causes and verifying that a set number of symptoms are present.[3][4]

The treatment of fibromyalgia can be difficult. Recommendations often include getting enough sleep, exercising regularly, and eating a healthy diet.[4] Cognitive behavioral therapy may also be helpful.[3] The medications duloxetine, milnacipran, or pregabalin may be used.[4] Use of opioid pain medication is controversial with some stating their use is poorly supported by evidence[4][7] and others saying that weak opioids may be reasonable if other medications are not effective.[8] Dietary supplements also lack evidence to support their use. While fibromyalgia can last a long time, it does not result in death or tissue damage.[4]

Fibromyalgia is estimated to affect 2–8% of the population. Females are affected about twice as often as males. Rates appear similar in different areas of the world and among different cultures. Fibromyalgia was first defined in 1990 with updated criteria in 2011.[3] There is controversy about the classification, diagnosis, and treatment of fibromyalgia.[9][10]

While some feel the diagnosis of fibromyalgia may negatively affect a person, other research finds it to be beneficial.[3] The term "fibromyalgia" is from New Latin, *fibro-*, meaning "fibrous tissues", Greek μυώ *myo-*, "muscle", and Greek ἀλγος *algos*, "pain"; thus the term literally means "muscle and fibrous connective tissue pain".[11]

## Classification [edit]

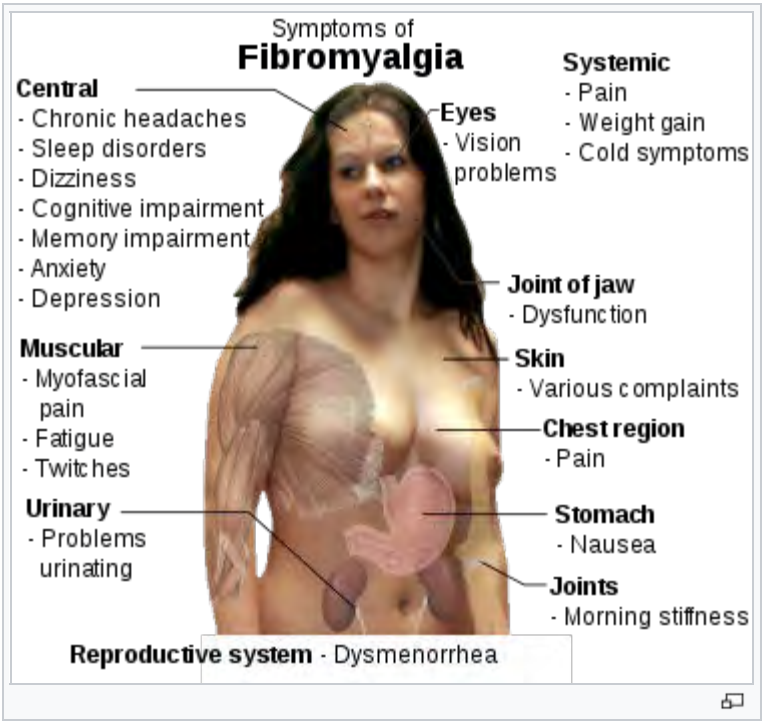
Fibromyalgia is classed as a disorder of pain processing due to abnormalities in how pain signals are processed in the central nervous system.[12] The American College of Rheumatology classify fibromyalgia as being a functional somatic syndrome.[9] The expert committee of the European League Against Rheumatism classify fibromyalgia as a neurobiological disorder and as a result exclusively give pharmacotherapy their highest level of support.[9] The International Classification of Diseases (ICD-10) lists fibromyalgia as a diagnosable disease under "Diseases of the musculoskeletal system and connective tissue," under the code

M79-7, and states that fibromyalgia syndrome should be classified as a functional somatic syndrome rather than a mental disorder. Although mental disorders and some physical disorders commonly are co-morbid with fibromyalgia – especially anxiety, depression, irritable bowel syndrome, and chronic fatigue syndrome – the ICD states that these should be diagnosed separately.[9]

Differences in psychological and autonomic nervous system profiles among affected individuals may indicate the existence of fibromyalgia subtypes. A 2007 review divides individuals with fibromyalgia into four groups as well as "mixed types":[13]

1. "extreme sensitivity to pain but no associated psychiatric conditions" (may respond to medications that block the 5-HT3 receptor)
2. "fibromyalgia and comorbid, pain-related depression" (may respond to antidepressants)
3. "depression with concomitant fibromyalgia syndrome" (may respond to antidepressants)
4. "fibromyalgia due to somatization" (may respond to psychotherapy)

## Signs and symptoms [edit]



The defining symptoms of fibromyalgia are chronic widespread pain, fatigue, sleep disturbance, and heightened pain in response to tactile pressure (allodynia).[14] Other symptoms may include tingling of the skin (paresthesias),[14] prolonged muscle spasms, weakness in the limbs, nerve pain, muscle twitching, palpitations,[15] and functional bowel disturbances.[16][17]

Many people experience cognitive dysfunction[14][18] (known as "fibrofog"), which may be characterized by impaired concentration,[19] problems with short[19][20] and long-term memory, short-term memory consolidation,[20] impaired speed of performance,[19][20] inability to multi-task, cognitive overload,[19][20] and diminished attention span. Fibromyalgia is often associated with anxiety and depressive symptoms.[20]

Other symptoms often attributed to fibromyalgia that may be due to a comorbid disorder include myofascial pain syndrome, also referred to as chronic myofascial pain, diffuse non-dermatomal paresthesias, functional bowel disturbances and irritable bowel syndrome, genitourinary symptoms and interstitial cystitis, dermatological disorders, headaches, myoclonic twitches, and symptomatic hypoglycemia. Although fibromyalgia is classified based on the presence of chronic widespread pain, pain may also be localized in areas such as the shoulders, neck, low back, hips, or other areas. Many sufferers also experience varying degrees of myofascial pain and have high rates of comorbid temporomandibular joint dysfunction. 20–30% of people with rheumatoid arthritis and systemic lupus erythematosus may also have fibromyalgia.[21]

## Cause [edit]

The cause of fibromyalgia is unknown. However, several hypotheses have been developed including "central sensitization".[14] This theory proposes that people with fibromyalgia have a lower threshold for pain because of increased reactivity of pain-sensitive nerve cells in the spinal cord or brain.[2] Neuropathic pain and major depressive disorder often co-occur with fibromyalgia – the reason for this comorbidity appears to be due to shared genetic abnormalities, which leads to impairments in monoaminergic, glutamatergic,

neurotrophic, opioid and proinflammatory cytokine signaling. In these vulnerable individuals, psychological stress or illness can cause abnormalities in inflammatory and stress pathways which regulate mood and pain. Eventually, a sensitization and kindling effect occur in certain neurons leading to the establishment of fibromyalgia and sometimes a mood disorder.[22] The evidence suggests that the pain in fibromyalgia results primarily from pain processing pathways functioning abnormally. In simple terms, it can be described as the volume of the neurons being set too high and this hyper-excitability of pain processing pathways and under-activity of inhibitory pain pathways in the brain results in the affected individual experiencing pain. Some neurochemical abnormalities that occur in fibromyalgia also regulate mood, sleep, and energy, thus explaining why mood, sleep, and fatigue problems are commonly co-morbid with fibromyalgia.[12]

## Genetics [edit]

A mode of inheritance is currently unknown, but it is most probably polygenic.[5] Research has also demonstrated that fibromyalgia is potentially associated with polymorphisms of genes in the serotoninergic,[23] dopaminergic[24] and catecholaminergic systems.[25] However, these polymorphisms are not specific for fibromyalgia and are associated with a variety of allied disorders (e.g. chronic fatigue syndrome,[26] irritable bowel syndrome[27]) and with depression.[28] Individuals with the 5-HT2A receptor 102T/C polymorphism have been found to be at increased risk of developing fibromyalgia.[29]

## Lifestyle [edit]

Stress may be an important precipitating factor in the development of fibromyalgia.[30] Fibromyalgia is frequently comorbid with stress-related disorders such as chronic fatigue syndrome, posttraumatic stress disorder, irritable bowel syndrome and depression.[31] A systematic review found significant association between fibromyalgia and physical and sexual abuse in both childhood and adulthood, although the quality of studies was poor.[32] Poor lifestyles including being a smoker, obesity and lack of physical activity may increase the risk of an individual developing fibromyalgia.[33]

Two studies that employed single-voxel magnetic resonance spectroscopy (1H-MRS) reported metabolic abnormalities within the hippocampal complex in people with fibromyalgia. As the hippocampus plays crucial roles in maintenance of cognitive functions, sleep regulation, and pain perception, it was suggested that metabolic dysfunction of the hippocampus may be implicated in the appearance of these symptoms.[34][35]

Some authors have proposed that, because exposure to stressful conditions can alter the function of the hypothalamic-pituitary-adrenal (HPA) axis, the development of fibromyalgia may stem from stress-induced disruption of the HPA axis.[36]

## Sleep disturbances [edit]

In 1975, Moldofsky and colleagues reported the presence of anomalous alpha wave activity (typically associated with arousal states) measured by electroencephalogram (EEG) during non-rapid eye movement sleep of "fibrositis syndrome".[17] By disrupting stage IV sleep consistently in young, healthy subjects, the researchers reproduced a significant increase in muscle tenderness similar to that experienced in "neurasthenic musculoskeletal pain syndrome" but which resolved when the subjects were able to resume their normal sleep patterns.[37]

## Psychological factors [edit]

There is strong evidence that major depression is associated with fibromyalgia (1999),[38] although the nature of the association is debated.[39] A comprehensive review into the relationship between fibromyalgia and major depressive disorder (MDD) found substantial similarities in neuroendocrine abnormalities, psychological characteristics, physical symptoms and treatments between fibromyalgia and MDD, but currently available findings do not support the assumption that MDD and fibromyalgia refer to the same underlying construct or can be seen as subsidiaries of one disease concept.[40] Indeed, the sensation of

pain has at least two dimensions: a sensory dimension which processes the magnitude and location of the pain, and an affective-motivational dimension which processes the unpleasantness. Accordingly, a study that employed functional magnetic resonance imaging to evaluate brain responses to experimental pain among people with fibromyalgia found that depressive symptoms were associated with the magnitude of clinically induced pain response specifically in areas of the brain that participate in affective pain processing, but not in areas involved in sensory processing which indicates that the amplification of the sensory dimension of pain in fibromyalgia occurs independently of mood or emotional processes.[41] Fibromyalgia has also been linked with bipolar disorder, particularly the hypomania component.[42]

### Non-celiac gluten sensitivity [edit]

Non-celiac gluten sensitivity (NCGS) may be an underlying cause of fibromyalgia symptoms but further research is needed.[43][44]

## Pathophysiology [edit]

The brains of people with fibromyalgia show functional and structural differences from those of people without fibromyalgia, but it is unclear whether the brain anomalies cause fibromyalgia symptoms, or are the product of an unknown underlying common cause. Some research suggests that these brain anomalies may be the result of childhood stress, or prolonged or severe stress.[31]

### Monoamines [edit]

The "dopamine hypothesis of fibromyalgia" proposes that the central abnormality responsible for symptoms associated with fibromyalgia is a disruption of normal dopamine-related neurotransmission.[45] Decreased CSF levels of dopamine were reported in 1992, which may explain the efficacy of some dopaminergic agents in fibromyalgia.[46]

Serotonin is a neurotransmitter involved in pathways that project to the dorsal horns and inhibit pain perception. In 1975, researchers hypothesized that serotonin could be involved in the pathophysiology of fibromyalgia-associated symptoms.[17] In 1992, decreased serotonin metabolites in people's blood samples[47] and cerebrospinal fluid were reported.[46]However, the relevance of dysregulated serotonin metabolism to pathophysiology is a matter of debate.[48] Complicating the analysis, one of the more effective types of medication for the treatment of the disorder (i.e. serotonin 5-HT3 antagonists) actually blocks some effects of serotonin.[49]

Decreased metabolites of norepinephrine, another monoamine involved in the descending pain inhibitory pathways, have been observed.[50]

### Poly-modal sensitivity [edit]

Results from studies examining responses to experimental stimulation suggest that people with fibromyalgia may have heightened sensitivity of the nociceptive system, which senses pressure, heat, cold, electrical and chemical stimulation.[51] Experiments examining pain regulatory systems have shown that people with fibromyalgia display an exaggerated wind-up in response to repetitive stimulation[52] and an absence of exercise-induced analgesic response.[53]

### Neuroendocrine disruption [edit]

Levels of hormones under the direct or indirect control of growth hormone (GH), including insulin-like growth factor 1 (IGF-1), cortisol, leptin and neuropeptide Y may be abnormal in people with fibromyalgia.[54] Support for a causal role for growth hormone deficiency comes from observations that such deficiency in adults has been associated with many of the symptoms described by people with fibromyalgia. Growth hormone is important in maintaining muscle homeostasis, and it has been suggested [55]

that low levels may be responsible for delayed healing of muscle microtrauma in fibromyalgia. Low (IGF-1) levels in some people with fibromyalgia have led to the theory that these people may actually have a different, treatable syndrome, adult growth hormone deficiency.[56] However, there remains some disagreement about the role of HGH in fibromyalgia.[57] It has been hypothesized that the decreased IGF-1 may be a result of slow wave sleep disruption found in fibromyalgia patients.[58]

People with fibromyalgia may have alterations of normal neuroendocrine function, characterized by mild hypocortisolemia,[59] hyperreactivity of pituitary adrenocorticotropin hormone release in response to challenge, and glucocorticoid feedback resistance.[60]

Other abnormalities include reduced responsivity of thyrotropin and thyroid hormones to thyroid-releasing hormone,[61] a mild elevation of prolactin levels with disinhibition of prolactin release in response to challenge[62] and hyposecretion of adrenal androgens.[63]

These changes might result from chronic stress, which, after being perceived and processed by the central nervous system, activates hypothalamic corticotrophin-releasing hormone neurons. Chronic overactivity of these neurons could disrupt normal function of the pituitary-adrenal axis and cause an increased stimulation of hypothalamic somatostatin secretion, which, in turn, could inhibit the secretion of other hormones.[64]

## Sympathetic hyperactivity [edit]

Functional analysis of the autonomic system in people with fibromyalgia has demonstrated disturbed activity characterized by hyperactivity of the sympathetic nervous system at baseline[65] with reduced sympathoadrenal reactivity in response to a variety of stressors including physical exertion and mental stress.[66][67] People with fibromyalgia demonstrate lower heart rate variability, an index of sympathetic/parasympathetic balance, indicating sustained sympathetic hyperactivity, especially at night.[68] In addition, plasma levels of neuropeptide Y, which is co-localized with norepinephrine in the sympathetic nervous system, have been reported as low in people with fibromyalgia,[69] while circulating levels of epinephrine and norepinephrine have been variously reported as low, normal and high.[70][71] Administration of interleukin-6, a cytokine capable of stimulating the release of hypothalamic corticotropin-releasing hormone which in turn stimulates activity within the sympathetic nervous system, results in a dramatic increase in circulating norepinephrine levels and a significantly greater increase in heart rate over baseline in people with fibromyalgia as compared to healthy controls.[72]

## Cerebrospinal fluid [edit]

One of the most reproduced laboratory finding in people with fibromyalgia is an elevation in cerebrospinal fluid levels of substance P, a putative nociceptive neurotransmitter.[73][74] However, despite increased CSF levels of substance P, drugs that manipulate this system have failed to be effective in treating fibromyalgia.[75] Metabolites for the monoamine neurotransmitters serotonin, norepinephrine, and dopamine – all of which play a role in natural analgesia – have been shown to be lower,[76] while concentrations of endogenous opioids (i.e., endorphins and enkephalins) appear to be higher.[77] The mean concentration of nerve growth factor, a substance known to participate in structural and functional plasticity of nociceptive pathways within the dorsal root ganglia and spinal cord, is elevated.[78] There is also evidence for increased excitatory amino acid release within cerebrospinal fluid, with a correlation demonstrated between levels for metabolites of glutamate and nitric oxide and clinical indices of pain.[79] Increased levels of glutamate have also been observed in the insula, a region involved in pain processing.[80]

## Brain imaging studies [edit]

Evidence of abnormal brain involvement in fibromyalgia has been provided via functional neuroimaging. The first findings reported were decreased blood flow within the thalamus and elements of the basal ganglia and mid-brain (i.e., pontine nucleus).[81][82] Differential activation in response to painful stimulation has [83][84]

also been demonstrated. Brain centers showing hyperactivation in response to noxious stimulation include such pain-related brain centers as the primary and secondary somatosensory cortices, anterior cingulate cortex, and insular cortex. People also exhibit neural activation in brain regions associated with pain perception in response to nonpainful stimuli in such areas as the prefrontal, supplemental motor, insular, and cingulate cortices.

Evidence of hippocampal disruption indicated by reduced brain metabolite ratios has been demonstrated by studies using single-voxel magnetic resonance spectroscopy (1H-MRS).[34][35] A significant negative correlation was demonstrated between abnormal metabolite ratios and a validated index of the clinical severity (i.e. the Fibromyalgia Impact Questionnaire).[85] Correlations between clinical pain severity and concentrations of the excitatory amino acid neurotransmitter glutamate within the insular cortex have also been demonstrated using 1H-MRS.[86]

An acceleration of normal age-related brain atrophy has been demonstrated using voxel-based morphometry (VBM) with areas of reduced gray matter located in the cingulate cortex, insula and parahippocampal gyrus. Grey matter loss appears to increase 9.5 times the normal rate with each year.[87] Studies utilizing positron emission tomography have demonstrated reduced dopamine synthesis in the brainstem and elements of the limbic cortex.[88]

A significant negative correlation between pain severity and dopamine synthesis was demonstrated within the insular cortex. A subsequent study demonstrated gross disruption of dopaminergic reactivity in response to a tonic pain stimulus within the basal ganglia with a significant positive correlation between the defining feature of the disorder (i.e. tender point index) and dopamine D2 receptor binding potential specifically in the right putamen.[89]

Finally, reduced availability of mu-opioid receptors in the ventral striatum/nucleus accumbens and cingulate cortex has been demonstrated, with a significant negative correlation between affective pain levels and receptor availability in the nucleus accumbens.[90]

People with FMS consistently demonstrate altered activity in the insula, amygdala, anterior/mid cingulate cortex, superior temporal gyrus, the primary and secondary somatosensory cortex, and lingual gyrus. The changes show similarities to those found in other chronic pain conditions, but it is not known whether these specific features relate to all chronic pain or just to FMS.[91]

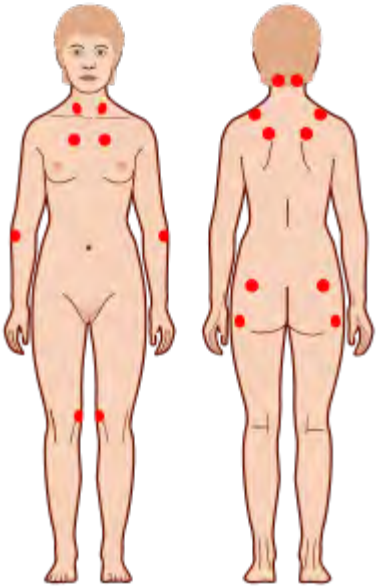
### Inflammation [edit]

Increased circulating levels of IL-1RA, IL-6, IL-8 and chemokines have been observed in patients with fibromyalgia.[92][93]

## Diagnosis [edit]

There is no single test that can fully diagnose fibromyalgia and there is debate over what should be considered essential diagnostic criteria and whether an objective diagnosis is possible. In most cases, people with fibromyalgia symptoms may also have laboratory test results that appear normal and many of their symptoms may mimic those of other rheumatic conditions such as arthritis or osteoporosis. The most widely accepted set of classification criteria for research purposes was elaborated in 1990 by the Multicenter Criteria Committee of the American College of Rheumatology. These criteria, which are known informally as "the ACR 1990", define fibromyalgia according to the presence of the following criteria:

- A history of widespread pain lasting more than three months – affecting all four quadrants of the body, i.e., both sides, and above and below the waist.
- Tender points – there are 18 designated possible tender points



The location of the nine paired tender points that comprise the 1990 American College of Rheumatology criteria for fibromyalgia.

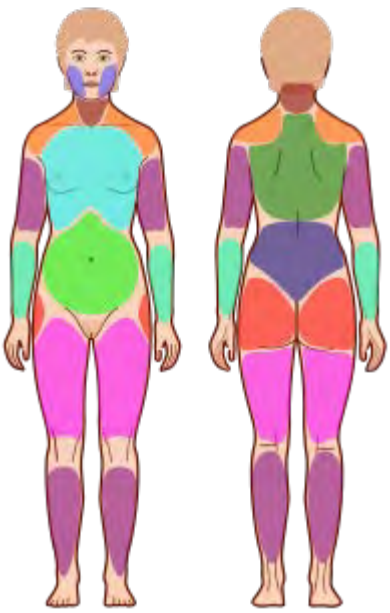
(although a person with the disorder may feel pain in other areas as well). Diagnosis is no longer based on the number of tender points.[94][95]

The ACR criteria for the classification of patients were originally established as inclusion criteria for research purposes and were not intended for clinical diagnosis but have now become the *de facto* diagnostic criteria in the clinical setting. It should be noted that the number of tender points that may be active at any one time may vary with time and circumstance. A controversial study was done by a legal team looking to prove their client's disability based primarily on tender points and their widespread presence in non-litigious communities prompted the lead author of the ACR criteria to question now the useful validity of tender points in diagnosis.[96] Use of control points has been used to cast doubt on whether a person has fibromyalgia, and to claim the person is malingering; however, no research has been done for the use of control points to diagnose fibromyalgia, and such diagnostic tests have been advised against, and people complaining of pain all over should still have fibromyalgia considered as a diagnosis.[9]

## 2010 provisional criteria [edit]

In 2010, the American College of Rheumatology approved provisional revised diagnostic criteria for fibromyalgia that eliminated the 1990 criteria's reliance on tender point testing.[97] The revised criteria use a widespread pain index (WPI) and symptom severity scale (SS) in place of tender point testing under the 1990 criteria. The WPI counts up to 19 general body areas[a] in which the person has experienced pain in the preceding two weeks. The SS rates the severity of the person's fatigue, unrefreshed waking, cognitive symptoms, and general somatic symptoms,[b] each on a scale from 0 to 3, for a composite score ranging from 0 to 12. The revised criteria for diagnosis are:

- WPI ≥ 7 and SS ≥ 5 *OR* WPI 3–6 and SS ≥ 9,
- Symptoms have been present at a similar level for at least three months, *and*
- No other diagnosable disorder otherwise explains the pain.[97]:607



Widespread Pain Index (WPI) Areas

## Differential diagnosis [edit]

Two patients initially diagnosed with fibromyalgia were subsequently shown to have myotonia congenita.[98] Both patients had been seen by rheumatologists and diagnosed with fibromyalgia. The diagnoses were revised when electromyographic studies revealed myotonic discharges in

some of the muscles. Genetic analysis of the skeletal muscle chloride channel which is the underlying cause of myotonia congenita revealed that both patients had mutations in this gene. Over 130 mutations in this gene have been described and the phenotype is very variable which may account for the difficulty in the initial diagnosis.[99][100]

## Management [edit]

As with many other medically unexplained syndromes, there is no universally accepted treatment or cure for fibromyalgia, and treatment typically consists of symptom management. Developments in the understanding of the pathophysiology of the disorder have led to improvements in treatment, which include prescription medication, behavioral intervention, and exercise. Indeed, integrated treatment plans that incorporate medication, patient education, aerobic exercise and cognitive behavioral therapy have been shown to be effective in alleviating pain and other fibromyalgia-related symptoms.[101]

The Association of the Scientific Medical Societies in Germany,[102] the European League Against Rheumatism[103] and the Canadian Pain Society[104] currently publish guidelines for the diagnosis and management of FMS.

### Medications [edit]

Health Canada and the US Food and Drug Administration (FDA) have approved pregabalin[105] and duloxetine, for the management of fibromyalgia. The FDA also approved milnacipran, but the European Medicines Agency refused marketing authority.[106]

### Antidepressants [edit]

Antidepressants are "associated with improvements in pain, depression, fatigue, sleep disturbances, and health-related quality of life in people with FMS."[107] The goal of antidepressants should be symptom reduction and if used long term, their effects should be evaluated against side effects. A small number of people benefit significantly from the SNRIs duloxetine and milnacipran and the tricyclic antidepressants (TCAs), such as amitriptyline. However many people experience more adverse effects than benefits.[108][109] While amitriptyline has been used as a first line treatment, the quality of evidence to support this use is poor.[110]

It can take up to three months to derive benefit from the antidepressant amitriptyline and up to six months to gain the maximal response from duloxetine, milnacipran, and pregabalin. Some medications have the potential to cause withdrawal symptoms when stopping so gradual discontinuation may be warranted particularly for antidepressants and pregabalin.[9]

SSRIs and (TCAs) have more favorable response rates and fewer side effects compared to Pregabalin and the SNRIs Duloxetine and Milnacipram, making them the most effective agents for treating fibromyalgia.[111]

### Anti-seizure medication [edit]

The anti-convulsant drugs gabapentin[112] and pregabalin can be used to reduce pain.[113] Gabapentin is of a significant benefit in about 30% of people who take it. However, it is commonly associated with adverse effects.[112] Pregabalin demonstrates a substantial benefit in about 9% of people.[114] Pregabalin reduced time off work by 0.2 days per week.[115]

### Opioids [edit]

The use of opioids is controversial. As of 2015, no opioid is approved for use in this condition by the FDA.[116] The National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS) in 2014 stated that there was a lack of evidence for opioids.[4] The Association of the Scientific Medical Societies in

Germany in 2012 made no recommendation either for or against the use of weak opioids because of the limited amount of scientific research addressing their use in the treatment of FM. They strongly advise against using strong opioids.[102] The Canadian Pain Society in 2012 said that opioids, starting with a weak opioid like tramadol, can be tried but only for people with moderate to severe pain that is not well-controlled by non-opioid painkillers. They discourage the use of strong opioids and only recommend using them while they continue to provide improved pain and functioning. Healthcare providers should monitor people on opioids for ongoing effectiveness, side effects and possible unwanted drug behaviors.[104]

The European League Against Rheumatism in 2008 recommends tramadol and other weak opioids may be used for pain but not strong opioids.[103] A 2015 review found fair evidence to support tramadol use if other medications do not work.[116] Goldenberg *et al* suggest that tramadol works via its serotonin and norepinephrine reuptake inhibition, rather than via its action as a weak opioid receptor agonist.[7] The combination of tramadol and paracetemol has demonstrated efficacy, safety and tolerability (for up to two years in the management of other pain conditions) without the development of tolerance. It is as effective as a combination of codeine (another mild opioid) and paracetamol but produces less sleepiness and constipation.[117]

A large study of US people with fibromyalgia found that between 2005 and 2007 37.4% were prescribed short-acting opioids and 8.3% were prescribed long-acting opioids,[118] with around 10% of those prescribed short-acting opioids using tramadol;[119] and a 2011 Canadian study of 457 people with FM found 32% used opioids and two thirds of those used strong opioids.[104]

## Others [edit]

A 2007 review of three randomized placebo controlled studies concluded that a period of nine months of growth hormone was required to reduce fibromyalgia symptoms and normalize IGF-1.[120] A 2014 also found some evidence support its use.[121] Sodium oxybate increases growth hormone production levels through increased slow-wave sleep patterns. However, this medication was not approved by the FDA for the indication for use in people with fibromyalgia due to the concern for abuse.[122]

The muscle relaxants cyclobenzaprine and tizanidine are sometimes used to treat fibromyalgia; however as of 2015 they are not approved for this use in the United States.[123] The use of NSAIDs is not recommended as first line therapy.[124]

Dopamine agonists (e.g. pramipexole and ropinirole) resulted in some improvement in a minority of people,[125] but numerous side effects, including the onset of impulse control disorders like compulsive gambling and shopping, have led to concern about this approach.[126]

There is some evidence that $5HT_3$ antagonists may be beneficial.[127] Preliminary clinical data finds that low-dose naltrexone (LDN) may provide symptomatic improvement.[128]

## Therapy [edit]

Due to the uncertainty about the pathogenesis of FM, current treatment approaches focus on management of symptoms to improve quality of life,[129] using integrated pharmacological and non-pharmacological approaches.[130] There is no single intervention shown to be effective for all patients [131] and no gold treatment standard exists for FM.[132] Multimodal/multidisciplinary therapy is recommended to target multiple underlying factors of FM.[133] A meta-analysis of 1,119 subjects found "strong evidence that multicomponent treatment has beneficial short-term effects on key symptoms of FMS." [134]

## Cognitive behavioural therapy [edit]

Non-pharmacological components include cognitive-behavioural therapy (CBT), exercise and psychoeducation (specifically, sleep hygiene).[135][136][137][138] CBT and related psychological and behavioural therapies have a small to moderate effect in reducing symptoms of fibromyalgia.[139][140] Effect

sizes tend to be small when CBT is used as a stand-alone treatment for FM patients, but these improve significantly when CBT is part of a wider multidisciplinary treatment program.[141] The greatest benefit occurs when CBT is used along with exercise.[101][142]

A 2010 systematic review of 14 studies reported that CBT improves self-efficacy or coping with pain and reduces the number of physician visits at post-treatment, but has no significant effect on pain, fatigue, sleep or health-related quality of life at post-treatment or follow-up. Depressed mood was also improved but this could not be distinguished from some risks of bias.[143]

### Exercise [edit]

Exercise improves fitness and sleep and may reduce pain and fatigue in some people with fibromyalgia.[144][145] In particular, there is strong evidence that cardiovascular exercise is effective for some people.[146] Long-term aquatic-based exercise has been proven beneficial as it combines cardiovascular exercise with resistance training.[147]

In children, fibromyalgia is often treated with an intense physical and occupational therapy program for amplified musculoskeletal pain syndromes. These programs also employ counseling, art therapy, and music therapy. These programs are evidence-based and report long-term total pain resolution rates as high as 88%.[148]

## Prognosis [edit]

Although in itself neither degenerative nor fatal, the chronic pain of fibromyalgia is pervasive and persistent. Most people with fibromyalgia report that their symptoms do not improve over time. An evaluation of 332 consecutive new people with fibromyalgia found that disease-related factors such as pain and psychological factors such as work status, helplessness, education, and coping ability had an independent and significant relationship to FM symptom severity and function.[149]

## Epidemiology [edit]

Fibromyalgia is estimated to affect 2–8% of the population,[3][150] with a female to male incidence ratio that is somewhere between 7:1 and 9:1.[14][151]

Fibromyalgia may not be diagnosed in up to 75% of affected people.[12]

## History [edit]

Chronic widespread pain had already been described in the literature in the 19th century but the term fibromyalgia was not used until 1976 when Dr P.K. Hench used it to describe these symptoms.[9] Many names, including "muscular rheumatism", "fibrositis", "psychogenic rheumatism", and "neurasthenia" were applied historically to symptoms resembling those of fibromyalgia.[152] The term *fibromyalgia* was coined by researcher Mohammed Yunus as a synonym for fibrositis and was first used in a scientific publication in 1981.[153] Fibromyalgia is from the Latin *fibra* (fiber)[154] and the Greek words *myo* (muscle)[155] and *algos* (pain).[156]

Historical perspectives on the development of the fibromyalgia concept note the "central importance" of a 1977 paper by Smythe and Moldofsky on fibrositis.[157][158] The first clinical, controlled study of the characteristics of fibromyalgia syndrome was published in 1981,[159] providing support for symptom associations. In 1984, an interconnection between fibromyalgia syndrome and other similar conditions was proposed,[160] and in 1986, trials of the first proposed medications for fibromyalgia were published.[160]

A 1987 article in the *Journal of the American Medical Association* used the term "fibromyalgia syndrome"[161]

while saying it was a "controversial condition". The American College of Rheumatology (ACR) published its first classification criteria for fibromyalgia in 1990,[162] although these are not strictly diagnostic criteria.[13]

## Economics [edit]

People with fibromyalgia generally have higher health care costs and utilization rates. A study of almost 20,000 Humana members enrolled in Medicare Advantage and commercial plans compared costs and medical utilizations and found that people with fibromyalgia used twice as much pain-related medication as those without fibromyalgia. Furthermore, the use of medications and medical necessities increased markedly across many measures once diagnosis was made.[163]

## Controversies [edit]

Being a disorder defined relatively recently and still not completely understood, fibromyalgia continues to be a diagnosis that sometimes is disputed. Dr. Frederick Wolfe, lead author of the 1990 paper that first defined the diagnostic guidelines for fibromyalgia, stated in 2008, that he believed it "clearly" not to be a disease but instead a physical response to depression and stress,[164] and in 2013 that its causes "are controversial in a sense" and "there are many factors that produce these symptoms – some are psychological and some are physical and it does exist on a continuum".[165]

Some members of the medical community do not consider fibromyalgia a disease because of a lack of abnormalities on physical examination and the absence of objective diagnostic tests.[157][166] Yunus objects to the psychological characterization of FM. He argues that data indicating it is not psychological has been ignored or manipulated.[167]

Neurologists and pain specialists tend to view fibromyalgia as a pathology due to dysfunction of muscles and connective tissue as well as functional abnormalities in the central nervous system. Rheumatologists define the syndrome in the context of "central sensitization" – heightened brain response to normal stimuli in the absence of disorders of the muscles, joints, or connective tissues. On the other hand, psychiatrists often view fibromyalgia as a type of affective disorder, whereas specialists in psychosomatic medicine tend to view fibromyalgia as being a somatic symptom disorder. However, there is extensive research evidence to support the view that the central symptom of fibromyalgia, namely pain, has a neurogenic origin. These controversies don't engage healthcare specialists alone; some patients object to fibromyalgia being described in purely somatic terms.[9][12]

The validity of fibromyalgia as a unique clinical entity is a matter of contention because "no discrete boundary separates syndromes such as FMS, chronic fatigue syndrome, irritable bowel syndrome, or chronic muscular headaches".[146][168] Because of this symptomatic overlap, some researchers have proposed that fibromyalgia and other analogous syndromes be classified together as functional somatic syndromes for some purposes.[169]

# Research [edit]

Investigational medications include cannabinoids and the 5-HT3 receptor antagonist tropisetron.[170] Low quality evidence found an improvement in symptoms with a gluten free diet among those without celiac disease.[171] A controlled study of guaifenesin failed to demonstrate any benefits from this treatment.[172][173]

# Gout

From Wikipedia, the free encyclopedia

*"Podagra" redirects here. For the moth genus, see Podagra (moth).*

**Gout** is a form of inflammatory arthritis characterized by recurrent attacks of a red, tender, hot, and swollen joint.[3] Pain typically comes on rapidly in less than twelve hours.[5] The joint at the base of the big toe is affected in about half of cases.[6] It may also result in tophi, kidney stones, or urate nephropathy.[5]

Gout is due to elevated levels of uric acid in the blood. This occurs due to a combination of diet and genetic factors. At high levels, uric acid crystallizes and the crystals deposit in joints, tendons and surrounding tissues, resulting in an attack of gout. Gout occurs more commonly in those who eat a lot of meat, drink a lot of beer, or are overweight. Diagnosis of gout may be confirmed by seeing the crystals in joint fluid or tophus. Blood uric acid levels may be normal during an attack.[5]

Treatment with nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, or colchicine improves symptoms. Once the acute attack subsides, levels of uric acid can be lowered via lifestyle changes and in those with frequent attacks, allopurinol or probenecid provides long-term prevention.[5] Taking vitamin C and eating a diet high in low fat dairy products may be preventive.[7]

Gout affects about 1 to 2% of the Western population at some point in their lives. It has become more common in recent decades. This is believed to be due to increasing risk factors in the population, such as metabolic syndrome, longer life expectancy and changes in diet. Older males are most commonly affected.[5] Gout was historically known as "the disease of kings" or "rich man's disease".[5][8] It has been recognized at least since the time of the ancient Egyptians.[5]

## Signs and symptoms

Gout can present in multiple ways, although the most usual is a recurrent attack of acute inflammatory arthritis (a red, tender, hot, swollen joint).[3] The metatarsal-phalangeal joint at the base of the big toe is affected most often, accounting for half of cases.[6] Other joints, such as the heels, knees, wrists and fingers, may also be affected.[6] Joint pain usually begins over 2–4 hours and during the night.[6] This is mainly due to lower body temperature.[9] Other symptoms may rarely occur along with the joint pain, including fatigue and a high fever.[6][9]

Gout presenting in the metatarsal-phalangeal joint of the big toe: Note the slight redness of the skin overlying the joint.

Long-standing elevated uric acid levels (hyperuricemia) may result in other symptoms, including hard, painless deposits of uric acid crystals known as tophi. Extensive tophi may lead to chronic arthritis due to bone erosion.[10] Elevated levels of uric acid may also lead to crystals precipitating in the kidneys, resulting in stone formation and subsequent urate nephropathy.[11]

## Cause

The crystallization of uric acid, often related to relatively high levels in the blood, is the underlying cause of gout. This can occur because of diet, genetic predisposition, or underexcretion of urate, the salts of uric acid.[3] Underexcretion of uric acid by the kidney is the primary cause of hyperuricemia in about 90% of cases, while overproduction is the cause in less than 10%.[5] About 10% of people with hyperuricemia develop gout at some point in their lifetimes.[12] The risk, however, varies depending on the degree of hyperuricemia. When levels are between 415 and 530 μmol/l (7 and 8.9 mg/dl), the risk is 0.5% per year, while in those with a level greater than 535 μmol/l (9 mg/dL), the risk is 4.5% per year.[9]

### Lifestyle

Dietary causes account for about 12% of gout,[3] and include a strong association with the consumption of alcohol, fructose-sweetened drinks, meat, and seafood.[10][13] Other triggers include physical trauma and surgery.[5]

Studies in the early 2000s found that other dietary factors are not relevant.[13][14] Specifically, moderate consumption of purine-rich vegetables (e.g., beans, peas, lentils and spinach) are not associated with gout.[15] Neither is total consumption of protein.[14][15] Alcohol consumption is strongly associated with an increased risk, with wine presenting somewhat less of a risk than beer and spirits.[15][16]

The consumption of coffee, vitamin C and dairy products, as well as physical fitness, appear to decrease the risk.[17][18][19][20] This is believed to be partly due to their effect in reducing insulin resistance.[19]

### Genetics

Gout is partly genetic, contributing to about 60% of variability in uric acid level.[5] The *SLC2A9*, *SLC22A12* and *ABCG2* genes have been found to be commonly associated with gout and variations in them can approximately double the risk.[21][22] Loss-of-function mutations in *SLC2A9* and *SLC22A12* cause hereditary hypouricaemia by reducing urate absorption and unopposed urate secretion.[22] The rare genetic disorders familial juvenile hyperuricemic nephropathy, medullary cystic kidney disease, phosphoribosylpyrophosphate synthetase superactivity and hypoxanthine-guanine phosphoribosyltransferase deficiency as seen in Lesch-Nyhan syndrome, are complicated by gout.[5]

### Medical conditions

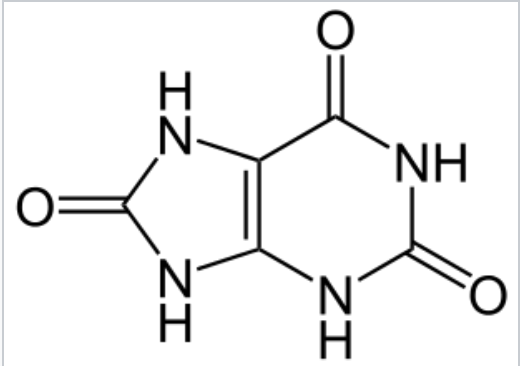
Gout frequently occurs in combination with other medical problems. Metabolic syndrome, a combination of abdominal obesity, hypertension, insulin resistance and abnormal lipid levels, occurs in nearly 75% of cases.[6] Other conditions commonly complicated by gout include polycythemia, lead poisoning, kidney failure, hemolytic anemia, psoriasis and solid organ transplants.[5][23] A body mass index greater than or equal to 35 increases male risk of gout threefold.[13] Chronic lead exposure and lead-contaminated alcohol are risk factors for gout due to the harmful effect of lead on kidney function.[24] Lesch-Nyhan syndrome is often associated with gouty arthritis.

### Medication

Diuretics have been associated with attacks of gout. However, a low dose of hydrochlorothiazide does not seem to increase risk.[25] Other medications that increase the risk include niacin, aspirin (acetylsalicylic acid), ACE inhibitors, angiotensin receptor blockers (except losartan), beta blockers, ritonavir, and pyrazinamide.[10][26] The immunosuppressive drugs ciclosporin and tacrolimus are also associated with gout,[5] the former more so when used in combination with hydrochlorothiazide.[27]

## Pathophysiology

Gout is a disorder of purine metabolism,[5] and occurs when its final metabolite, uric acid, crystallizes in the form of monosodium urate, precipitating and forming deposits (tophi) in joints, on tendons and in the surrounding tissues.[10] Microscopic tophi may be walled off by a ring of proteins, which blocks interaction of the crystals with cells and therefore avoids inflammation.[28] Naked crystals may break out of walled-off tophi due to minor physical damage to the joint, medical or surgical stress, or rapid changes in uric acid levels.[28] When they break through the tophi, they trigger a local immune-mediated inflammatory reaction in macrophages, which is initiated by the NLRP3 inflammasome protein complex.[10][26][28] Activation of the NLRP3 inflammasome recruits the enzyme caspase 1, which converts pro-interleukin 1β into active interleukin 1β, one of the key proteins in the inflammatory cascade.[26] An evolutionary loss of urate oxidase (uricase), which breaks down uric acid, in humans and higher primates has made this condition common.[5]



Chemical structure of uric acid

The triggers for precipitation of uric acid are not well understood. While it may crystallize at normal levels, it is more likely to do so as levels increase.[10][29] Other triggers believed to be important in acute episodes of arthritis include cool temperatures, rapid changes in uric acid levels, acidosis,[30][31] articular hydration and extracellular matrix proteins, such as proteoglycans, collagens and chondroitin sulfate.[5] The increased precipitation at low temperatures partly explains why the joints in the feet are most commonly affected.[3] Rapid changes in uric acid may occur due to factors including trauma, surgery, chemotherapy, diuretics and stopping or starting allopurinol.[9] Calcium channel blockers and losartan are associated with a lower risk of gout compared to other medications for hypertension.[32]

## Diagnosis

Gout may be diagnosed and treated without further investigations in someone with hyperuricemia and the classic acute arthritis of the base of the great toe (known as podagra). Synovial fluid analysis should be done, however, if the diagnosis is in doubt.[9] X-rays, while useful for identifying chronic gout, have little utility in acute attacks.[5]

Gout on X-rays of a left foot. The typical location is the big toe joint. Note also the soft tissue swelling at the lateral border of the foot.

### Synovial fluid

A definitive diagnosis of gout is based upon the identification of monosodium urate crystals in synovial fluid or a tophus.[6] All synovial fluid samples obtained from undiagnosed inflamed joints by arthrocentesis should be examined for these crystals.[5] Under polarized light microscopy, they have a needle-like morphology and strong negative birefringence. This test is difficult to perform and requires a trained observer.[33] The fluid must be examined relatively soon after aspiration, as temperature and pH affect solubility.[5]

### Blood tests

Hyperuricemia is a classic feature of gout, but it occurs nearly half of the time without hyperuricemia and most people with raised uric acid levels never develop gout.[6][34] Thus, the diagnostic utility of measuring uric acid levels is limited.[6] Hyperuricemia is defined as a plasma urate level greater than 420 μmol/l (7.0 mg/dl) in males and 360 μmol/l (6.0 mg/dl) in females.[35] Other blood tests commonly performed are white blood cell count, electrolytes, kidney function and erythrocyte sedimentation rate (ESR). However, both the white blood cells and ESR may be elevated due to gout in the absence of infection.[36][37] A white blood cell count as high as $40.0\times10^9$/l (40,000/mm$^3$) has been documented.[9]

### Differential diagnosis

The most important differential diagnosis in gout is septic arthritis.[5][6] This should be considered in those with signs of infection or those who do not improve with treatment.[6] To help with diagnosis, a synovial fluid Gram stain and culture may be performed.[6] Other conditions that can look similar include pseudogout, rheumatoid arthritis, psoriatic arthritis, and reactive arthritis.[6][26] Gouty tophi, in particular when not located in a joint, can be mistaken for basal cell carcinoma[38]

or other neoplasms.[39]

## Prevention

Both lifestyle changes and medications can decrease uric acid levels. Dietary and lifestyle choices that are effective include reducing intake of purine-rich foods of animal origin such as meat and seafood, alcohol, and fructose (especially high fructose corn syrup).[40] Eating dairy products, vitamin C, coffee, and cherries may help prevent gout attacks, as does losing weight.[40][41] Gout may be secondary to sleep apnea via the release of purines from oxygen-starved cells. Treatment of apnea can lessen the occurrence of attacks.[42]

## Treatment

The initial aim of treatment is to settle the symptoms of an acute attack.[43] Repeated attacks can be prevented by medications that reduce serum uric acid levels.[43] Tentative evidence supports the application of ice for 20 to 30 minutes several times a day to decrease pain.[44] Options for acute treatment include nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine and steroids,[3] while options for prevention include allopurinol, febuxostat, and probenecid. Lowering uric acid levels can cure the disease.[5] Treatment of associated health problems is also important.[5] Lifestyle interventions have been poorly studied.[44] It is unclear whether dietary supplements have an effect in people with gout.[45]

### NSAIDs

NSAIDs are the usual first-line treatment for gout. No specific agent is significantly more or less effective than any other.[3] Improvement may be seen within four hours and treatment is recommended for one to two weeks.[3][5] They are not recommended, however, in those with certain other health problems, such as gastrointestinal bleeding, kidney failure, or heart failure.[46] While indometacin has historically been the most commonly used NSAID, an alternative, such as ibuprofen, may be preferred due to its better side effect profile in the absence of superior effectiveness.[25] For those at risk of gastric side effects from NSAIDs, an additional proton pump inhibitor may be given.[47] There is some evidence that COX-2 inhibitors may work as well as nonselective NSAIDs for acute gout attack with fewer side effects.[48][49]

### Colchicine

Colchicine is an alternative for those unable to tolerate NSAIDs.[3] At high doses, side effects (primarily gastrointestinal upset) limit its usage.[50] At lower doses, which are still effective, it is well tolerated.[25][51] Colchicine may interact with other commonly prescribed drugs, such as atorvastatin and erythromycin, among others.[50]

### Steroids

Glucocorticoids have been found to be as effective as NSAIDs[52][53] and may be used if contraindications exist for NSAIDs. They also lead to improvement when injected into the joint. A joint infection must be excluded, however, as steroids worsen this condition.[3]

### Pegloticase

Pegloticase was approved in the USA to treat gout in 2010.[54] It is an option for the 3% of people who are intolerant to other medications.[54] Pegloticase is administered as an intravenous infusion every two weeks,[54] and reduces uric acid levels.[55] It is likely useful for tophi but has a high rate of side effects.[56]

### Prophylaxis

A number of medications are useful for preventing further episodes of gout, including xanthine oxidase inhibitors (including

allopurinol and febuxostat) and uricosurics (including probenecid and sulfinpyrazone). They are not usually started until one to two weeks after an acute flare has resolved, due to theoretical concerns of worsening the attack.[3] They are often used in combination with either an NSAID or colchicine for the first three to six months.[5] They are not recommended until a person has had two attacks of gout,[3] unless destructive joint changes, tophi, or urate nephropathy exist,[11] because the medications have not been found to be cost-effective.[3] Urate-lowering measures should be increased until serum uric acid levels are below 300–360 µmol/l (5.0–6.0 mg/dl) and continue indefinitely.[3][5][57] If these medications are in chronic use at the time of an attack, discontinuation is recommended.[6] Levels that cannot be brought below 6.0 mg/dl while attacks continue indicates treatment failure or refractory gout.[58] Overall, probenecid appears to be less effective than allopurinol.[3]

Uricosuric medications are typically preferred if undersecretion of uric acid, as indicated by a 24-hour collection of urine results in a uric acid amount of less than 800 mg, is found.[59] They are, however, not recommended if a person has a history of kidney stones.[59] A 24-hour urine excretion of more than 800 mg, which indicates overproduction, is an indication for a xanthine oxidase inhibitor.[59]

Xanthine oxidase inhibitors block uric acid production. Long-term therapy is safe and well tolerated and can be used in people with decreased kidney function or urate stones, although allopurinol has caused hypersensitivity in a small number of individuals.[3] In such cases febuxostat is recommended.[60]

## Prognosis

Without treatment, an acute attack of gout usually resolves in five to seven days; however, 60% of people have a second attack within one year.[9] Those with gout are at increased risk of hypertension, diabetes mellitus, metabolic syndrome and kidney and cardiovascular disease and thus are at increased risk of death.[5][61] This may be partly due to its association with insulin resistance and obesity, but some of the increased risk appears to be independent.[61]

Without treatment, episodes of acute gout may develop into chronic gout with destruction of joint surfaces, joint deformity and painless tophi.[5] These tophi occur in 30% of those who are untreated for five years, often in the helix of the ear, over the olecranon processes, or on the Achilles tendons.[5] With aggressive treatment, they may dissolve. Kidney stones also frequently complicate gout, affecting between 10 and 40% of people and occur due to low urine pH promoting the precipitation of uric acid.[5] Other forms of chronic kidney dysfunction may occur.[5]

## Epidemiology

Gout affects around 1–2% of the Western population at some point in their lifetimes and is becoming more common.[3][5] Some 5.8 million people were affected in 2013.[62] Rates of gout approximately doubled between 1990 and 2010.[10] This rise is believed to be due to increasing life expectancy, changes in diet and an increase in diseases associated with gout, such as metabolic syndrome and high blood pressure.[13] Factors that influence rates of gout, include age, race and the season of the year. In men over 30 and women over 50, rates are 2%.[46]

In the United States, gout is twice as likely in males of African descent than those of European descent.[63] Rates are high among Pacific Islanders and the Māori, but rare in aboriginal Australians, despite a higher mean uric acid serum concentration in the latter group.[64] It has become common in China, Polynesia and urban sub-Saharan Africa.[5] Some studies found that attacks of gout occur more frequently in the spring. This has been attributed to seasonal changes in diet, alcohol consumption, physical activity and temperature.[65]

## History

The term "gout" was initially used by Randolphus of Bocking, around 1200 AD. It is [66]

derived from the Latin word *gutta*, meaning "a drop" (of liquid). According to the Oxford English Dictionary, this is derived from humorism and "the notion of the 'dropping' of a morbid material from the blood in and around the joints".[67]

Gout has been known since antiquity. Historically, it was referred to as "the king of diseases and the disease of kings"[5][68] or "rich man's disease".[8] The first documentation of the disease is from Egypt in 2,600 BC in a description of arthritis of the big toe. Greek physician Hippocrates around 400 BC commented on it in his *Aphorisms*, noting its absence in eunuchs and premenopausal women.[66][69] Aulus Cornelius Celsus (30 AD) described the linkage with alcohol, later onset in women and associated kidney problems:

> Again thick urine, the sediment from which is white, indicates that pain and disease are to be apprehended in the region of joints or viscera... Joint troubles in the hands and feet are very frequent and persistent, such as occur in cases of podagra and cheiragra. These seldom attack eunuchs or boys before coition with a woman, or women except those in whom the menses have become suppressed... some have obtained lifelong security by refraining from wine, mead and venery.[70]

In 1683, Thomas Sydenham, an English physician, described its occurrence in the early hours of the morning and its predilection for older males:

> Gouty patients are, generally, either old men or men who have so worn themselves out in youth as to have brought on a premature old age—of such dissolute habits none being more common than the premature and excessive indulgence in venery and the like exhausting passions. The victim goes to bed and sleeps in good health. About two o'clock in the morning he is awakened by a severe pain in the great toe; more rarely in the heel, ankle or instep. The pain is like that of a dislocation and yet parts feel as if cold water were poured over them. Then follows chills and shivers and a little fever... The night is passed in torture, sleeplessness, turning the part affected and perpetual change of posture; the tossing about of body being as incessant as the pain of the tortured joint and being worse as the fit comes on.[71]

Antonie van Leeuwenhoek described the microscopic appearance of uric acid crystals in 1679.[66]

Dutch scientist Antonie van Leeuwenhoek first described the microscopic appearance of urate crystals in 1679.[66] In 1848, English physician Alfred Baring Garrod identified excess uric acid in the blood as the cause of gout.[72]

## Other animals

Gout is rare in most other animals due to their ability to produce uricase, which breaks down uric acid.[73] Humans and other great apes do not have this ability, thus gout is common.[9][73] Other animals with uricase include fish, amphibians and most non primate mammals.[74] The *Tyrannosaurus rex* specimen known as "Sue", however, is believed to have suffered from gout.[75]

## Research

A number of new medications are under study for treating gout, including anakinra, canakinumab and rilonacept.[76] Canakinumab may result in better outcomes than a low dose of a steroid but costs five thousand times more.[77] A recombinant uricase enzyme (rasburicase) is available; its use, however, is limited, as it triggers an immune response. Less antigenic versions are in development.[9]

# Low back pain

From Wikipedia, the free encyclopedia

**Low back pain** (**LBP**) is a common disorder involving the muscles, nerves, and bones of the back.[1] Pain can vary from a dull constant ache to a sudden sharp feeling.[1] Low back pain may be classified by duration as acute (pain lasting less than 6 weeks), sub-chronic (6 to 12 weeks), or chronic (more than 12 weeks).[2] The condition may be further classified by the underlying cause as either mechanical, non-mechanical, or referred pain.[3] The symptoms of low back pain usually improve within a few weeks from the time they start, with 40-90% of people completely better by six weeks.[4]

In most episodes of low back pain, a specific underlying cause is not identified or even looked for, with the pain believed to be due to mechanical problems such as muscle or joint strain.[1][5] If the pain does not go away with conservative treatment or if it is accompanied by "red flags" such as unexplained weight loss, fever, or significant problems with feeling or movement, further testing may be needed to look for a serious underlying problem.[3] In most cases, imaging tools such as X-ray computed tomography are not useful and carry their own risks.[6][7] Despite this, the use of imaging in low back pain has increased.[8] Some low back pain is caused by damaged intervertebral discs, and the straight leg raise test is useful to identify this cause.[3] In those with chronic pain, the pain processing system may malfunction, causing large amounts of pain in response to non-serious events.[9]

The treatment of acute nonspecific low back pain of rapid onset is typically with simple pain medications and the continuation of as much normal activity as the pain allows.[4] Medications are recommended for the duration that they are helpful, with paracetamol (also known as acetaminophen) as the preferred first medication.[10] A number of other options are available for those who do not improve with usual treatment. Opioids may be useful if simple pain medications are not enough, but they are not generally recommended due to side effects.[1][10] Surgery may be beneficial for those with disc-related chronic pain and disability or spinal stenosis.[11][12] No clear benefit has been found for other cases of non-specific low back pain.[11] Low back pain often affects mood, which may be improved by counseling or antidepressants.[10][13] Additionally, there are many alternative medicine therapies, including the Alexander technique and herbal remedies, but there is not enough evidence to recommend them confidently.[14] The evidence for chiropractic care[15] and spinal manipulation is mixed.[14][16][17][18]

Approximately 9 to 12% of people (632 million) have LBP at any given point in time, and nearly 25% report having it at some point over any one-month period.[19][20] About 40% of people have LBP at some point in their lives,[19] with estimates as high as 80% among people in the developed world.[21] Difficulty most often begins between 20 and 40 years of age.[5] Men and women are equally affected.[1] Low back pain is more common among people aged 40–80 years, with the overall number of individuals affected expected to increase as the population ages.[19]

## Signs and symptoms [edit]

In the common presentation of acute low back pain, pain develops after movements that involve lifting, twisting, or forward-bending. The symptoms may start soon after the movements or upon waking up the following morning. The description of the symptoms may range from tenderness at a particular point to diffuse pain. It may or may not worsen with certain movements, such as raising a leg, or positions, such as sitting or standing. Pain radiating down the legs (known as sciatica) may be present. The first experience of acute low back pain is typically between the ages of 20 and 40. This is often a person's first reason to see a medical professional as an adult.[5] Recurrent episodes occur in more than half of people[22] with the repeated episodes being generally more painful than the first.[5]

Other problems may occur along with low back pain. Chronic low back pain is associated with sleep problems, including a greater amount of time needed to fall asleep, disturbances during sleep, a shorter duration of sleep, and less satisfaction with sleep.[23] In addition, a majority of those with chronic low back pain show symptoms of depression[10] or anxiety.[14]

## Causes [edit]

Low back pain is not a specific disease but rather a complaint that may be caused by a large number of underlying problems of varying levels of seriousness.[24] The majority of LBP does not have a clear cause[5] but is believed to be the result of non-serious muscle or skeletal issues such

A herniated disc as seen on MRI, one possible cause of low back pain

as sprains or strains.[25] Obesity, smoking, weight gain during pregnancy, stress, poor physical condition, poor posture and poor sleeping position may also contribute to low back pain.[25] A full list of possible causes includes many less common conditions.[3] Physical causes may include osteoarthritis, degeneration of the discs between the vertebrae or a spinal disc herniation, broken vertebra(e) (such as from osteoporosis) or, rarely, an infection or tumor of the spine.[26]

Women may have acute low back pain from medical conditions affecting the female reproductive system, including endometriosis, ovarian cysts, ovarian cancer, or uterine fibroids.[27] Nearly half of all pregnant women report pain in the lower back or sacral area during pregnancy, due to changes in their posture and center of gravity causing muscle and ligament strain.[28]

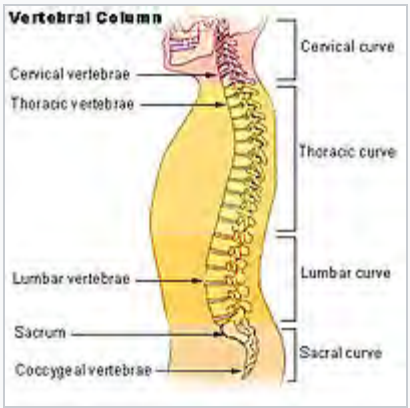
Low back pain can be broadly classified into four main categories:

- Musculoskeletal - mechanical (including muscle strain, muscle spasm, or osteoarthritis); herniated nucleus pulposus, herniated disk; spinal stenosis; or compression fracture
- Inflammatory - HLA-B27 associated arthritis including ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and inflammatory bowel disease
- Malignancy - bone metastasis from lung, breast, prostate, thyroid, among others
- Infectious - osteomyelitis; abscess

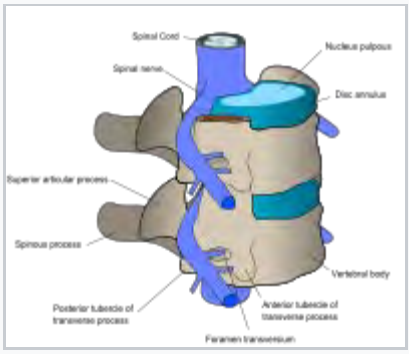
# Pathophysiology [edit]

## Back structures [edit]

The lumbar (or lower back) region is made up of five vertebrae (L1-L5), sometimes including the sacrum. In between these vertebrae are fibrocartilaginous discs, which act as cushions, preventing the vertebrae from rubbing together while at the same time protecting the spinal cord. Nerves come from and go to the spinal cord through specific openings between the vertebrae, providing the skin with sensations and messages to muscles. Stability of the spine is provided by the ligaments and muscles of the back and abdomen. Small joints called facet joints limit and direct the motion of the spine.[29]



The five lumbar vertebrae define the lower back region.



The structures surrounding and supporting the vertebrae can be sources of low back pain.

The multifidus muscles run up and down along the back of the spine, and are important for keeping the spine straight and stable during many common movements such as sitting, walking and lifting.[9] A problem with these muscles is often found in someone with chronic low back pain, because the back pain causes the person to use the back muscles improperly in trying to avoid the pain.[30] The problem with the multifidus muscles continues even after the pain goes away, and is probably an important reason why the pain comes back.[30] Teaching people with chronic low back pain how to use these muscles is recommended as part of a recovery program.[30]

An intervertebral disc has a gelatinous core surrounded by a fibrous ring.[31] When in its normal, uninjured state, most of the disc is not served by either the circulatory or nervous systems – blood and nerves only run to the outside of the disc.[31] Specialized cells that can survive without direct blood supply are in the inside of the disc.[31] Over time, the discs lose flexibility and the ability to absorb physical forces.[24] This decreased ability to handle physical forces increases stresses on other parts of the spine, causing the ligaments of the spine to thicken and bony growths to develop on the vertebrae.[24] As a result, there is less space through which the spinal cord and nerve roots may pass.[24] When a disc degenerates as a result of injury or disease, the makeup of a disc changes: blood vessels and nerves may grow into its interior and/or herniated disc material can push directly on a nerve root.[31] Any of these changes may result in back pain.[31]

### Pain sensation [edit]

Pain is generally an unpleasant feeling in response to an event that either damages or can potentially damage the body's tissues. There are four main steps in the process of feeling pain: transduction, transmission, perception, and modulation.[9] The nerve cells that detect pain have cell bodies located in the dorsal root ganglia and fibers that transmit these signals to the spinal cord.[32] The process of pain sensation starts when the pain-causing event triggers the endings of appropriate sensory nerve cells. This type of cell converts the event into an electrical signal by transduction. Several different types of nerve fibers carry out the transmission of the electrical signal from the transducing cell to the posterior horn of spinal cord, from there to the brain stem, and then from the brain stem to the various parts of the brain such as the thalamus and the limbic system. In the brain, the pain signals are processed and given context in the process of pain perception. Through modulation, the brain can modify the sending of further nerve impulses by decreasing or increasing the release of neurotransmitters.[9]

Parts of the pain sensation and processing system may not function properly; creating the feeling of pain when no outside cause exists, signaling too much pain from a particular cause, or signaling pain from a normally non-painful event. Additionally, the pain modulation mechanisms may not function properly. These phenomena are involved in chronic pain.[9]

## Diagnosis [edit]

As the structure of the back is complex and the reporting of pain is subjective and affected by social factors, the diagnosis of low back pain is not straightforward.[3] While most low back pain is caused by muscle and joint problems, this cause must be separated from neurological problems, spinal tumors, fracture of the spine, and infections, among others.[2][5]

### Classification [edit]

There are a number of ways to classify low back pain with no consensus that any one method is best.[3] There are three general types of low back pain by cause: mechanical back pain (including nonspecific musculoskeletal strains, herniated discs, compressed nerve roots, degenerative discs or joint disease, and broken vertebra), non-mechanical back pain (tumors, inflammatory conditions such as spondyloarthritis, and infections), and referred pain from internal organs (gallbladder disease, kidney stones, kidney infections, and aortic aneurysm, among others).[3] Mechanical or musculoskeletal problems underlie most cases (around 90% or more),[3][33] and of those, most (around 75%) do not have a specific cause identified, but are thought to be due to muscle strain or injury to ligaments.[3][33] Rarely, complaints of low back pain result from systemic or psychological problems, such as fibromyalgia and somatoform disorders.[33]

Low back pain may be classified based on the signs and symptoms. Diffuse pain that does not change in response to particular movements, and is localized to the lower back without radiating beyond the buttocks, is classified as *nonspecific*, the most common classification.[3] Pain that radiates down the leg below the knee, is located on one side (in the case of disc herniation), or is on both sides (in spinal stenosis), and

changes in severity in response to certain positions or maneuvers is *radicular*, making up 7% of cases.[3] Pain that is accompanied by red flags such as trauma, fever, a history of cancer or significant muscle weakness may indicate a more serious underlying problem and is classified as *needing urgent or specialized attention*.[3]

The symptoms can also be classified by duration as acute, sub-chronic (also known as sub-acute), or chronic. The specific duration required to meet each of these is not universally agreed upon, but generally pain lasting less than six weeks is classified as *acute*, pain lasting six to twelve weeks is *sub-chronic*, and more than twelve weeks is *chronic*.[2] Management and prognosis may change based on the duration of symptoms.

## Red flags [edit]

The presence of certain signs, termed *red flags*, indicate the need for further testing to look for more serious underlying problems, which may require immediate or specific treatment.[3][35] The presence of a red flag does not mean that there is a significant problem. It is only suggestive,[36][37] and most people with red flags have no serious underlying problem.[2][5] If no red flags are present, performing diagnostic imaging or laboratory testing in the first four weeks after the start of the symptoms has not been shown to be useful.[3]

The usefulness of many red flags are poorly supported by evidence.[38] The most useful for detecting a fracture are: older age, corticosteroid use, and significant trauma especially if it results in skin markings.[38] The best determinant of the presence of cancer is a history of the same.[38]

With other causes ruled out, people with non-specific low back pain are typically treated symptomatically, without exact determination of the cause.[2][5] Efforts to uncover factors that might complicate the diagnosis, such as depression, substance abuse, or an agenda concerning insurance payments may be helpful.[3]

| Red flag[34] | Possible cause[5] |
|---|---|
| Previous history of cancer | Cancer |
| Unintentional weight loss | |
| Loss of bladder or bowel control | Cauda equina syndrome |

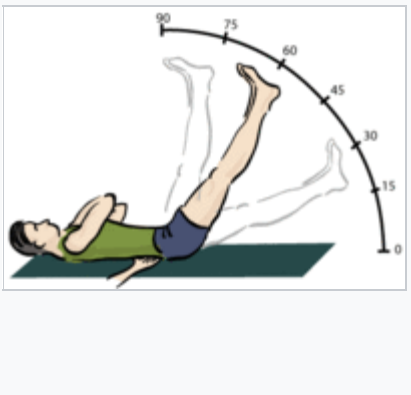
## Tests [edit]

Imaging is indicated when there are red flags, ongoing neurological symptoms that do not resolve, or ongoing or worsening pain.[3] In particular, early use of imaging (either MRI or CT) is recommended for suspected cancer, infection, or cauda equina syndrome.[3] MRI is slightly better than CT for identifying disc disease; the two technologies are equally useful for diagnosing spinal stenosis.[3] Only a few physical diagnostic tests are helpful.[3] The straight leg raise test is almost always positive in those with disc herniation.[3] Lumbar provocative discography may be useful to identify a specific disc



The straight leg raise test can detect pain originating

from a herniated disc. When warranted, imaging such as MRI can provide clear detail about disc related causes of back pain (L4–L5 disc herniation shown)

causing pain in those with chronic high levels of low back pain.[39] Similarly, therapeutic procedures such as nerve blocks can be used to determine a specific source of pain.[3] Some evidence supports the use of facet joint injections, transforminal epidural injections and sacroilliac injections as diagnostic tests.[3] Most other physical tests, such as evaluating for scoliosis, muscle weakness or wasting, and impaired reflexes, are of little use.[3]

Complaints of low back pain are one of the most common reasons people visit doctors.[6][40] For pain that has lasted only a few weeks, the pain is likely to subside on its own.[41] Thus, if a person's medical history and physical examination do not suggest a specific disease as the cause, medical societies advise against imaging tests such as X-rays, CT scans, and MRIs.[40] Individuals may want such tests but, unless red flags are present,[7][42] they are unnecessary health care.[6][41] Routine imaging increases costs, is associated with higher rates of surgery with no overall benefit,[43][44] and the radiation used may be harmful to one's health.[43] Fewer than 1% of imaging tests identify the cause of the problem.[6] Imaging may also detect harmless abnormalities, encouraging people to request further unnecessary testing or to worry.[6] Even so, MRI scans of the lumbar region increased by more than 300% among United States Medicare beneficiaries from 1994 to 2006.[8]

## Prevention [edit]

Exercise appears to be useful for preventing low back pain.[45] Exercise is also probably effective in preventing recurrences in those with pain that has lasted more than six weeks.[5][46] Medium-firm mattresses are more beneficial for chronic pain than firm mattresses.[47] There is little to no evidence that back belts are any more helpful in preventing low back pain than education about proper lifting techniques.[45][48] Shoe insoles do not help prevent low back pain.[45][49]

## Management [edit]

Management of low back pain depends on which of the three general categories is the cause: mechanical problems, non-mechanical problems, or referred pain.[50] For acute pain that is causing only mild to moderate problems, the goals are to restore normal function, return the individual to work, and minimize pain. The condition is normally not serious, resolves without much being done, and recovery is helped by attempting to return to normal activities as soon as possible within the limits of pain.[2] Providing individuals with coping skills through reassurance of these facts is useful in speeding recovery.[5] For those with sub-chronic or chronic low back pain, multidisciplinary treatment programs may help.[51]

### Physical management [edit]

Increasing general physical activity has been recommended, but no clear relationship to pain or disability has been found when used for the treatment of an acute episode of pain.[46][52] For acute pain, low- to moderate-quality evidence supports walking.[53] Treatment according to McKenzie method is somewhat effective for recurrent acute low back pain, but its benefit in the short term does not appear significant.[5] There is tentative evidence to support the use of heat therapy for acute and sub-chronic low back pain[54] but little evidence for the use of either heat or cold therapy in chronic pain.[55] Weak evidence suggests that back belts might decrease the number of missed workdays, but there is nothing to suggest that they will help with the pain.[48] Ultrasound and shock wave therapies do not appear effective and therefore are not recommended.[56][57]

Exercise therapy is effective in decreasing pain and improving function for those with chronic low back

pain.[48] It also appears to reduce recurrence rates for as long as six months after the completion of program[58] and improves long-term function.[55] There is no evidence that one particular type of exercise therapy is more effective than another.[59] The Alexander technique appears useful for chronic back pain,[60] and there is tentative evidence to support the use of yoga.[61] Transcutaneous electrical nerve stimulation (TENS) has not been found to be effective in chronic low back pain.[62] Evidence for the use of shoe insoles as a treatment is inconclusive.[49] Peripheral nerve stimulation, a minimally-invasive procedure, may be useful in cases of chronic low back pain that do not respond to other measures, although the evidence supporting it is not conclusive, and it is not effective for pain that radiates into the leg.[63]

## Medications [edit]

The management of low back pain often includes medications for the duration that they are beneficial. With the first episode of low back pain the hope is a complete cure; however, if the problem becomes chronic, the goals may change to pain management and the recovery of as much function as possible. As pain medications are only somewhat effective, expectations regarding their benefit may differ from reality, and this can lead to decreased satisfaction.[10]

The medication typically recommended first is acetaminophen (paracetamol) or NSAIDs (though not aspirin), and these are enough for most people. Standard doses of acetaminophen are very safe; however, high doses may cause liver problems, and very high doses can be fatal.[10] High-quality reviews have found acetaminophen (paracetamol) to be no more effective than placebo at improving pain, quality of life, or function.[64][65] NSAIDs are more effective for acute episodes than acetaminophen; however, they carry a greater risk of side effects including: kidney failure, stomach ulcers and possibly heart problems. Thus, NSAIDs are a second choice to acetaminophen, recommended only when the pain is not handled by the latter. NSAIDs are available in several different classes; there is no evidence to support the use of COX-2 inhibitors over any other class of NSAIDs with respect to benefits.[10][66] With respect to safety naproxen may be best.[67] Muscle relaxants may be beneficial.[10]

If the pain is still not managed adequately, short term use of opioids such as morphine may be useful.[68][10] These medications carry a risk of addiction, may have negative interactions with other drugs, and have a greater risk of side effects, including dizziness, nausea, and constipation.[10] The effect of long term use is unknown.[69] Specialist groups advise against general long-term use of opioids for chronic low back pain.[10][70]

For older people with chronic pain, opioids may be used in those for whom NSAIDs present too great a risk, including those with diabetes, stomach or heart problems. They may also be useful for a select group of people with neuropathic pain.[71]

Antidepressants may be effective for treating chronic pain associated with symptoms of depression, but they have a risk of side effects. Although the antiseizure drugs gabapentin and carbamazepine are sometimes used for chronic low back pain and may relieve sciatic pain, there is insufficient evidence to support their use.[10] Systemic oral steroids have not been shown to be useful in low back pain.[5][10] Facet joint injections and steroid injections into the discs have not been found to be effective in those with persistent, non-radiating pain; however, they may be considered for those with persistent sciatic pain.[72] Epidural corticosteroid injections provide a slight and questionable short-term improvement in those with sciatica but are of no long term benefit.[73] There are also concerns of potential side effects.[74]

## Surgery [edit]

Surgery may be useful in those with a herniated disc that is causing significant pain radiating into the leg, significant leg weakness, bladder problems, or loss of bowel control.[11] It may also be useful in those with spinal stenosis.[12] In the absence of these issues, there is no clear evidence of a benefit from surgery.[11]

Discectomy (the partial removal of a disc that is causing leg pain) can provide pain relief sooner than nonsurgical treatments.[11] Discectomy has better outcomes at one year but not at four to ten years.[11]

The less invasive microdiscectomy has not been shown to result in a different outcome than regular discectomy.[11] For most other conditions, there is not enough evidence to provide recommendations for surgical options.[11] The long-term effect surgery has on degenerative disc disease is not clear.[11] Less invasive surgical options have improved recovery times, but evidence regarding effectiveness is insufficient.[11]

For those with pain localized to the lower back due to disc degeneration, fair evidence supports spinal fusion as equal to intensive physical therapy and slightly better than low-intensity nonsurgical measures.[12] Fusion may be considered for those with low back pain from acquired displaced vertebra that does not improve with conservative treatment,[11] although only a few of those who have spinal fusion experience good results.[12] There are a number of different surgical procedures to achieve fusion, with no clear evidence of one being better than the others.[75] Adding spinal implant devices during fusion increases the risks but provides no added improvement in pain or function.[8]

## Alternative medicine [edit]

It is unclear if chiropractic care or spinal manipulation therapy (SMT) improves outcomes in those with low back pain more or less than other treatments.[15] Some reviews find that SMT results in equal or better improvements in pain and function when compared with other commonly used interventions for short, intermediate, and long-term follow-up;[16][17] other reviews find it to be no more effective in reducing pain than either inert interventions, sham manipulation, or other treatments, and conclude that adding SMT to other treatments does improve outcomes.[14][18] National guidelines reach different conclusions, with some not recommending spinal manipulation, some describing manipulation as optional, and others recommending a short course for those who do not improve with other treatments.[2] Manipulation under anaesthesia, or medically assisted manipulation, has not enough evidence to make any confident recommendation.[76]

Acupuncture is no better than placebo, usual care, or sham acupuncture for nonspecific acute pain or sub-chronic pain.[77] For those with chronic pain, it improves pain a little more than no treatment and about the same as medications, but it does not help with disability.[77] This pain benefit is only present right after treatment and not at follow-up.[77] Acupuncture may be a reasonable method to try for those with chronic pain that does not respond to other treatments like conservative care and medications.[5][78]

While massage therapy does not appear to provide much benefit for acute low back pain,[5] it may help those with sub-chronic and chronic pain, particularly when combined with physical exercises and education.[79][*needs update*] Tentative evidence suggests that acupuncture and massage together may be better than massage alone.[79]

Prolotherapy – the practice of injecting solutions into joints (or other areas) to cause inflammation and thereby stimulate the body's healing response – has not been found to be effective by itself, although it may be helpful when added to another therapy.[14]

Herbal medicines, as a whole, are poorly supported by evidence.[80] The herbal treatments Devil's claw and white willow may reduce the number of individuals reporting high levels of pain; however, for those taking pain relievers, this difference is not significant.[14] Capsicum, in the form of either a gel or a plaster cast, has been found to reduce pain and increase function.[14]

Behavioral therapy may be useful for chronic pain.[13] There are several types available, including operant conditioning, which uses reinforcement to reduce undesirable behaviors and increase desirable behaviors; cognitive behavioral therapy, which helps people identify and correct negative thinking and behavior; and respondent conditioning, which can modify an individual's physiological response to pain. Medical providers may develop an integrated program of behavioral therapies.[14] The evidence is inconclusive as to whether mindfulness-based stress reduction reduces chronic back pain intensity or associated disability, although it suggests that it may be useful in improving the acceptance of existing pain.[81]

Tentative evidence supports neuroreflexotherapy (NRT), in which small pieces of metal are placed just

under the skin of the ear and back, for non-specific low back pain.[82][83]

## Prognosis [edit]

Overall, the outcome for acute low back pain is positive. Pain and disability usually improve a great deal in the first six weeks, with complete recovery reported by 40 to 90%.[4] In those who still have symptoms after six weeks, improvement is generally slower with only small gains up to one year. At one year, pain and disability levels are low to minimal in most people. Distress, previous low back pain, and job satisfaction are predictors of long-term outcome after an episode of acute pain.[4] Certain psychological problems such as depression, or unhappiness due to loss of employment may prolong the episode of low back pain.[10] Following a first episode of back pain, recurrences occur in more than half of people.[22]

For persistent low back pain, the short-term outcome is also positive, with improvement in the first six weeks but very little improvement after that. At one year, those with chronic low back pain usually continue to have moderate pain and disability.[4] People at higher risk of long-term disability include those with poor coping skills or with fear of activity (2.5 times more likely to have poor outcomes at one year),[84] those with a poor ability to cope with pain, functional impairments, poor general health, or a significant psychiatric or psychological component to the pain (Waddell's signs).[84]

## Epidemiology [edit]

Low back pain that lasts at least one day and limits activity is a common complaint.[19] Globally, about 40% of people have LBP at some point in their lives,[19] with estimates as high as 80% of people in the developed world.[21] Approximately 9 to 12% of people (632 million) have LBP at any given point in time, and nearly one quarter (23.2%) report having it at some point over any one-month period.[19][20] Difficulty most often begins between 20 and 40 years of age.[5] Low back pain is more common among people aged 40–80 years, with the overall number of individuals affected expected to increase as the population ages.[19]

It is not clear whether men or women have higher rates of low back pain.[19][20] A 2012 review reported a rate of 9.6% among males and 8.7% among females.[20] Another 2012 review found a higher rate in females than males, which the reviewers felt was possibly due to greater rates of pains due to osteoporosis, menstruation, and pregnancy among women, or possibly because women were more willing to report pain than men.[19] An estimated 70% of women experience back pain during pregnancy with the rate being higher the further along in pregnancy.[85] Current smokers – and especially those who are adolescents – are more likely to have low back pain than former smokers, and former smokers are more likely to have low back pain than those who have never smoked.[86]

## History [edit]

Low back pain has been with humans since at least the Bronze Age. The oldest known surgical treatise – the Edwin Smith Papyrus, dating to about 1500 BCE – describes a diagnostic test and treatment for a vertebral sprain. Hippocrates (c. 460 BCE – c. 370 BCE) was the first to use a term for sciatic pain and low back pain; Galen (active mid to late second century CE) described the concept in some detail. Physicians through the end of the first millennium did not attempt back surgery and recommended watchful waiting. Through the Medieval period, folk medicine practitioners provided treatments for back pain based on the belief that it was caused by spirits.[87]

At the start of the 20th century, physicians thought low back pain was

Harvey Williams Cushing, 1920s

caused by inflammation of or damage to the nerves,[87] with neuralgia and neuritis frequently mentioned by them in the medical literature of the time.[88] The popularity of such proposed causes decreased during the 20th century.[88] In the early 20th century, American neurosurgeon Harvey Williams Cushing increased the acceptance of surgical treatments for low back pain.[11] In the 1920s and 1930s, new theories of the cause arose, with physicians proposing a combination of nervous system and psychological disorders such as nerve weakness (neurasthenia) and female hysteria.[87] Muscular rheumatism (now called fibromyalgia) was also cited with increasing frequency.[88]

Emerging technologies such as X-rays gave physicians new diagnostic tools, revealing the intervertebral disc as a source for back pain in some cases. In 1938, orthopedic surgeon Joseph S. Barr reported on cases of disc-related sciatica improved or cured with back surgery.[88] As a result of this work, in the 1940s, the vertebral disc model of low back pain took over,[87] dominating the literature through the 1980s, aiding further by the rise of new imaging technologies such as CT and MRI.[88] The discussion subsided as research showed disc problems to be a relatively uncommon cause of the pain. Since then, physicians have come to realize that it is unlikely that a specific cause for low back pain can be identified in many cases and question the need to find one at all as most of the time symptoms resolve within 6 to 12 weeks regardless of treatment.[87]

## Society and culture [edit]

Low back pain results in large economic costs. In the United States, it is the most common type of pain in adults, responsible for a large number of missed work days, and is the most common musculoskeletal complaint seen in the emergency department.[24] In 1998, it was estimated to be responsible for $90 billion in annual health care costs, with 5% of individuals incurring most (75%) of the costs.[24] Between 1990 and 2001 there was a more than twofold increase in spinal fusion surgeries in the US, despite the fact that there were no changes to the indications for surgery or new evidence of greater usefulness.[8] Further costs occur in the form of lost income and productivity, with low back pain responsible for 40% of all missed work days in the United States.[89] Low back pain causes disability in a larger percentage of the workforce in Canada, Great Britain, the Netherlands and Sweden than in the US or Germany.[89]

Workers who experience acute low back pain as a result of a work injury may be asked by their employers to have x-rays.[90] As in other cases, testing is not indicated unless red flags are present.[90] An employer's concern about legal liability is not a medical indication and should not be used to justify medical testing when it is not indicated.[90] There should be no legal reason for encouraging people to have tests which a health care provider determines are not indicated.[90]

## Research [edit]

Total disc replacement is an experimental option,[31] but no significant evidence supports its use over

lumbar fusion.[11] Researchers are investigating the possibility of growing new intervertebral structures through the use of injected human growth factors, implanted substances, cell therapy, and tissue engineering.[31]

# Osteoarthritis

From Wikipedia, the free encyclopedia

**Osteoarthritis** (**OA**) is a type of joint disease that results from breakdown of joint cartilage and underlying bone.[1] The most common symptoms are joint pain and stiffness. Initially, symptoms may occur only following exercise, but over time may become constant. Other symptoms may include joint swelling, decreased range of motion, and when the back is affected weakness or numbness of the arms and legs. The most commonly involved joints are those near the ends of the fingers, at the base of the thumb, neck, lower back, knee, and hips. Joints on one side of the body are often more affected than those on the other. Usually the symptoms come on over years. It can affect work and normal daily activities. Unlike other types of arthritis, only the joints are typically affected.[2]

Causes include previous joint injury, abnormal joint or limb development, and inherited factors. Risk is greater in those who are overweight, have one leg of a different length, and have jobs that result in high levels of joint stress.[2][3] Osteoarthritis is believed to be caused by mechanical stress on the joint and low grade inflammatory processes.[4] It develops as cartilage is lost and the underlying bone becomes affected.[2] As pain may make it difficult to exercise, muscle loss may occur.[3][5] Diagnosis is typically based on signs and symptoms, with medical imaging and other tests occasionally used to either support or rule out other problems. In contrast to rheumatoid arthritis, which is primarily an inflammatory condition, in osteoarthritis, the joints do not typically become hot or red.[2]

Treatment includes exercise, efforts to decrease joint stress, support groups, and pain medications.[2][6] Efforts to decrease joint stress include resting and the use of a cane. Weight loss may help in those who are overweight. Pain medications may include paracetamol (acetaminophen) as well as NSAIDs such as naproxen or ibuprofen.[2] Long-term opioid use is generally discouraged due to lack of information on benefits as well as risks of addiction and other side effects.[2][6] If pain interferes with normal life despite other treatments, joint replacement surgery may help.[3] An artificial joint typically lasts 10 to 15 years.[7]

Osteoarthritis is the most common form of arthritis with disease of the knee and hip affecting about 3.8% of people as of 2010.[8][9] Among those over 60 years old, about 10% of males and 18% of females are affected.[3] It is the cause of about 2% of years lived with disability.[9] In Australia, about 1.9 million people are affected,[10] and in the United States, 30 to 52.5 million people are affected.[11][12] It becomes more common in both sexes as people become older.[2]

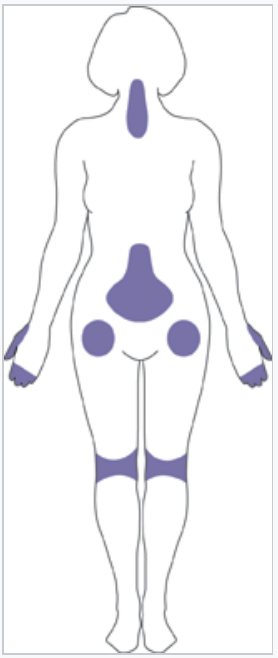
## Signs and symptoms [edit]

The main symptom is pain, causing loss of ability and often stiffness. "Pain" is generally described as a sharp ache or a burning sensation in the associated muscles and tendons, and is typically made worse by prolonged activity and relieved by rest. Stiffness is most common in the morning, and typically lasts less than thirty minutes after beginning daily activities, but may return after periods of inactivity. Osteoarthritis can cause a crackling noise (called "crepitus") when the affected joint is moved or touched and people may experience muscle spasms and contractions in the tendons. Occasionally, the joints may also be filled with fluid.[13] Some people report increased pain associated with cold temperature, high humidity, and/or a drop in barometric pressure, but studies have had mixed results.[14]

Osteoarthritis commonly affects the hands, feet, spine, and the large weight-bearing joints, such as the hips and knees, although in theory, any joint in the body can be affected. As osteoarthritis progresses, the affected joints appear larger, are stiff, painful and may swell, but usually feel better with gentle use but worse with excessive or prolonged use, thus distinguishing it from rheumatoid arthritis. [*citation needed*]

In smaller joints, such as at the fingers, hard bony enlargements, called Heberden's nodes (on the distal interphalangeal joints) and/or Bouchard's nodes (on the proximal interphalangeal joints), may form, and though they are not necessarily painful, they do limit the movement of the fingers significantly. Osteoarthritis at the toes leads to the formation of bunions, rendering them red or swollen. Some people notice these physical changes before they experience any pain, in part because the cartilage damage in osteoarthritis is generally painless because cartilage is aneural.[*citation needed*]

Osteoarthritis is the most common cause of a joint effusion of the knee.[15]



Osteoarthritis most often occurs in the hands (at the ends of the fingers and thumbs), neck, lower back, knees, and hips

## Risk factors [edit]

Damage from mechanical stress with insufficient self repair by joints is believed to be the primary cause of osteoarthritis.[16] Sources of this stress may include misalignments of bones caused by congenital or pathogenic causes; mechanical injury; excess body weight; loss of strength in the muscles supporting a joint; and impairment of peripheral nerves, leading to sudden or uncoordinated movements.[16] However exercise, including running in the absence of injury, has not been found to increase the risk.[17] Nor has cracking one's knuckles been found to play a role.[18]

### Primary [edit]

A number of studies have shown that there is a greater prevalence of the disease among siblings and especially identical twins, indicating a hereditary basis.[19] Although a single factor is not generally sufficient to cause the disease, about half of the variation in susceptibility has been assigned to genetic factors.[20]

As early human ancestors evolved into bipeds, changes occurred in the pelvis, hip joint and spine which increased the risk of osteoarthritis.[21] Additionally genetic variations that increase the risk were likely not selected against because usually problems only occur after reproductive success.[22]

The development of osteoarthritis is correlated with a history of previous joint injury and with obesity, especially with respect to knees.[23] Since the correlation with obesity has been observed not only for knees but also for non-weight bearing joints and the loss of body fat is more closely related to symptom relief than the loss of body weight, it has been suggested that there may be a metabolic link to body fat as opposed to just mechanical loading.[24]

Changes in sex hormone levels may play a role in the development of osteoarthritis as it is more prevalent among post-menopausal women than among men of the same age.[25][26] A study of mice found natural female hormones to be protective while injections of the male hormone dihydrotestosterone reduced protection.[27]

### Secondary [edit]

This type of osteoarthritis is caused by other factors but the resulting pathology is the same as for primary osteoarthritis:

- Alkaptonuria
- Congenital disorders of joints

lateral front

Secondary osteoarthritis (due to an old injury with fracture) of the ankle in a woman of 82 years old

Diabetes doubles the risk of having a joint replacement due to osteoarthritis and people with diabetes have joint replacements at a younger age than those without diabetes.[28]
- Ehlers-Danlos Syndrome
- Hemochromatosis and Wilson's disease
- Inflammatory diseases (such as Perthes' disease), (Lyme disease), and all chronic forms of arthritis (e.g., costochondritis, gout, and rheumatoid arthritis). In gout, uric acid crystals cause the cartilage to degenerate at a faster pace.
- Injury to joints or ligaments (such as the ACL), as a result of an accident or orthopedic operations.
- Ligamentous deterioration or instability may be a factor.
- Marfan syndrome
- Obesity
- Joint infection

## Pathophysiology [edit]

While osteoarthritis is a degenerative joint disease that may cause gross cartilage loss and morphological damage to other joint tissues, more subtle biochemical changes occur in the earliest stages of osteoarthritis progression. The water content of healthy cartilage is finely balanced by compressive force driving water out and hydrostatic and osmotic pressure drawing water in.[30][31] Collagen fibres exert the compressive force, whereas the Gibbs–Donnan effect and cartilage proteoglycans create osmotic pressure which tends to draw water in.[31]

However, during onset of osteoarthritis, the collagen matrix becomes more disorganized and there is a decrease in proteoglycan content within cartilage. The breakdown of collagen fibers results in a net increase in water content.[32][33][34][35][36] This increase occurs because whilst there is an overall loss of proteoglycans (and thus a decreased osmotic pull),[33][37] it is outweighed by a loss of collagen.[31][37] Without the protective effects of the proteoglycans, the collagen fibers of the cartilage can become susceptible to degradation and thus exacerbate the degeneration. Inflammation of the synovium (joint cavity lining) and the surrounding joint capsule can also occur, though often mild (compared to the synovial inflammation that occurs in rheumatoid arthritis). This can happen as breakdown products from the cartilage are released into the synovial space, and the cells lining the joint attempt to remove them.[*citation needed*]

Other structures within the joint can also be affected.[38] The ligaments within the joint become thickened and fibrotic and the menisci can become damaged and wear away.[39] Menisci can be completely absent by the time a person undergoes a joint replacement. New bone outgrowths, called "spurs" or osteophytes, can form on the margins of the joints, possibly in an attempt to improve the congruence of the articular cartilage surfaces in the absence of the menisci. The subchondral bone volume increases and becomes less mineralized (hypomineralization).[40] All these changes can cause problems functioning. The pain in an osteoarthritic joint has been related to thickened synovium[41] and subchondral bone lesions.[42]

## Diagnosis [edit]

Diagnosis is made with reasonable certainty based on history and clinical examination.[43][44] X-rays may confirm the diagnosis. The typical changes seen on X-ray include: joint space narrowing, subchondral sclerosis (increased bone formation around the joint), subchondral cyst formation, and osteophytes.[45] Plain films may not correlate with the findings on physical examination or with the degree of pain.[46] Usually other imaging techniques are not necessary to clinically diagnose osteoarthritis.

In 1990, the American College of Rheumatology, using data from a multi-center study, developed a set of criteria for the diagnosis of hand osteoarthritis based on hard tissue enlargement and swelling of certain joints.[47] These criteria were found to be 92% sensitive and 98% specific for hand osteoarthritis versus other entities such as rheumatoid arthritis and spondyloarthropathies.[48]

Related pathologies whose names may be confused with osteoarthritis include pseudo-arthrosis. This is derived from the Greek roots *pseudo-*, meaning "false", and *arthr-*, meaning "joint", together with the ending *-osis* used for disorders. Radiographic diagnosis results in diagnosis of a fracture within a joint, which is not to be confused with osteoarthritis which is a degenerative pathology affecting a high incidence of distal phalangeal joints of female patients. A polished ivory-like appearance may also develop on the bones of the affected joints, reflecting a change called eburnation.[49]

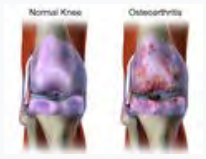
In a healthy joint, the ends of bones are encased in smooth cartilage. Together, they are protected by a joint capsule lined with a synovial membrane that produces synovial fluid. The capsule and fluid protect the cartilage, muscles, and connective tissues.

With osteoarthritis, the cartilage becomes worn away. Spurs grow out from the edge of the bone, and synovial fluid increases. Altogether, the joint feels stiff and sore.



Osteoarthritis

## Classification [edit]

*Further information: Radiographic classification of osteoarthritis*

A number of classification systems are used for gradation of osteoarthritis:

- WOMAC scale, taking into account pain, stiffness and functional limitation.[50]
- Kellgren-Lawrence grading scale for osteoarthritis of the knee. It uses only projectional radiography features.
- Tönnis classification for osteoarthritis of the hip joint, also using only projectional radiography features.[51]

Osteoarthritis can be classified into either primary or secondary depending on whether or not there is an identifiable underlying cause.

Both primary generalized nodal osteoarthritis and erosive osteoarthritis (EOA, also called inflammatory osteoarthritis) are sub-sets of primary osteoarthritis. EOA is a much less common, and more aggressive inflammatory form of osteoarthritis which often affects the distal interphalangeal joints of the hand and has characteristic articular erosive changes on x-ray.[52]

# Management [edit]

Lifestyle modification (such as weight loss and exercise) and analgesics are the mainstays of treatment. Acetaminophen (also known as paracetamol) is recommended first line with NSAIDs being used as add on therapy only if pain relief is not sufficient.[53] This is due to the relative greater safety of acetaminophen.[53]

## Lifestyle changes [edit]

For overweight people, weight loss may be an important factor.[54] Patient education has been shown to be helpful in the self-management of arthritis.[54] It decreases pain, improves

People with osteoarthritis should do different kinds of exercise for different benefits to the body.

function, reduces stiffness and fatigue, and reduces medical usage.[54] Patient education can provide on average 20% more pain relief when compared to NSAIDs alone in patients with hip osteoarthritis.[54]

## Physical measures [edit]

Moderate exercise is beneficial with respect to pain and function in those with osteoarthritis of the knee and hip.[55][56] These exercises should occur at least three times per week.[57] While some evidence supports certain physical therapies, evidence for a combined program is limited.[58] There is not enough evidence to determine the effectiveness of massage therapy.[59] The evidence for manual therapy is inconclusive.[60] Functional, gait, and balance training have been recommended to address impairments of position sense, balance, and strength in individuals with lower extremity arthritis as these can contribute to a higher rate of falls in older individuals.[61]

Lateral wedge insoles and neutral insoles do not appear to be useful in osteoarthritis of the knee.[62][63][64] Knee braces may help[65] but their usefulness has also been disputed.[64] For pain management heat can be used to relieve stiffness, and cold can relieve muscle spasms and pain.[66] Among people with hip and knee osteoarthritis, exercise in water may reduce pain and disability, and increase quality of life in the short term.[67]

## Medication [edit]

The pain medication acetaminophen is the first line treatment for osteoarthritis.[53][69] However, a 2015 review found acetaminophen to only have a small short term benefit.[70] For mild to moderate symptoms effectiveness is similar to non-steroidal anti-inflammatory drugs (NSAIDs), though for more severe symptoms NSAIDs may be more effective.[53] NSAIDs such as naproxen, while more effective in severe cases, are associated with greater side effects, such as gastrointestinal bleeding.[53] Diclofenac may be the most effective NSAID.[71]

| Treatment recommendations by risk factors | | |
|---|---|---|
| **GI risk** | **CVD risk** | **Option** |
| Low | Low | NSAID, or paracetamol[68] |
| Moderate | Low | Paracetamol, or low dose NSAID with antacid[68] |
| Low | Moderate | Paracetamol, or low dose aspirin with an antacid[68] |
| Moderate | Moderate | Low dose paracetamol, aspirin, and antacid. Monitoring for abdominal pain or black stool.[68] |

Another class of NSAIDs, COX-2 selective inhibitors (such as celecoxib) are equally effective when compared to nonselective NSAIDs, and have lower rates of adverse gastrointestinal effects, but higher rates of cardiovascular disease such as myocardial infarction.[72] They are also more expensive than non-specific NSAIDs.[73] Benefits and risks vary in individuals and need consideration when making treatment decisions.[74] NSAIDS applied topically are effective for a small number of people.[75]

Failure to achieve desired pain relief in osteoarthritis after 2 weeks should trigger reassessment of dosage and pain medication.[76] Opioids by mouth, including both weak opioids such as tramadol and stronger opioids, are also often prescribed. Their appropriateness is uncertain, and opioids are often recommended only when first line therapies have failed or are contraindicated.[77][78] This is due to their small benefit and relatively large risk of side effects.[79] Oral steroids are not recommended in the treatment of osteoarthritis.[69]

There are several NSAIDs available for topical use, including diclofenac. A Cochrane review from 2016 concluded that reasonably reliable evidence is available only for use of topical diclofenac and ketoprofen in people aged over 40 years with painful knee arthritis.[80] Transdermal opioid pain medications are not typically recommended in the treatment of osteoarthritis.[81] The use of topical capsaicin to treat osteoarthritis is controversial, as some reviews found benefit[82][83] while others did not.[84]

Joint injections of glucocorticoids (such as hydrocortisone) leads to short term pain relief that may last between a few weeks and a few months.[85] Injections of hyaluronic acid have not been found to lead to much improvement compared to placebo when the knee joint is affected[86][87] but have been associated with harm.[86] This may stand true for hip osteoarthritis. In ankle osteoarthritis, evidence is unclear.[88] The effectiveness of injections of platelet-rich plasma is unclear; there are suggestions that such injections improve function but not pain, and are associated with increased risk.[*vague*][89][90]

## Surgery [edit]

If the impact of symptoms of osteoarthritis on quality of life is significant and more conservative management is ineffective, joint replacement surgery or resurfacing may be recommended. Evidence supports joint replacement for both knees and hips as it is both clinically effective,[91][92] and cost-effective.[93][94] Surgery to transfer articular cartilage from a non-weight-bearing area to the damaged area is one possible procedure that has some success, but there are problems getting the transferred cartilage to integrate well with the existing cartilage at the transfer site.[95]

Osteotomy may be useful in people with knee osteoarthritis, but has not been well studied.[96] Arthroscopic surgery is largely not recommended, as it does not improve outcomes in knee osteoarthritis,[97][98] and may result in harm.[99]

## Alternative medicine [edit]

### Glucosamine and chondroitin [edit]

The effectiveness of glucosamine is controversial.[100] Reviews have found it to be equal to[101][102] or slightly better than placebo.[103][104] A difference may exist between glucosamine sulfate and glucosamine hydrochloride, with glucosamine sulfate showing a benefit and glucosamine hydrochloride not.[105] The evidence for glucosamine sulfate having an effect on osteoarthritis progression is somewhat unclear and if present likely modest.[106] The Osteoarthritis Research Society International recommends that glucosamine be discontinued if no effect is observed after six months[107] and the National Institute for Health and Care Excellence no longer recommends its use.[5] Despite the difficulty in determining the efficacy of glucosamine, it remains a viable treatment option.[108] Its use as a therapy for osteoarthritis is usually safe.[108][109]

A 2015 Cochrane review of clinical trials of chondroitin found that most were of low quality, but that there was some evidence of short-term improvement in pain and few side effects; it does not appear to improve or maintain the health of affected joints.[64] Glucosamine and chondroitin are generally manufactured from fish or animal products, respectively,[110][111] although there are some glucosamine products derived from fungi or plants.[112]

### Other remedies [edit]

Avocado/soybean unsaponifiables (ASU) is an extract made from avocado oil and soybean oil[113] that is sold under many brand names worldwide as a dietary supplement[114] and as a drug in France.[115] A 2014 Cochrane review found that while ASU might help relieve pain in the short term for some people with osteoarthritis, it does not appear to improve or maintain the health of affected joints; the review noted a high quality two year clinical trial comparing to ASU to chondroitin, which has uncertain efficacy in arthritis—the study found no difference between the two.[113] The review also found that while ASU appears to be safe, it has not been adequately studied to be sure.[113]

SKI 306X (trade name, Joins) is marketed as a botanical drug in Korea for osteoarthritis; it is a combination of standardized extracts of *Clematis mandshurica*, *Trichosanthes kirilowii*, and *Prunella vulgaris*, each of which has a history in traditional Korean medicine as well as in other asian cultures.[116] Joins has been marketed in Korea as a drug since since 2001 and has been marketed as a dietary supplement outside Korea; its approval and use has been controversial in Korea and other countries.[117]

Phytodolor is a brand name herbal remedy composed of extracts from European aspen leaf and bark, common ash bark, and goldenrod; clinical trials have been conducted by its manufacturer and have not provided sufficient evidence to determine if the remedy is safe or effective to treat osteoarthritis.[113]

Devil's claw,[118] Curcumin[119] and SAMe,[82][120] may be effective in improving pain. There is tentative evidence to support ashwagandha,[121] cat's claw,[122] hyaluronan,[123] MSM,[82] and rose hip.[82] A few high-quality studies of *Boswellia serrata* show consistent, but small, improvements in pain and function.[113]

There is little evidence supporting benefits for some supplements, including: the Ayurvedic herbal preparations with brand names Articulin F and Eazmov, collagen, Duhuo Jisheng Wan (a Chinese herbal preparation), fish liver oil, ginger, the herbal preparation gitadyl, omega-3 fatty acids, the brand-name product Reumalax, stinging nettle, vitamins A, C, and E in combination, vitamin E alone, vitamin K and willow bark. There is insufficient evidence to make a recommendation about the safety and efficacy of these treatments.[82][122]

### Acupuncture and other interventions [edit]

While acupuncture leads to improvements in pain relief, this improvement is small and may be of questionable importance. Waiting list-controlled trials for peripheral joint osteoarthritis do show clinically relevant benefits, but these may be due to placebo effects.[124] Acupuncture does not seem to produce long-term benefits.[125] While electrostimulation techniques such as TENS have been used for twenty years to treat osteoarthritis in the knee, there is no conclusive evidence to show that it reduces pain or disability.[126]

A Cochrane review of low level laser therapy found unclear evidence of benefit.[127] Another review found short term pain relief for osteoarthritic knees.[128]

## Epidemiology [edit]

Globally as of 2010, approximately 250 million people had osteoarthritis of the knee (3.6% of the population).[8][130] Hip osteoarthritis affects about 0.85% of the population.[8]

As of 2004, osteoarthritis globally causes moderate to severe disability in 43.4 million people.[131] Together, knee and hip osteoarthritis had a ranking for disability globally of 11th among 291 disease conditions assessed.[8]

### United States [edit]

As of 2012, osteoarthritis affected 52.5 million people in the United States, approximately 50% of whom were 65 years and older.[11] It is estimated that 80% of the population have radiographic evidence of osteoarthritis by age 65, although only 60% of those will have symptoms.[132] The rate of osteoarthritis in the United States is forecast to be 78 million (26%) adults by 2040.[11]

In the United States, there were approximately 964,000 hospitalizations for osteoarthritis in 2011, a rate of 31 stays per 10,000 population.[133] With an aggregate cost of $14.8 billion ($15,400 per stay), it was the second-most expensive condition seen in U.S. hospital stays in 2011. By payer, it was the second-most costly condition billed to Medicare and private insurance.[134][135]

## History [edit]

Evidence for osteoarthritis found in the fossil record is studied by paleopathologists, specialists in ancient disease and injury. Osteoarthritis has been reported in fossils of the large carnivorous dinosaur *Allosaurus fragilis*.[136]

### Etymology [edit]

Osteoarthritis is derived from the Greek word part *osteo-*, meaning "of the bone", combined with *arthritis*: *arthr-*, meaning "joint", and *-itis*, the meaning of which has come to be associated with inflammation.[137] The *-itis* of osteoarthritis could be considered misleading as inflammation is not a conspicuous feature. Some clinicians refer to this condition as *osteoarthrosis* to signify the lack of inflammatory response.[*citation needed*]

## Research [edit]

There are ongoing efforts to determine if there are agents that modify outcomes in osteoarthritis. Sprifermin is one candidate drug. There is also tentative evidence that strontium ranelate may decrease degeneration in osteoarthritis and improve outcomes.[138][139]

As well as attempting to find disease-modifying agents for osteoarthritis, there is emerging evidence that a system-based approach is necessary to find the causes of osteoarthritis.[140] Changes may occur before clinical disease is evident due to abnormalities in biomechanics, biology and/or structure of joints that predispose them to develop clinical disease. Research is thus focusing on defining these early pre-osteoarthritis changes using biological, mechanical, and imaging markers of osteoarthritis risk, emphasising multi-disciplinary approaches, and looking into personalized interventions that can reverse osteoarthritis risk in healthy joints before the disease becomes evident.

Gene transfer strategies aim to target the disease process rather than the symptoms.[141]

### Biomarkers [edit]

Guidelines outlining requirements for inclusion of soluble biomarkers in osteoarthritis clinical trials were published in 2015,[142] but as yet, there are no validated biomarkers for osteoarthritis. A 2015 systematic review of biomarkers for osteoarthritis looking for molecules that could be used for risk assessments found 37 different biochemical markers of bone and cartilage turnover in 25 publications.[143] The strongest evidence was for urinary C-terminal telopeptide of collagen type II (uCTX-II) as a prognostic marker for knee osteoarthritis progression and serum cartilage oligomeric protein (COMP) levels as a prognostic marker for incidence of both knee and hip osteoarthritis. A review of biomarkers in hip osteoarthritis also found associations with uCTXII.[144]

One problem with using a specific collagen type II biomarker from the breakdown of articular cartilage is that the amount of cartilage is reduced (worn away) over time with progression of the disease so a patient can eventually have very advanced osteoarthritis with none of this biomarker detectable in their urine. Another problem with a systemic biomarker is that a patient can have osteoarthritis in multiple joints at different stages of disease at the same time, so the biomarker source cannot be determined. Some other collagen breakdown products in the synovial fluid correlated with each other after acute injuries (a known cause of secondary osteoarthritis) but did not correlate with the severity of the injury.[145]

# Osteoporosis

From Wikipedia, the free encyclopedia

**Osteoporosis** is a disease where decreased bone strength increases the risk of a broken bone. It is the most common reason for a broken bone among the elderly.[3] Bones that commonly break include the back bones, the bones of the forearm, and the hip.[4] Until a broken bone occurs there are typically no symptoms. Bones may weaken to such a degree that a break may occur with minor stress or spontaneously. Chronic pain and a decreased ability to carry out normal activities may occur following a broken bone.[3]

Osteoporosis may be due to lower than normal peak bone mass and greater than normal bone loss. Bone loss increases after menopause due to lower levels of estrogen. Osteoporosis may also occur due to a number of diseases or treatments including alcoholism, anorexia, hyperthyroidism, surgical removal of the ovaries, and kidney disease. Certain medications increase the rate of bone loss including some antiseizure medications, chemotherapy, proton pump inhibitors, selective serotonin reuptake inhibitors, and steroids. Not enough exercise and smoking are also risk factors.[3] Osteoporosis is defined as a bone density of 2.5 standard deviations below that of a young adult.[5] This is typically measured by dual-energy X-ray absorptiometry at the hip.[5]

Prevention of osteoporosis includes a proper diet during childhood and efforts to avoid medications that cause the condition. Efforts to prevent broken bones in those with osteoporosis include a good diet, exercise, and fall prevention. Lifestyle changes such as stopping smoking and not drinking alcohol may help.[3] Medication of the bisphosphonate type are useful in those with previous broken bones due to osteoporosis.[6][7] In those with osteoporosis but no previous broken bones they are less effective.[6][7][8] A number of other medications may also be useful.[3][9]

Osteoporosis becomes more common with age.[3] About 15% of white people in their 50s and 70% of those over 80 are affected.[10] It is more common in women than men.[3] In the developed world, depending on the method of diagnosis, 2% to 8% of males and 9% to 38% of females are affected.[11] Rates of disease in the developing world are unclear.[12] About 22 million women and 5.5 million men in the European Union had osteoporosis in 2010.[13] In the

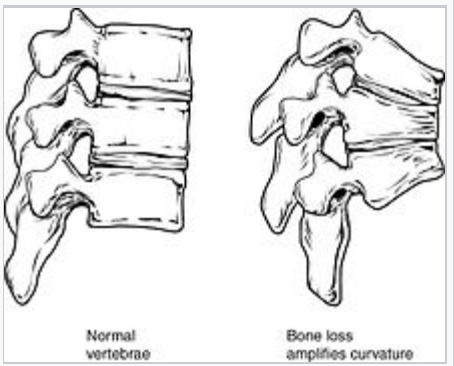
# Signs and symptoms [edit]

Osteoporosis itself has no symptoms; its main consequence is the increased risk of bone fractures. Osteoporotic fractures occur in situations where healthy people would not normally break a bone; they are therefore regarded as fragility fractures. Typical fragility fractures occur in the vertebral column, rib, hip and wrist.



Osteoporosis is an age-related disorder that causes the gradual loss of bone density and strength.

## Fractures [edit]

Fractures are the most dangerous aspect of osteoporosis. Debilitating acute and chronic pain in the elderly is often attributed to fractures from osteoporosis and can lead to further disability and early mortality.[16] These fractures may also be asymptomatic. The most common osteoporotic fractures are of the wrist, spine, shoulder and hip. The

symptoms of a vertebral collapse ("compression fracture") are sudden back pain, often with radicular pain (shooting pain due to nerve root compression) and rarely with spinal cord compression or cauda equina syndrome. Multiple vertebral fractures lead to a stooped posture, loss of height, and chronic pain with resultant reduction in mobility.[17]

When the thoracic vertebrae are affected, there can be a gradual collapse of the vertebrae. This results in kyphosis, an excessive curvature of the thoracic region.

Fractures of the long bones acutely impair mobility and may require surgery. Hip fracture, in particular, usually requires prompt surgery, as serious risks are associated with it, such as deep vein thrombosis and pulmonary embolism, and increased mortality.

Fracture risk calculators assess the risk of fracture based upon several criteria, including BMD, age, smoking, alcohol usage, weight, and gender. Recognized calculators include FRAX[18] and Dubbo.

The term "established osteoporosis" is used when a broken bone due to osteoporosis has occurred.[19] Osteoporosis is a part of frailty syndrome.

## Falls risk [edit]

The increased risk of falling associated with aging leads to fractures of the wrist, spine, and hip. The risk of falling, in turn, is increased by impaired eyesight due to any cause (e.g. glaucoma, macular degeneration), balance disorder, movement disorders (e.g. Parkinson's disease), dementia, and sarcopenia (age-related loss of skeletal muscle). Collapse (transient loss of postural tone with or without loss of consciousness) leads to a significant risk of falls; causes of syncope are manifold, but may include cardiac arrhythmias (irregular heart beat), vasovagal syncope, orthostatic hypotension (abnormal drop in blood pressure on standing up), and seizures. Removal of obstacles and loose carpets in the living environment may substantially reduce falls. Those with previous falls, as well as those with gait or balance disorders, are most at risk.[20]

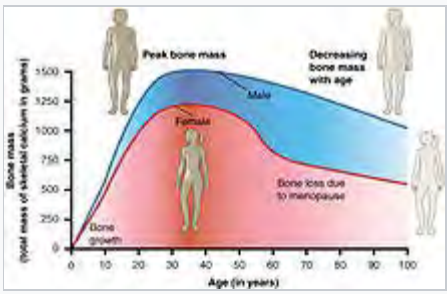
# Risk factors [edit]

Risk factors for osteoporotic fracture can be split between nonmodifiable and (potentially) modifiable. In addition, osteoporosis is a recognized complication of specific diseases and disorders. Medication use is theoretically modifiable, although in many cases, the use of medication that increases osteoporosis risk may be unavoidable. Caffeine is not a risk factor for osteoporosis.[21]

It is more likely in females than males.[3]

## Nonmodifiable [edit]

- The most important risk factors for osteoporosis are advanced age (in both men and women) and female sex; estrogen deficiency following menopause or surgical removal of the ovaries is correlated with a rapid reduction in bone mineral density, while in men, a decrease in testosterone levels has a comparable (but less pronounced) effect.[23][24]
- Race: While osteoporosis occurs in people from all ethnic groups, European or Asian ancestry predisposes for osteoporosis.[25]
- Heredity: Those with a family history of fracture or osteoporosis are at an increased risk; the heritability of the fracture, as well as low bone mineral density, is relatively high, ranging from 25 to 80%. At least 30 genes are associated with the development of [26]



Bone density peaks at about 30 years of age. Women lose bone mass more rapidly than men.[22]

osteoporosis.
- Those who have already had a fracture are at least twice as likely to have another fracture compared to someone of the same age and sex.[27] Early menopause/hysterectomy is another predisposing factor.
- Build: A small stature is also a nonmodifiable risk factor associated with the development of osteoporosis.[28]

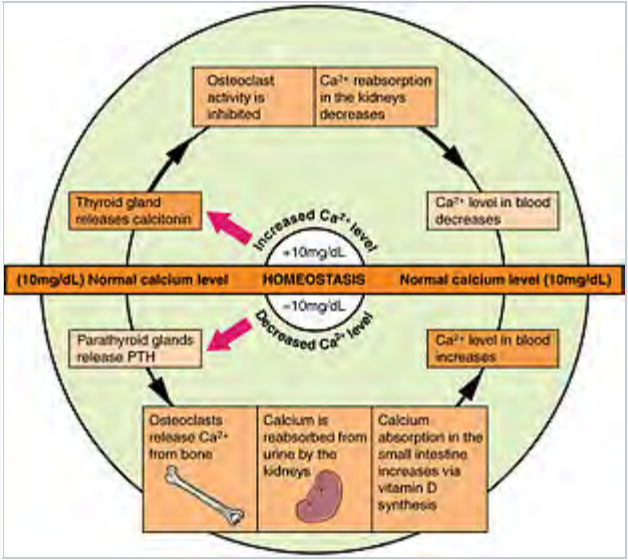
## Potentially modifiable [edit]

- Excess consumption of alcohol: Although small amounts of alcohol are probably beneficial (bone density increases with increasing alcohol intake), chronic heavy drinking (alcohol intake greater than three units/day) probably increases fracture risk despite any beneficial effects on bone density.[29][30]
- Vitamin D deficiency:[31][32] Low circulating Vitamin D is common among the elderly worldwide.[5] Mild vitamin D insufficiency is associated with increased parathyroid hormone (PTH) production.[5] PTH increases bone resorption, leading to bone loss. A positive association exists between serum 1,25-dihydroxycholecalciferol levels and bone mineral density, while PTH is negatively associated with bone mineral density.[5]
- Tobacco smoking: Many studies have associated smoking with decreased bone health, but the mechanisms are unclear. Tobacco smoking has been proposed to inhibit the activity of osteoblasts, and is an independent risk factor for osteoporosis.[29][33] Smoking also results in increased breakdown of exogenous estrogen, lower body weight and earlier menopause, all of which contribute to lower bone mineral density.[5]
- Malnutrition: Nutrition has an important and complex role in maintenance of good bone. Identified risk factors include low dietary calcium and/or phosphorus, magnesium, zinc, boron, iron, fluoride, copper, vitamins A, K, E and C (and D where skin exposure to sunlight provides an inadequate supply). Excess sodium is a risk factor. High blood acidity may be diet-related, and is a known antagonist of bone.[34] Some have identified low protein intake as associated with lower peak bone mass during adolescence and lower bone mineral density in elderly populations.[5] Conversely, some have identified low protein intake as a positive factor, protein is among the causes of dietary acidity. Imbalance of omega-6 to omega-3 polyunsaturated fats is yet another identified risk factor.[35]
- High dietary protein from animal sources: Research has found an association between diets high in animal protein and increased urinary calcium,[36][37][38] and have been linked to an increase in fractures.[39] However, the relevance of this observation to bone density is unclear[*citation needed*], since higher protein diets tend to increase absorption of calcium from the diet and are associated with higher bone density.[40] Indeed, it has recently been argued that low protein diets cause poor bone health.[41] No interventional trials have been performed on dietary protein in the prevention and treatment of osteoporosis.[42]
- Underweight/inactive: Bone remodeling occurs in response to physical stress, so physical inactivity can lead to significant bone loss.[5] Weight bearing exercise can increase peak bone mass achieved in adolescence,[5] and a highly significant correlation between bone strength and muscle strength has been determined.[43] The incidence of osteoporosis is lower in overweight people.[44]
- Endurance training: In female endurance athletes, large volumes of training can lead to decreased bone density and an increased risk of osteoporosis.[45] This effect might be caused by intense training suppressing menstruation, producing amenorrhea, and it is part of the female athlete triad.[46] However, for male athletes, the situation is less clear, and although some studies have reported low bone density in elite male endurance athletes,[47] others have instead seen increased leg bone density.[48][49]
- Heavy metals: A strong association between cadmium and lead with bone disease has been established. Low-level exposure to cadmium is associated with an increased loss of bone mineral density readily in both genders, leading to pain and increased risk of fractures, especially in the elderly and in females. Higher cadmium exposure results in osteomalacia (softening of the bone).[50]
- Soft drinks: Some studies indicate soft drinks (many of which contain phosphoric acid) may increase risk [51]

of osteoporosis, at least in women. Others suggest soft drinks may displace calcium-containing drinks from the diet rather than directly causing osteoporosis.[52]
- Proton pump inhibitors (such as lansoprazole, esomeprazole, or omeprazole) that decrease stomach acid, are a risk for bone fractures if taken for two or more years, due to decreased absorption of calcium in the stomach.[53]

## Medical disorders [edit]

Many diseases and disorders have been associated with osteoporosis.[54] For some, the underlying mechanism influencing the bone metabolism is straightforward, whereas for others the causes are multiple or unknown.



The body regulates calcium homeostasis with two pathways; one is signaled to turn on when blood calcium levels drop below normal and one is the pathway that is signaled to turn on when blood calcium levels are elevated.

- In general, immobilization causes bone loss (following the 'use it or lose it' rule). For example, localized osteoporosis can occur after prolonged immobilization of a fractured limb in a cast. This is also more common in active people with a high bone turn-over (for example, athletes). Other examples include bone loss during space flight or in people who are bedridden or use wheelchairs for various reasons.
- Hypogonadal states can cause secondary osteoporosis. These include Turner syndrome, Klinefelter syndrome, Kallmann syndrome, anorexia nervosa, andropause,[55] hypothalamic amenorrhea or hyperprolactinemia.[55] In females, the effect of hypogonadism is mediated by estrogen deficiency. It can appear as early menopause (<45 years) or from prolonged premenopausal amenorrhea (>1 year). Bilateral oophorectomy (surgical removal of the ovaries) and premature ovarian failure cause deficient estrogen production. In males, testosterone deficiency is the cause (for example, andropause or after surgical removal of the testes).
- Endocrine disorders that can induce bone loss include Cushing's syndrome,[5] hyperparathyroidism,[5] hyperthyroidism,[5] hypothyroidism, diabetes mellitus type 1 and 2,[56] acromegaly, and adrenal insufficiency. In pregnancy and lactation can cause reversible bone loss.[54]
- Malnutrition, parenteral nutrition[5] and malabsorption can lead to osteoporosis. Nutritional and gastrointestinal disorders that can predispose to osteoporosis include undiagnosed and untreated coeliac disease (both symptomatic and asymptomatic people),[5][57] Crohn's disease,[58] ulcerative colitis,[58] cystic fibrosis,[58] surgery[55] (after gastrectomy, intestinal bypass surgery or bowel resection) and severe liver disease (especially primary biliary cirrhosis).[55] People with lactose intolerance or milk allergy may develop osteoporosis due to restrictions of calcium-containing foods.[59] Individuals with bulimia can also develop osteoporosis. Those with an otherwise adequate calcium intake can develop osteoporosis due to the inability to absorb calcium and/or vitamin D. Other micronutrients such as vitamin K or vitamin $B_{12}$ deficiency may also contribute.
- People with rheumatologic disorders such as rheumatoid arthritis,[55] ankylosing spondylitis,[55] systemic lupus erythematosus and polyarticular juvenile idiopathic arthritis are at increased risk of osteoporosis, either as part of their disease or because of other risk factors (notably corticosteroid therapy). Systemic diseases such as amyloidosis and sarcoidosis can also lead to osteoporosis.
- Renal insufficiency can lead to renal osteodystrophy.
- Hematologic disorders linked to osteoporosis are multiple myeloma[55] and other monoclonal gammopathies,[56] lymphoma and leukemia, mastocytosis,[55] hemophilia, sickle-cell disease and thalassemia.
- Several inherited disorders have been linked to osteoporosis. These include osteogenesis imperfecta,[55]

Marfan syndrome,[55] hemochromatosis,[5] hypophosphatasia[60] (for which it is often misdiagnosed),[61] glycogen storage diseases, homocystinuria,[55] Ehlers–Danlos syndrome,[55] porphyria, Menkes' syndrome, epidermolysis bullosa and Gaucher's disease.

- People with scoliosis of unknown cause also have a higher risk of osteoporosis. Bone loss can be a feature of complex regional pain syndrome. It is also more frequent in people with Parkinson's disease and chronic obstructive pulmonary disease.
- People with Parkinson's disease have a higher risk of broken bones. This is related to poor balance and poor bone density.[62] In Parkinson's disease there may be a link between the loss of dopaminergic neurons and altered calcium metabolism[63] (and iron metabolism) causing a stiffening of the skeleton and kyphosis.

### Medication [edit]

Certain medications have been associated with an increase in osteoporosis risk; only steroids and anticonvulsants are classically associated, but evidence is emerging with regard to other drugs.

- Steroid-induced osteoporosis (SIOP) arises due to use of glucocorticoids – analogous to Cushing's syndrome and involving mainly the axial skeleton. The synthetic glucocorticoid prescription drug prednisone is a main candidate after prolonged intake. Some professional guidelines recommend prophylaxis in patients who take the equivalent of more than 30 mg hydrocortisone (7.5 mg of prednisolone), especially when this is in excess of three months.[64] Alternate day use may not prevent this complication.[65]
- Barbiturates, phenytoin and some other enzyme-inducing antiepileptics – these probably accelerate the metabolism of vitamin D.[66]
- L-Thyroxine over-replacement may contribute to osteoporosis, in a similar fashion as thyrotoxicosis does.[54] This can be relevant in subclinical hypothyroidism.
- Several drugs induce hypogonadism, for example aromatase inhibitors used in breast cancer, methotrexate and other antimetabolite drugs, depot progesterone and gonadotropin-releasing hormone agonists.
- Anticoagulants – long-term use of heparin is associated with a decrease in bone density,[67] and warfarin (and related coumarins) have been linked with an increased risk in osteoporotic fracture in long-term use.[68]
- Proton pump inhibitors – these drugs inhibit the production of stomach acid; this is thought to interfere with calcium absorption.[69] Chronic phosphate binding may also occur with aluminium-containing antacids.[54]
- Thiazolidinediones (used for diabetes) – rosiglitazone and possibly pioglitazone, inhibitors of PPARγ, have been linked with an increased risk of osteoporosis and fracture.[70]
- Chronic lithium therapy has been associated with osteoporosis.[54]

### Evolutionary [edit]

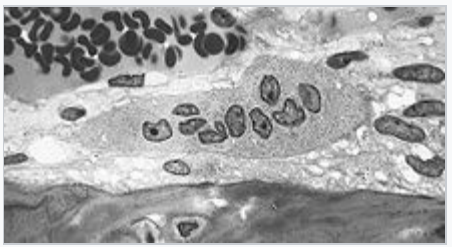
Age-related bone loss is common among humans due to exhibiting less dense bones than other primate species.[71] Because of the more porous bones of humans, frequency of severe osteoporosis and osteoporosis related fractures is higher.[72] The human vulnerability to osteoporosis is an obvious cost but it can be justified by the advantage of bipedalism inferring that this vulnerability is the byproduct of such.[72] It has been suggested that porous bones help to absorb the increased stress that we have on two surfaces compared to our primate counterparts who have four surfaces to disperse the force.[71] In addition, the porosity allows for more flexibility and a lighter skeleton that is easier to support.[72] One other consideration may be that diets today have much lower amounts of calcium than the diets of other primates or the tetrapedal ancestors to humans which may lead to higher likelihood to show signs of osteoporosis.[73]

## Pathogenesis [edit]

The underlying mechanism in all cases of osteoporosis is an imbalance between bone resorption and bone formation. In normal bone, matrix remodeling of bone is constant; up to 10% of all bone mass may be undergoing remodeling at any point in time. The process takes place in bone multicellular units (BMUs) as first described by Frost & Thomas in 1963.[74] Osteoclasts are assisted by transcription factor PU.1 to degrade the bone matrix, while osteoblasts rebuild the bone matrix. Low bone mass density can then occur when osteoclasts are degrading the bone matrix faster than the osteoblasts are rebuilding the bone.[75]

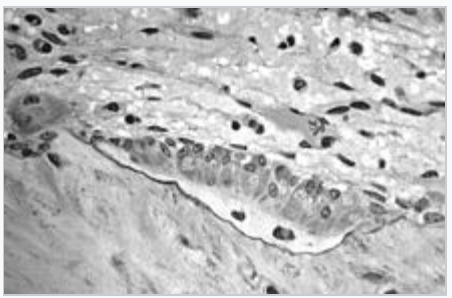
Osteoporosis locations

The three main mechanisms by which osteoporosis develops are an inadequate peak bone mass (the skeleton develops insufficient mass and strength during growth), excessive bone resorption, and inadequate formation of new bone during remodeling. An interplay of these three mechanisms underlies the development of fragile bone tissue.[26] Hormonal factors strongly determine the rate of bone resorption; lack of estrogen (e.g. as a result of menopause) increases bone resorption, as well as decreasing the deposition of new bone that normally takes place in weight-bearing bones. The amount of estrogen needed to suppress this process is lower than that normally needed to stimulate the uterus and breast gland. The α-form of the estrogen receptor appears to be the most important in regulating bone turnover.[26] In addition to estrogen, calcium metabolism plays a significant role in bone turnover, and deficiency of calcium and vitamin D leads to impaired bone deposition; in addition, the parathyroid glands react to low calcium levels by secreting parathyroid hormone (parathormone, PTH), which increases bone resorption to ensure sufficient calcium in the blood. The role of calcitonin, a hormone generated by the thyroid that increases bone deposition, is less clear and probably not as significant as that of PTH.[26]



Light micrograph of an osteoclast displaying typical distinguishing characteristics: a large cell with multiple nuclei and a "foamy" cytosol.

The activation of osteoclasts is regulated by various molecular signals, of which RANKL (receptor activator of nuclear factor kappa-B ligand) (receptor activator of nuclear factor kappa-B ligand) is one of the best studied. This molecule is produced by osteoblasts and other cells (e.g. lymphocytes), and stimulates RANK (receptor activator of nuclear factor κB). Osteoprotegerin (OPG) binds RANKL before it has an opportunity to bind to RANK, and hence suppresses its ability to increase bone resorption. RANKL, RANK and OPG are closely related to tumor necrosis factor and its receptors. The role of the Wnt signaling pathway is recognized, but less well understood. Local production of eicosanoids and interleukins is thought to participate in the regulation of bone turnover, and excess or reduced production of these mediators may underlie the development of osteoporosis.[26]



Light micrograph of osteoblasts, several displaying a prominent Golgi apparatus, actively synthesizing osteoid containing two osteocytes.

Trabecular bone (or cancellous bone) is the sponge-like bone in the ends of long bones and vertebrae. Cortical bone is the hard outer shell of bones and the middle of long bones. Because osteoblasts and osteoclasts inhabit the surface of bones, trabecular bone is more active and is more subject to bone turnover and remodeling. Not only is bone density decreased, but the microarchitecture of bone is also disrupted. The weaker spicules of trabecular bone break ("microcracks"), and are replaced by weaker bone. Common osteoporotic fracture sites, the wrist, the hip and the spine, have a relatively high trabecular bone to cortical bone ratio. These areas rely on the trabecular bone for strength, so the intense remodeling causes these areas to degenerate most when the remodeling is imbalanced.[*citation needed*] Around the ages of 30–35, cancellous or trabecular bone loss begins. Women may lose as much as 50%, while men lose about 30%.[28]

# Diagnosis [edit]

The diagnosis of osteoporosis can be made using conventional radiography and by measuring the bone mineral density (BMD).[76] The most popular method of measuring BMD is dual-energy X-ray absorptiometry. In addition to the detection of abnormal BMD, the diagnosis of osteoporosis requires investigations into potentially modifiable underlying causes; this may be done with blood tests. Depending on the likelihood of an underlying problem, investigations for cancer with metastasis to the bone, multiple myeloma, Cushing's disease and other above-mentioned causes may be performed.

## Conventional radiography [edit]

Conventional radiography is useful, both by itself and in conjunction with CT or MRI, for detecting complications of osteopenia (reduced bone mass; pre-osteoporosis), such as fractures; for differential diagnosis of osteopenia; or for follow-up examinations in specific clinical settings, such as soft tissue calcifications, secondary hyperparathyroidism, or osteomalacia in renal osteodystrophy. However, radiography is relatively insensitive to detection of early disease and requires a substantial amount of bone loss (about 30%) to be apparent on X-ray images.

The main radiographic features of generalized osteoporosis are cortical thinning and increased radiolucency. Frequent complications of osteoporosis are vertebral fractures for which spinal radiography can help considerably in diagnosis and follow-up. Vertebral height measurements can objectively be made using plain-film X-rays by using several methods such as height loss together with area reduction, particularly when looking at vertical deformity in T4-L4, or by determining a spinal fracture index that takes into account the number of vertebrae involved. Involvement of multiple vertebral bodies leads to kyphosis of the thoracic spine, leading to what is known as dowager's hump.

## Dual-energy X-ray [edit]

Dual-energy X-ray absorptiometry (DXA) is considered the gold standard for the diagnosis of osteoporosis. Osteoporosis is diagnosed when the bone mineral density is less than or equal to 2.5 standard deviations below that of a young (30–40-year-old[5]:58), healthy adult women reference population. This is translated as a T-score. But because bone density decreases with age, more people become osteoporotic with increasing age.[5]:58 The World Health Organization has established the following diagnostic guidelines:[5][19]

| Category | T-score range | % young women |
|---|---|---|
| Normal | T-score ≥ −1.0 | 85% |
| Osteopenia | −2.5 < T-score < −1.0 | 14% |
| Osteoporosis | T-score ≤ −2.5 | 0.6% |
| Severe osteoporosis | T-score ≤ −2.5 with fragility fracture[19] | |

The International Society for Clinical Densitometry takes the position that a diagnosis of osteoporosis in men under 50 years of age should not be made on the basis of densitometric criteria alone. It also states, for premenopausal women, Z-scores (comparison with age group rather than peak bone mass) rather than T-scores should be used, and the diagnosis of osteoporosis in such women also should not be made on the basis of densitometric criteria alone.[77]

## Biomarkers [edit]

Chemical biomarkers are a useful tool in detecting bone degradation. The enzyme cathepsin K breaks down type-I collagen protein, an important constituent in bones. Prepared antibodies can recognize the resulting fragment, called a neoepitope, as a way to diagnose osteoporosis.[78] Increased urinary excretion of C-telopeptides, a type-I collagen breakdown product, also serves as a biomarker for osteoporosis.[79]

## Other measuring tools [edit]

Quantitative computed tomography differs from DXA in that it gives separate estimates of BMD for trabecular and cortical bone and reports precise volumetric mineral density in $mg/cm^3$ rather than BMD's relative Z score. Among QCT's advantages: it can be performed at axial and peripheral sites, can be calculated from existing CT scans without a separate radiation dose, is sensitive to change over time, can analyze a region of any size or shape, excludes irrelevant tissue such as fat, muscle, and air, and does not require knowledge of the patient's subpopulation in order to create a clinical score (e.g. the Z-score of all females of a certain age). Among QCT's disadvantages: it requires a high radiation dose compared to DXA, CT scanners are large and expensive, and because its practice has been less standardized than BMD, its results are more operator-dependent. Peripheral QCT has been introduced to improve upon the limitations of DXA and QCT.[76]

Quantitative ultrasound has many advantages in assessing osteoporosis. The modality is small, no ionizing radiation is involved, measurements can be made quickly and easily, and the cost of the device is low compared with DXA and QCT devices. The calcaneus is the most common skeletal site for quantitative ultrasound assessment because it has a high percentage of trabecular bone that is replaced more often than cortical bone, providing early evidence of metabolic change. Also, the calcaneus is fairly flat and parallel, reducing repositioning errors. The method can be applied to children, neonates, and preterm infants, just as well as to adults.[76] Some ultrasound devices can be used on the tibia.[80]

## Screening [edit]

The U.S. Preventive Services Task Force (USPSTF) recommend that all women 65 years of age or older be screened by bone densitometry.[81] Additionally they recommend screening women with increased risk factors that puts them at risk equivalent to a 65 year old.[81] There is insufficient evidence to make recommendations about the intervals for repeated screening and the appropriate age to stop screening.[81] In men the harm versus benefit of screening for osteoporosis is unknown.[81] The International Society for Clinical Densitometry, however, suggest BMD testing for men 70 or older, or those who are indicated for

risk equal to that of a 70 year old.[82] A number of tools exist to help determine who is reasonable to test.[83]

# Prevention [edit]

Lifestyle prevention of osteoporosis is in many aspects the inverse of the potentially modifiable risk factors.[84] As tobacco smoking and high alcohol intake have been linked with osteoporosis, smoking cessation and moderation of alcohol intake are commonly recommended as ways to help prevent it.[85]

In people with coeliac disease adherence to a gluten-free diet decreases the risk of developing osteoporosis[86] and increases bone density.[57] The diet must ensure optimal calcium intake (of at least one gram daily) and measuring vitamin D levels is recommended, and to take specific supplements if necessary.[86]

## Nutrition [edit]

Studies of the benefits of supplementation with calcium and vitamin D are conflicting, possibly because most studies did not have people with low dietary intakes.[87] A 2013 review by the USPSTF found insufficient evidence to determine if supplementation with calcium and vitamin D results in greater harm or benefit in men and premenopausal women.[88] The USPSTF did not recommend low dose supplementation (less than 1 g of calcium and 400 IU of vitamin D) in postmenopausal women as there does not appear to be a difference in fracture risk.[88] It is unknown what effect higher doses have.[88] A 2015 review found little data that supplementation of calcium decreases the risk of fractures.[89]

While some meta-analyses have found a benefit of vitamin D supplements combined with calcium for fractures, they did not find a benefit of vitamin D supplements alone.[90][91]

While supplementation does not appear to affect the risk of death,[91] there is an increased risk of myocardial infarctions with calcium supplementation,[92][93] kidney stones,[88] and stomach problems.[91]

Vitamin K deficiency is also a risk factor for osteoporotic fractures. The gene gamma-glutamylcarboxylase (GGCX) is dependent on vitamin K. Functional polymorphisms in the gene could attribute to variation in bone metabolism and BMD. Vitamin K2 is also used as a means of treatment for osteoporosis and the polymorphisms of GGCX could explain the individual variation in the response to treatment of vitamin K.[94] Vitamin K supplementation may reduce the risk of fractures in postmenopausal women;[95] however, there is no evidence for men.[96]

## Physical exercise [edit]

A 2011 review reported a small benefit of physical exercise on bone density of postmenopausal women.[97] The chances of having a fracture were also slightly reduced (absolute difference 4%).[97] People who exercised had on average less bone loss (0.85% at the spine, 1.03% at the hip).[97]

# Management [edit]

## Lifestyle [edit]

Weight-bearing endurance exercise and/or exercises to strengthen muscles improve bone strength in those with osteoporosis.[97][98] Aerobics, weight bearing, and resistance exercises all maintain or increase BMD in postmenopausal women.[97] Fall prevention can help prevent osteoporosis complications. There is some evidence for hip protectors specifically among those who are in care homes.[99]

## Medications [edit]

Bisphosphonates are useful in decreasing the risk of future fractures in those who have already sustained a fracture due to osteoporosis.[6][7][85] This benefit is present when taken for three to four years.[100] Different bisphosphonates have not been directly compared, therefore it is unknown if one is better than another.[85] Fracture risk reduction is between 25 and 70% depending on the bone involved.[85] There are concerns of atypical femoral fractures and osteonecrosis of the jaw with long-term use, but these risks are low.[85][101] With evidence of little benefit when used for more than three to five years and in light of the potential adverse events, it may be appropriate to stop treatment after this time in some.[100] One medical organization recommends that after five years of medications by mouth or three years of intravenous medication among those at low risk, bisphosphonate treatment can be stopped.[102] In those at higher risk they recommend up to ten years of medication by mouth or six years of intravenous treatment.[102]

For those with osteoporosis but who have not had a fracture evidence does not support a reduction in fracture risk with risedronate[7] or etidronate.[8] Alendronate decreases fractures of the spine but does not have any effect on other types of fractures.[6] Half stop their medications within a year.[103]

Fluoride supplementation does not appear to be effective in postmenopausal osteoporosis, as even though it increases bone density, it does not decrease the risk of fractures.[104][105]

Teriparatide ( a recombinant parathyroid hormone ) has been shown to be effective in treatment of women with postmenopausal osteoporosis.[106] Some evidence also indicates strontium ranelate is effective in decreasing the risk of vertebral and nonvertebral fractures in postmenopausal women with osteoporosis.[107] Hormone replacement therapy, while effective for osteoporosis, is only recommended in women who also have menopausal symptoms.[85] Raloxifene, while effective in decreasing vertebral fractures, does not affect the risk of nonvertebral fracture.[85] And while it reduces the risk of breast cancer, it increases the risk of blood clots and strokes.[85] Denosumab is also effective for preventing osteoporotic fractures.[85] In hypogonadal men, testosterone has been shown to improve bone quantity and quality, but, as of 2008, no studies evaluated its effect on fracture risk or in men with a normal testosterone levels.[56] Calcitonin while once recommended is no longer due to the associated risk of cancer with its use and questionable effect on fracture risk.[108]

Certain medications like alendronate, etidronate, risedronate, raloxifene and strontium ranelate can be helpful for the preventing of osteoporotic fragility fractures in postmenopausal women with osteoporosis.[109]

# Prognosis [edit]

Although osteoporosis patients have an increased mortality rate due to the complications of fracture, it is rarely lethal.

**Hip fractures per 1000 person-years**[110]

| WHO category | Age 50–64 | Age > 64 | Overall |
|---|---|---|---|
| Normal | 5.3 | 9.4 | 6.6 |
| Osteopenia | 11.4 | 19.6 | 15.7 |
| Osteoporosis | 22.4 | 46.6 | 40.6 |

Hip fractures can lead to decreased mobility and additional risks of numerous complications (such as deep venous thrombosis and/or pulmonary embolism, and pneumonia). The six-month mortality rate following hip fracture is around 13.5%, and a substantial proportion (almost 13%) of people who have suffered a hip fracture need total assistance to mobilize after a hip fracture.[111]

Vertebral fractures, while having a smaller impact on mortality, can lead to a severe chronic pain of neurogenic origin, which can be hard to control, as well as deformity. Though rare, multiple vertebral fractures can lead to such severe hunch back (kyphosis), the resulting pressure on internal organs can impair one's ability to breathe.

Apart from risk of death and other complications, osteoporotic fractures are associated with a reduced

health-related quality of life.[112]

The condition is responsible for millions of fractures annually, mostly involving the lumbar vertebrae, hip, and wrist. Fragility fractures of ribs are also common in men.

### Hip fractures [edit]

Hip fractures are responsible for the most serious consequences of osteoporosis. In the United States, more than 250,000 hip fractures annually are attributable to osteoporosis.[113] A 50-year-old white woman is estimated to have a 17.5% lifetime risk of fracture of the proximal femur. The incidence of hip fractures increases each decade from the sixth through the ninth for both women and men for all populations. The highest incidence is found among men and women ages 80 or older.[114]

### Vertebral fractures [edit]

Between 35 and 50% of all women over 50 had at least one vertebral fracture. In the United States, 700,000 vertebral fractures occur annually, but only about a third are recognized. In a series of 9704 women aged 68.8 on average studied for 15 years, 324 had already suffered a vertebral fracture at entry into the study and 18.2% developed a vertebral fracture, but that risk rose to 41.4% in women who had a previous vertebral fracture.[115]

### Wrist fractures [edit]

In the United States, 250,000 wrist fractures annually are attributable to osteoporosis.[113] Wrist fractures are the third most common type of osteoporotic fractures. The lifetime risk of sustaining a Colles' fracture is about 16% for white women. By the time women reach age 70, about 20% have had at least one wrist fracture.[114]

### Rib fractures [edit]

Fragility fractures of the ribs are common in men as young as age 35. These are often overlooked as signs of osteoporosis, as these men are often physically active and suffer the fracture in the course of physical activity. An example would be as a result of falling while water skiing or jet skiing. However, a quick test of the individual's testosterone level following the diagnosis of the fracture will readily reveal whether that individual might be at risk.

## Epidemiology [edit]

It is estimated that 200 million people have osteoporosis.[116] Osteoporosis becomes more common with age.[3] About 15% of White people in their 50s and 70% of those over 80 are affected.[10] It is more common in women than men.[3] In the developed world, depending on the method of diagnosis, 2% to 8% of males and 9% to 38% of females are affected.[11] Rates of disease in the developing world are unclear.[12]

There are 8.9 million fractures worldwide per year due to osteoporosis.[117] Globally, 1 in 3 women and 1 in 5 men over the age of 50 will have an osteoporotic fracture.[117] Data from the United States shows a decrease in osteoporosis within the general population and in white women, from 18% in 1994 to 10% in 2006.[118] White and Asian people are at greater risk.[3] People of African descent are at a decreased risk of fractures due to osteoporosis, although they have the highest risk of death following an osteoporotic fracture.[118]

It has been shown that latitude affects risk of osteoporotic fracture.[119] Areas of higher latitude such as Northern Europe receive less Vitamin D through sunlight compared to regions closer to the equator, and consequently have higher fracture rates in comparison to lower latitudes.[119] For example, Swedish men and women have a 13.% and 28.5% risk of hip fracture by age 50, respectively, whereas this risk is only

1.9% and 2.4% in Chinese men and women.[118] Diet may also be a factor that is responsible for this difference, as vitamin D, calcium, magnesium, and folate are all linked to bone mineral density.[120]

About 22 million women and 5.5 million men in the European Union had osteoporosis in 2010.[13] In the United States in 2010 about 8 million women and one to 2 million men had osteoporosis.[11][14] This places a large economic burden on the healthcare system due to costs of treatment, long-term disability, and loss of productivity in the working population. The EU spends 37 billion euros per year in healthcare costs related to osteoporosis, and the USA spends an estimated 19 billion USD annually for related healthcare costs.[117]

## History [edit]

The link between age-related reductions in bone density and fracture risk goes back at least to Astley Cooper, and the term "osteoporosis" and recognition of its pathological appearance is generally attributed to the French pathologist Jean Lobstein.[121] The American endocrinologist Fuller Albright linked osteoporosis with the postmenopausal state.[122] Bisphosphonates were discovered in the 1960s.[123]

Anthropologists have studied skeletal remains that showed loss of bone density and associated structural changes that were linked to a chronic malnutrition in the agricultural area in which these individuals lived. "It follows that the skeletal deformation may be attributed to their heavy labor in agriculture as well as to their chronic malnutrition", causing the osteoporosis seen when radiographs of the remains were made.[124]

Osteoporosis means "porous bones", from Greek: οστούν/*ostoun* meaning "bone" and πόρος/*poros* meaning "pore".

# Plantar fasciitis

From Wikipedia, the free encyclopedia

**Plantar fasciitis** is a [disorder] that results in [pain] in the [heel] and bottom of the foot.[1] The pain is usually most severe with the first steps of the day or following a period of rest.[2] Pain is also frequently brought on by [bending the foot and toes up towards the shin] and may be worsened by a tight [Achilles tendon].[2][3] The condition typically comes on slowly.[3] In about a third of people both legs are affected.[1] Typically there are no [fevers] or night sweats.[3]

The causes of plantar fasciitis are not entirely clear. Risk factors include overuse such as from long periods of standing, an increase in [exercise], and [obesity].[1] It is also associated with [inward rolling of the foot] and a lifestyle that involves little exercise.[1][2] While [heel spurs] are frequently found it is unclear if they have a role in causing the condition. Plantar fasciitis is a [disorder of the insertion site of the ligament on the bone] characterized by micro tears, breakdown of collagen, and scarring.[1] As [inflammation] plays a lesser role, many feel the condition should be renamed plantar fasciosis.[1][4] The diagnosis is typically based on signs and symptoms with [ultrasound] sometimes used to help.[1] Other conditions with similar symptoms include [osteoarthritis], [ankylosing spondylitis], [heel pad syndrome], and [reactive arthritis].[5][6]

Most cases of plantar fasciitis resolve with time and conservative methods of treatment.[2][7] Usually for the first few weeks people are advised to rest, change their activities, take [pain medications], and stretch. If this is not sufficient [physiotherapy], [orthotics], [splinting], or [steroid injections] may be options. If other measures do not work [extracorporeal shockwave therapy] or surgery may be tried.[2]

Between 4% and 7% of people have heel pain at any given time and about 80% of these cases are due to plantar fasciitis.[1][5] Approximately 10% of people have the disorder at some point during their life.[8] It becomes more common with age. It is unclear if one sex is more affected than the other.[1]

## Signs and symptoms [edit]

When plantar fasciitis occurs, the pain is typically sharp[9] and usually unilateral (70% of cases).[7] Heel pain is worsened by bearing weight on the heel after long periods of rest.[10] Individuals with plantar fasciitis often report their symptoms are most intense during their first steps after getting out of bed or after prolonged periods of sitting.[2] Improvement of symptoms is usually seen with continued walking.[2][6][9] Rare, but reported symptoms include numbness, tingling, swelling, or radiating pain.[11]

If the plantar fascia continues to be overused in the setting of plantar fasciitis, the plantar fascia can rupture. Typical signs and symptoms of plantar fascia rupture include a clicking or snapping sound, significant local swelling, and acute pain in the sole of the foot.[9]

## Risk factors [edit]

Identified risk factors for plantar fasciitis include excessive running, standing on hard surfaces for prolonged periods of time, high arches of the feet, the presence of a leg length inequality, and flat feet. The tendency of flat feet to excessively roll inward during walking or running makes them more susceptible to plantar fasciitis.[2][10][12] Obesity is seen in 70% of individuals who present with plantar fasciitis and is an independent risk factor.[3] Studies have suggested a strong association exists between an increased body mass index and the development of plantar fasciitis in the non-athletic population; this association between weight and plantar fasciitis has not been observed in the athletic population.[7] Achilles tendon tightness and inappropriate footwear have also been identified as significant risk factors.[13]

## Pathophysiology [edit]

The cause of plantar fasciitis is poorly understood and is thought to likely have several contributing factors.[13] The plantar fascia is a thick fibrous band of connective tissue that originates from the medial tubercle and anterior aspect of the heel bone. From there, the fascia extends along the sole of the foot before inserting at the base of the toes, and supports the arch of the foot.[3][10][12]

Drawing of the plantar fascia of

Originally, plantar fasciitis was believed to be an inflammatory condition of the plantar fascia. However, within the last decade, studies have observed microscopic anatomical changes indicating that plantar fasciitis is actually due to a noninflammatory structural breakdown of the plantar fascia rather than an inflammatory process.[7][13]

Due to this shift in thought about the underlying mechanisms in plantar fasciitis, many in the academic community have stated the condition should be renamed plantar fasciosis.[6] The structural breakdown of the

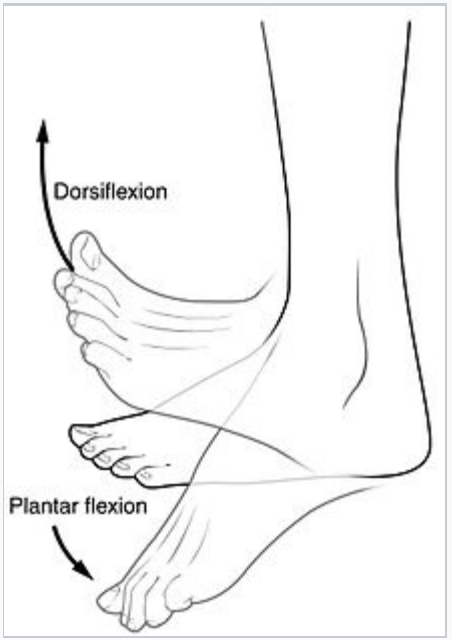
the foot

plantar fascia is believed to be the result of repetitive microtrauma (small tears).[11][12] Microscopic examination of the plantar fascia often shows myxomatous degeneration, connective tissue calcium deposits, and disorganized collagen fibers.[4]

Disruptions in the plantar fascia's normal mechanical movement during standing and walking (known as the Windlass mechanism) are thought to contribute to the development of plantar fasciitis by placing excess strain on the calcaneal tuberosity.[13] Other studies have also suggested that plantar fasciitis is not actually due to inflamed plantar fascia, but may be a tendon injury involving the flexor digitorum brevis muscle located immediately deep to the plantar fascia.[12]

## Diagnosis [edit]

Plantar fasciitis is usually diagnosed by a health care provider after consideration of a person's presenting history, risk factors, and clinical examination.[2][14][15] Tenderness to palpation along the inner aspect of the heel bone on the sole of the foot may be elicited during the physical examination.[2][10] The foot may have limited dorsiflexion due to tightness of the calf muscles or the Achilles tendon.[7] Dorsiflexion of the foot may elicit the pain due to stretching of the plantar fascia with this motion.[2][11] Diagnostic imaging studies are not usually needed to diagnose plantar fasciitis.[7] However, in certain cases a physician may decide imaging studies (such as X-rays, diagnostic ultrasound or MRI) are warranted to rule out serious causes of foot pain.



Achilles tendon tightness is a risk factor for plantar fasciitis. It can lead to decreased dorsiflexion of the foot.

Other diagnoses that are typically considered include fractures, tumors, or systemic disease if plantar fasciitis pain fails to respond appropriately to conservative medical treatments.[2][10] Bilateral heel pain or heel pain in the context of a systemic illness may indicate a need for a more in-depth diagnostic investigation. Diagnostic tests such as a CBC or serological markers of inflammation, infection, or autoimmune disease such as C-reactive protein, erythrocyte sedimentation rate, anti-nuclear antibodies, rheumatoid factor, HLA-B27, uric acid, or Lyme disease antibodies may also be obtained.[5] Neurological deficits may prompt an investigation with electromyography to evaluate for damage to the nerves or muscles.[11]

An incidental finding associated with this condition is a heel spur, a small bony calcification on the calcaneus (heel bone), which can be found in up to 50% of those with plantar fasciitis.[6] In such cases, it is the underlying plantar fasciitis that produces the heel pain, and not the spur itself.[12] The condition is responsible for the creation of the spur though the clinical significance of heel spurs in plantar fasciitis remains unclear.[11]

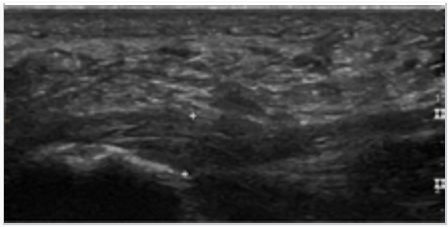
### Imaging [edit]

Medical imaging is not routinely needed as it is expensive and does not typically change how plantar fasciitis is managed.[13] When the diagnosis is not clinically apparent, lateral view x-rays of the ankle are the recommended imaging modality to assess for other causes of heel pain such as stress fractures or bone spur development.[7]

Normally the plantar fascia has three fascicles with the central fascicle thickest at 4 mm, the lateral fascicle at 2 mm and the medial at less



Thickened plantar fascia in ultrasound

than a millimeter in thickness.[16] In theory, the likeliness of fasciitis increases with increasing thickness of plantar fascia at the calcaneal insertion, with thickness of more than 4.5 mm being somewhat useful on ultrasound and 4 mm on MRI.[17] Findings on imaging such as plantar aponeurosis thickening, however, may be absent in symptomatic individuals or present in asymptomatic individuals thereby limiting the utility of such observations.[12]

3-phase bone scan is a sensitive modality to detect active plantar fasciitis. Furthermore, 3-phase bone scan can be used to monitor response to therapy, as demonstrated by decreased uptake after corticosteroid injections.[18]

### Differential diagnosis [edit]

The differential diagnosis for heel pain is extensive and includes pathological entities including, but not limited to the following: calcaneal stress fracture, calcaneal bursitis, osteoarthritis, spinal stenosis involving the nerve roots of lumbar spinal nerve 5 (L5) or sacral spinal nerve 1 (S1), calcaneal fat pad syndrome, hypothyroidism, seronegative spondyloparthopathies such as reactive arthritis, ankylosing spondylitis, or rheumatoid arthritis (more likely if pain is present in both heels),[5] plantar fascia rupture, and compression neuropathies such as tarsal tunnel syndrome or impingement of the medial calcaneal nerve.[3][5][7]

A determination about a diagnosis of plantar fasciitis can usually be made based on a person's medical history and physical examination.[19] In cases in which the physician suspects fracture, infection, or some other serious underlying condition, an x-ray may be used to make a differential diagnosis.[19] However, and especially for people who stand or walk a lot at work, x-rays should not be used to screen for plantar fasciitis unless imaging is otherwise indicated as using it outside of medical guidelines is unnecessary health care.[19]

## Treatment [edit]

### Non-surgical [edit]

About 90% of plantar fasciitis cases will improve within six months with conservative treatment,[8] and within a year regardless of treatment.[2][7] Many treatments have been proposed for plantar fasciitis. Most have not been adequately investigated and there is little evidence to support recommendations for such treatments.[2] First-line conservative approaches include rest, heat, ice, and calf-strengthening exercises; techniques to stretch the calf muscles, Achilles tendon, and plantar fascia; weight reduction in the overweight or obese; and nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin or ibuprofen.[6][10][20] NSAIDs are commonly used to treat plantar fasciitis, but fail to resolve the pain in 20% of people.[10]

Extracorporeal shockwave therapy (ESWT) is an effective treatment modality for plantar fasciitis pain unresponsive to conservative nonsurgical measures for at least three months. Evidence from meta-analyses suggests significant pain relief lasts up to one year after the procedure.[8][21] However, debate about the therapy's efficacy has persisted.[4] ESWT can be performed with or without anesthesia though studies have suggested that the therapy is less effective when anesthesia is given.[22] Complications from ESWT are rare and typically mild when present.[22] Known complications of ESWT include the development of a mild hematoma or an ecchymosis, redness around the site of the procedure, or migraine.[22]

Corticosteroid injections are sometimes used for cases of plantar fasciitis refractory to more conservative measures. The injections may be an effective modality for short-term pain relief up to one month, but studies failed to show effective pain relief after three months.[4] Notable risks of corticosteroid injections for [3]

plantar fasciitis include plantar fascia rupture, skin infection, nerve or muscle injury, or atrophy of the plantar fat pad.[2][10] Custom orthotic devices have been demonstrated as an effective method to reduce plantar fasciitis pain for up to 12 weeks.[23] The long-term effectiveness of custom orthotics for plantar fasciitis pain reduction requires additional study.[24] Orthotic devices and certain taping techniques are proposed to reduce pronation of the foot and therefore reduce load on the plantar fascia resulting in pain improvement.[12]

Another treatment technique known as plantar iontophoresis involves applying anti-inflammatory substances such as dexamethasone or acetic acid topically to the foot and transmitting these substances through the skin with an electric current.[10] Moderate evidence exists to support the use of night splints for 1–3 months to relieve plantar fasciitis pain that has persisted for six months.[7] The night splints are designed to position and maintain the ankle in a neutral position thereby passively stretching the calf and plantar fascia overnight during sleep.[7] Other treatment approaches may include supportive footwear, arch taping, and physical therapy.[6]

### Surgery [edit]

Plantar fasciotomy is often considered after conservative treatment has failed to resolve the issue after six months and is viewed as a last resort.[2][6] Minimally invasive and endoscopic approaches to plantar fasciotomy exist but require a specialist who is familiar with certain equipment. The availability of these surgical techniques is currently limited.[5] A 2012 study found 76% of patients who underwent endoscopic plantar fasciotomy had complete relief of their symptoms and had few complications (level IV evidence).[4] Heel spur removal during plantar fasciotomy has not been found to improve the surgical outcome.[25] Plantar heel pain may occur for multiple reasons and release of the lateral plantar nerve branch may be performed alongside the plantar fasciotomy in select cases.[5][25] Possible complications of plantar fasciotomy include nerve injury, instability of the medial longitudinal arch of the foot,[26] fracture of the calcaneus, prolonged recovery time, infection, rupture of the plantar fascia, and failure to improve the pain.[2] Coblation surgery has recently been proposed as alternative surgical approaches for the treatment of recalcitrant plantar fasciitis.[25]

### Unproven treatments [edit]

Botulinum Toxin A injections as well as similar techniques such as platelet-rich plasma injections and prolotherapy remain controversial.[4][7][10][27]

Dry needling is also being researched for treatment of plantar fasciitis.[28] A systematic review of available research found limited evidence of effectiveness for this technique.[29] The studies were reported to be inadequate in quality and too diverse in methodology to enable reaching a firm conclusion.[29]

## Epidemiology [edit]

Plantar fasciitis is the most common type of plantar fascia injury[9] and is the most common reason for heel pain, responsible for 80% of cases. The condition tends to occur more often in women, military recruits, older athletes, the obese, and young male athletes.[7][11][12]

Plantar fasciitis is estimated to affect 1 in 10 people at some point during their lifetime and most commonly affects people between 40–60 years of age.[3][4] In the United States alone, more than two million people receive treatment for plantar fasciitis.[3] The cost of treating plantar fasciitis in the United States is estimated to be $284 million each year.[3]

# Rheumatoid arthritis

From Wikipedia, the free encyclopedia

**Rheumatoid arthritis** (**RA**) is a long-lasting autoimmune disorder that primarily affects joints. It typically results in warm, swollen, and painful joints. Pain and stiffness often worsen following rest. Most commonly, the wrist and hands are involved, with the same joints typically involved on both sides of the body. The disease may also affect other parts of the body. This may result in a low red blood cell count, inflammation around the lungs, and inflammation around the heart. Fever and low energy may also be present.[1] Often, symptoms come on gradually over weeks to months.[2]

While the cause of rheumatoid arthritis is not clear, it is believed to involve a combination of genetic and environmental factors. The underlying mechanism involves the body's immune system attacking the joints. This results in inflammation and thickening of the joint capsule. It also affects the underlying bone and cartilage.[1] The diagnosis is made mostly on the basis of a person's signs and symptoms.[2] X-rays and laboratory testing may support a diagnosis or exclude other diseases with similar symptoms.[1] Other diseases that may present similarly include systemic lupus erythematosus, psoriatic arthritis, and fibromyalgia among others.[2]

The goal of treatment is to reduce pain, decrease inflammation, and improve a person's overall functioning. This may be helped by balancing rest and exercise, the use of splints and braces, or the use of assistive devices. Pain medications, steroids, and NSAIDs are frequently used to help with symptoms. A group of medications called disease-modifying antirheumatic drugs (DMARDs) may be used to try to slow the progression of disease. They include the medications hydroxychloroquine and methotrexate.[1] Biological DMARDs may be used when disease does not respond to other treatments.[3] However, they may have a greater rate of adverse effects.[4] Surgery to repair, replace, or fuse joints may help in certain situations.[1] Most alternative medicine treatments are not supported by evidence.[5][6]

RA affects between 0.5 and 1% of adults in the developed world with between 5 and 50 per 100,000 people newly developing the condition each year.[3] Onset is most frequent during middle age and women are affected 2.5 times as frequently as men.[1] In 2013, it resulted in 38,000 deaths up from 28,000 deaths in 1990.[7] The first recognized description of RA was made in 1800 by Dr. Augustin Jacob Landré-Beauvais (1772–1840) of Paris.[8] The term *rheumatoid arthritis* is based on the Greek for watery and inflamed joints.[9]

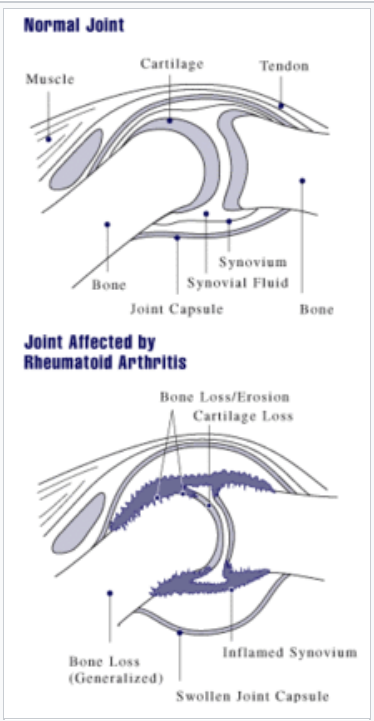
## Signs and symptoms [edit]

RA primarily affects joints, but it also affects other organs in more than 15–25% of individuals.[10]

### Joints [edit]

Arthritis of joints involves inflammation of the synovial membrane. Joints become swollen, tender and warm, and stiffness limits their movement. With time, multiple joints are affected (polyarthritis). Most commonly involved are the small joints of the hands, feet and cervical spine, but larger joints like the shoulder and knee can also be involved.[11]:1089 Synovitis can lead to tethering of tissue with loss of movement and erosion of the joint surface causing deformity and loss of function.[2]



A diagram showing how rheumatoid arthritis affects a joint

RA typically manifests with signs of inflammation, with the affected joints being swollen, warm, painful and stiff, particularly early in the morning on waking or following prolonged inactivity. Increased stiffness early in the morning is often a prominent feature of the disease and typically lasts for more than an hour. Gentle movements may relieve symptoms in early stages of the disease. These signs help distinguish rheumatoid from non-inflammatory problems of the joints, often referred to as osteoarthritis. In arthritis of non-inflammatory causes, signs of inflammation and early morning stiffness are less prominent with stiffness typically less than one hour, and movements induce pain caused by mechanical arthritis.[12] The pain associated with RA is induced at the site of inflammation and classified as nociceptive as opposed to neuropathic.[13] The joints are often affected in a fairly symmetrical fashion, although this is not specific, and the initial presentation may be asymmetrical.[11]:1089

As the pathology progresses the inflammatory activity leads to tendon tethering and erosion and destruction of the joint surface, which impairs range of movement and leads to deformity. The fingers may suffer from almost any deformity depending on which joints are most involved. Specific deformities, which also occur in osteoarthritis, include ulnar deviation, boutonniere deformity (also "buttonhole deformity", flexion of proximal interphalangeal joint and extension of distal interphalangeal joint), swan neck deformity (hyperextension at proximal interphalangeal joint and flexion at distal interphalangeal joint) and "Z-thumb." "Z-thumb" or "Z-deformity" consists of hyperextension of the interphalangeal joint, fixed flexion and subluxation of the metacarpophalangeal joint and gives a "Z" appearance to the thumb.[11]:1089 The hammer toe deformity may be seen. In the worst case, joints are known as arthritis mutilans due to the mutilating nature of the deformities.[14] "Spindling of fingers" of hand occurs due to swelling of the PIP but not DIP joints. "Piano key movement" of the ulnar styloid occurs due to inflammation around the ulnar styloid and tenosynovitis of extensor carpi ulnaris.[*citation needed*]

### Skin [edit]

The rheumatoid nodule, which is sometimes in the skin, is the most common non joint feature.[15] They occur in 30% of people.[15] It is a type of inflammatory reaction known to pathologists as a "necrotizing granuloma". The initial pathologic process in nodule formation is unknown but may be essentially the same as the synovitis, since similar structural features occur in both. The nodule has a central area of fibrinoid necrosis that may be fissured and which corresponds to the fibrin-rich necrotic material found in and around an affected synovial space. Surrounding the necrosis is a layer of palisading macrophages and fibroblasts, corresponding to the intimal layer in synovium and a cuff of connective tissue containing clusters of lymphocytes and plasma cells, corresponding to the subintimal zone in synovitis. The typical rheumatoid nodule may be a few millimetres to a few centimetres in diameter and is usually found over bony prominences, such as the elbow, the heel, the knuckles, or other areas that sustain repeated mechanical stress. Nodules are associated with a positive RF (rheumatoid factor) titer and severe erosive arthritis. Rarely, these can occur in internal organs or at diverse sites on the body.[*citation needed*]

Several forms of *vasculitis* occur in RA. A benign form occurs as microinfarcts around the nailfolds. More severe forms include livedo reticularis, which is a network (reticulum) of erythematous to purplish discoloration of the skin caused by the presence of an obliterative cutaneous capillaropathy.[*citation needed*].

Other, rather rare, skin associated symptoms include pyoderma gangrenosum, Sweet's syndrome, drug reactions, erythema nodosum, lobe panniculitis, atrophy of finger skin, palmar erythema, diffuse thinning (rice paper skin), and skin fragility (often worsened by corticosteroid use).[*citation needed*].

## Lungs [edit]

Fibrosis of the lungs is a recognized response to rheumatoid disease. It is also a rare but well-recognized consequence of therapy (for example with methotrexate and leflunomide). Caplan's syndrome describes lung nodules in individuals with RA and additional exposure to coal dust. Pleural effusions are also associated with RA. Another complication of RA is Rheumatoid Lung Disease. It is estimated that about one-quarter of Americans with RA develop Rheumatoid Lung Disease.[16]

## Kidneys [edit]

Renal amyloidosis can occur as a consequence of chronic inflammation.[17] RA may affect the kidney glomerulus directly through a vasculopathy or a mesangial infiltrate but this is less well documented (though this is not surprising, considering immune complex-mediated hypersensitivities are known for pathogenic deposition of immune complexes in organs where blood is filtered at high pressure to form other fluids, such as urine and synovial fluid[18]). Treatment with penicillamine and gold salts are recognized causes of membranous nephropathy.

## Heart and blood vessels [edit]

People with RA are more prone to atherosclerosis, and risk of myocardial infarction (heart attack) and stroke is markedly increased.[19][20] Other possible complications that may arise include: pericarditis, endocarditis, left ventricular failure, valvulitis and fibrosis.[21] Many people with RA do not experience the same chest pain that others feel when they have angina or myocardial infarction. To reduce cardiovascular risk, it is crucial to maintain optimal control of the inflammation caused by RA (which may be involved in causing the cardiovascular risk), and to use exercise and medications appropriately to reduce other cardiovascular risk factors such as blood lipids and blood pressure. Doctors who treat people with RA should be sensitive to cardiovascular risk when prescribing anti-inflammatory medications, and may want to consider prescribing routine use of low doses of aspirin if the gastrointestinal effects are tolerable.[21]

## Other [edit]

**Eyes**

The eye can be directly affected in the form of episcleritis or scleritis. Scleritis when severe can very rarely progress to perforating scleromalacia. Rather more common is the indirect effect of keratoconjunctivitis sicca, which is a dryness of eyes and mouth caused by lymphocyte infiltration of lacrimal and salivary glands. When severe, dryness of the cornea can lead to keratitis and loss of vision. Preventive treatment of severe dryness with measures such as nasolacrimal duct blockage is important.

**Liver**

Liver problems in people with rheumatoid arthritis may be due to the underlying disease process or as a result of the medications used to treat the disease.[22] A coexisting autoimmune liver disease, such as primary biliary cirrhosis or autoimmune hepatitis may also cause problems.[22]

**Blood**

Anemia is by far the most common abnormality of the blood cells which can be caused by a variety of mechanisms. The chronic inflammation caused by RA leads to raised hepcidin levels, leading to anemia of chronic disease where iron is poorly absorbed and also sequestered into macrophages. RA may also cause a warm autoimmune hemolytic anemia.[23] The red cells are of normal size and color (normocytic and normochromic). A low white blood cell count usually only occurs in people with Felty's syndrome with an enlarged liver and spleen. The mechanism of neutropenia is complex. An increased platelet count occurs when inflammation is uncontrolled.

**Neurological**

Peripheral neuropathy and mononeuritis multiplex may occur. The most common problem is carpal tunnel syndrome caused by compression of the median nerve by swelling around the wrist. Atlanto-axial subluxation can occur, owing to erosion of the odontoid process and/or transverse ligaments in the cervical spine's connection to the skull. Such an erosion (>3mm) can give rise to vertebrae slipping over one another and compressing the spinal cord. Clumsiness is initially experienced, but without due care, this can progress to quadriplegia.

**Constitutional symptoms**

Constitutional symptoms including fatigue, low grade fever, malaise, morning stiffness, loss of appetite and loss of weight are common systemic manifestations seen in people with active RA.

**Bones**

Local osteoporosis occurs in RA around inflamed joints. It is postulated to be partially caused by inflammatory cytokines. More general osteoporosis is probably contributed to by immobility, systemic cytokine effects, local cytokine release in bone marrow

and corticosteroid therapy.

**Cancer**

The incidence of lymphoma is increased in RA, although it is uncommon.[24][25]

## Causes [edit]

RA is a chronic autoimmune disorder the causes of which are not completely understood. It is a systemic (whole body) disorder principally affecting synovial tissues. There is no evidence that physical and emotional effects or stress could be a trigger for the disease. The many negative findings suggest that either the trigger varies, or that it might, in fact, be a chance event inherent with the immune response.[26]

Half of the risk for RA is believed to be genetic.[3] It is strongly associated with the inherited tissue type major histocompatibility complex (MHC) antigen HLA-DRB1 (most specifically the shared epitope alleles, including *0401 and born 0404), and the genes PTPN22 and PADI4—hence family history is an important risk factor.[27][28] Inheriting the PTPN22 gene has been shown to double a person's susceptibility to RA. PADI4 has been identified as a major risk factor in people of Asian descent, but not in those of European descent.[29] First-degree relatives prevalence rate is 2–3% and disease genetic concordance in monozygotic twins is approximately 15–20%.[30][31]

Smoking is the most significant non-genetic risk[3] with RA being up to three times more common in smokers than non-smokers, particularly in men, heavy smokers, and those who are rheumatoid factor positive.[32] Modest alcohol consumption may be protective.[33]

Epidemiological studies have confirmed a potential association between RA and two herpesvirus infections: Epstein-Barr virus (EBV) and Human Herpes Virus 6 (HHV-6).[34] Individuals with RA are more likely to exhibit an abnormal immune response to EBV and have high levels of anti-EBV antibodies.[35]

Vitamin D deficiency is more common in people with rheumatoid arthritis than in the general population.[36][37] However, whether vitamin D deficiency is a cause or a consequence of the disease remains unclear.[38] 1α,25-dihydroxyvitamin D3 (1,25D), an active metabolite of vitamin D, affects bone metabolism indirectly through control of calcium and phosphate homeostasis. Interaction between 1,25D and the vitamin D receptor (VDR) affects the production of RANKL and delays osteoclastogenesis.[39] Some trials have found a decreased risk for RA with vitamin D supplementation while others have not.[37]

## Pathophysiology [edit]

Both genetic, as well as environmental factors, are implicated in the pathophysiology of the disease. Smoking is the main environmental risk to RA.[3] 50% of the risk of having RA is attributable to genetic factors.[3] No infectious agent has been consistently linked with RA and there is no evidence of disease clustering to indicate its infectious etiology.[40] HLA-DR4 is the major genetic factor implicated – but its relative importance varies across ethnic groups.[40][41] Related allotypes of MHC Class II and the T cell-associated protein PTPN22 has also been found associated in many studies.[41]

RA primarily starts as a state of persistent cellular activation leading to autoimmunity and immune complexes in both joints and other, organs where it manifests. The initial site of disease is the synovial membrane, where swelling and congestion leads to infiltration by immune cells. The various phases of progression of RA are:[14]

- Initiation phase, due to non-specific inflammation.
- Amplification phase, due to T cell activation
- Chronic inflammatory phase with tissue injury, due to cytokines IL–1, TNF-alpha and IL–6.

The factors that allow an abnormal immune response, once initiated, to become permanent and chronic, are becoming more clearly understood. The genetic association with HLA-DR4, as well as the newly discovered associations with the gene PTPN22 and with two additional genes,[41] all implicate altered thresholds in regulation of the adaptive immune response. It has also become clear from recent studies that these genetic factors may interact with the most clearly defined environmental risk factor for RA, namely cigarette smoking.[32][42] Other environmental factors also appear to modulate the risk of acquiring RA, and hormonal factors in the individual may explain some features of the disease, such as the higher occurrence in women, the not-infrequent onset after childbirth, and the (slight) modulation of disease risk by hormonal medications. Exactly how altered regulatory thresholds allow the triggering of a specific autoimmune response remains uncertain. However, one possibility is that negative feedback mechanisms that normally maintain tolerance of self are overtaken by aberrant positive feedback mechanisms for certain antigens such as IgG Fc (bound by RF) and citrullinated fibrinogen (bound by ACPA) (see the entry on autoimmunity).The debate on the relative roles of immune complexes and T cell products in inflammation in RA has continued for 30 years. There is little doubt that both B and T cells are essential to the disease. However, there is good evidence for neither cell being necessary at the site of inflammation. This tends to favor immune complexes (based on antibody synthesized elsewhere) as the initiators, even if not the sole perpetuators of inflammation.[*citation needed*] The presence of autoantibodies to IgGFc, known as rheumatoid factors (RF), and antibodies to citrullinated peptides (ACPA) is an integral part of RA disease process. As is the case with many other autoimmune diseases, people with RA have abnormally glycosylated antibodies.[43] It is believed that these glycan (oligosaccharide) alterations promote joint inflammation.[43]

Once the abnormal immune response has become established (which may take several years before any symptoms occur), plasma cells derived from B lymphocytes produce rheumatoid factors and ACPA of the IgG and IgM classes in large quantities. These are not deposited in the way that they are in systemic lupus. Rather, they activate macrophages through Fc receptor and complement binding, which seems to play an important role in the intense inflammatory response present in RA.[44] Binding of an autoreactive antibody to the Fc receptors is mediated through the antibody's N-glycans, which are altered to promote inflammation in people with RA.[43] This contributes to inflammation of the synovium, in terms of edema, vasodilation and infiltration by activated T-cells (mainly CD4 in nodular aggregates and CD8 in diffuse infiltrates). Synovial macrophages and dendritic cells further function as antigen presenting cells by expressing MHC class II molecules, leading to an established local immune reaction in the tissue. The disease progresses in concert with the formation of granulation tissue at the edges of the synovial lining (pannus) with extensive angiogenesis and production of enzymes that cause tissue damage. Modern pharmacological treatments of RA target these mediators. Once the inflammatory reaction is established, the synovium thickens, the cartilage and the underlying bone begins to disintegrate and evidence of joint destruction accrues.

TNF (alpha) plays a major role in the pathogenesis of RA. There are several theories on how TNF release happens in disease process. If TNF release is stimulated by B cell products in the form of RF or ACPA -containing immune complexes, through activation of immunoglobulin Fc receptors, then RA can be seen as a form of Type III hypersensitivity.[45][46] If TNF release is stimulated by T cell products such as interleukin-17 it might be considered closer to type IV hypersensitivity although this terminology may be getting somewhat dated and unhelpful.[47]

Although TNF appears to be the dominant, other cytokines (chemical mediators) are likely to be involved in inflammation in RA. Blockade of TNF does not benefit all persons or all tissues (lung disease and nodules may get worse). Blockade of IL-1, IL-15 and IL-6 also have beneficial effects and IL-17 may be important.[*citation needed*] Constitutional symptoms such as fever, malaise, loss of appetite and weight loss are also caused by cytokines released into the blood stream. As with most autoimmune diseases, it is important to distinguish between the cause(s) that trigger the process and those that may permit it to persist and progress.[*citation needed*]

## Diagnosis [edit]

### Imaging [edit]

X-rays of the hands and feet are generally performed in people with many joints affected. In RA, there may be no changes in the early stages of the disease or the x-ray may demonstrate juxta-articular osteopenia, soft tissue swelling, and loss of joint space. As the disease advances, there may be bony erosions and subluxation. X-rays of other joints may be taken if symptoms of pain or swelling occur in those joints.

Other medical imaging techniques such as magnetic resonance imaging (MRI) and ultrasound are also used in RA.[14]

There have been technical advances in ultrasonography. High-frequency transducers (10 MHz or higher) have improved the spatial resolution of ultrasound images; these images can depict 20% more erosions than conventional radiography. Also, color Doppler and power Doppler ultrasound, which show vascular signals of active synovitis depending on the degree of inflammation, are useful in assessing synovial inflammation. This is important, since in the early stages of RA, the synovium is primarily affected, and synovitis seems to be the best predictive marker of future joint damage.[48]

### Blood tests [edit]

When RA is clinically suspected, testing for the presence of rheumatoid factor (RF, a non-specific antibody) and (ACPAs) may be required.[49] A negative RF does not rule out RA; rather, the arthritis is called *seronegative*. This is the case in about 15% of people with RA.[50][51] During the first year of illness, rheumatoid factor is more likely to be negative with some individuals converting to seropositive status over time. RF is also seen in other illnesses, for example Sjögren's syndrome, hepatitis C, systemic lupus erythematosus, chronic infections and in approximately 10% of the healthy population, therefore the test is not very specific.[14]

Because of this low specificity, new serological tests have been developed, which test for the presence of the anti-citrullinated protein antibodies (ACPAs) or anti-CCP. Like RF, these tests are positive in only a proportion (67%) of all RA cases, but are rarely positive if RA is not present, giving it a specificity of around 95%.[50] As with RF, there is evidence for ACPAs being present in many cases even before onset of clinical disease.[14]

The most common tests for ACPAs are the anti-CCP (cyclic citrullinated peptide) test and the Anti-MCV assay (antibodies against mutated citrullinated Vimentin). Recently a serological point-of-care test (POCT) for the early detection of RA has been developed. This assay combines the detection of rheumatoid factor and anti-MCV for diagnosis of RA and shows a sensitivity of 72% and specificity of 99.7%.[52][53]

Also, several other blood tests are usually done to allow for other causes of arthritis, such as lupus erythematosus. The erythrocyte sedimentation rate (ESR), C-reactive protein, full blood count, kidney function, liver enzymes and other immunological tests (e.g., antinuclear antibody/ANA) are all performed at this stage. Elevated ferritin levels can reveal hemochromatosis, a mimic of RA, or be a sign of Still's disease, a seronegative, usually juvenile, variant of rheumatoid arthritis.[*citation needed*]

## Classification Criteria [edit]

In 2010 the *2010 ACR / EULAR Rheumatoid Arthritis Classification Criteria* were introduced.[54][55] The new criterion is not a diagnostic criterion but a classification criterion to identify disease with a high likelihood of developing a chronic form.[14] However a score of 6 or greater unequivocally classifies a person with a diagnosis of rheumatoid arthritis.

These new classification criteria overruled the "old" ACR criteria of 1987 and are adapted for early RA diagnosis. The "new" classification criteria, jointly published by the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) establish a point value between 0 and 10. Four areas are covered in the diagnosis:[54]

- joint involvement, designating the metacarpophalangeal joints, proximal interphalangeal joints, the interphalangeal joint of the thumb, second through fifth metatarsophalangeal joint and wrist as *small joints*, and shoulders, elbows, hip joints, knees, and ankles as *large joints*:
  - Involvement of 1 large joint gives 0 points
  - Involvement of 2–10 large joints gives 1 point
  - Involvement of 1–3 small joints (with or without involvement of large joints) gives 2 points
  - Involvement of 4–10 small joints (with or without involvement of large joints) gives 3 points
  - Involvement of more than 10 joints (with involvement of at least 1 small joint) gives 5 points
- serological parameters – including the rheumatoid factor as well as ACPA – "ACPA" stands for "anti-citrullinated protein antibody":
  - Negative RF *and* negative ACPA gives 0 points
  - Low-positive RF *or* low-positive ACPA gives 2 points
  - High-positive RF *or* high-positive ACPA gives 3 points
- acute phase reactants: 1 point for elevated erythrocyte sedimentation rate, ESR, or elevated CRP value (c-reactive protein)
- duration of arthritis: 1 point for symptoms lasting six weeks or longer

The new criteria accommodate to the growing understanding of RA and the improvements in diagnosing RA and disease treatment. In the "new" criteria serology and autoimmune diagnostics carries major weight, as ACPA detection is appropriate to diagnose the disease in an early state, before joints destructions occur. Destruction of the joints viewed in radiological images was a significant point of the ACR criteria from 1987.[56] This criterion no longer is regarded to be relevant, as this is just the type of damage that treatment is meant to avoid.

In clinical practice, the following criteria apply:[*citation needed*]

- two or more swollen joints
- morning stiffness lasting more than one hour for at least six weeks
- the detection of rheumatoid factors or autoantibodies against ACPA such as autoantibodies to mutated citrullinated vimentin can confirm the suspicion of RA. A negative autoantibody result does not exclude a diagnosis of RA.

Signs of destruction and inflammation on ultrasonography and magnetic resonance imaging in the second metacarpophalangeal joint in established RA. Thin arrows indicate an erosive change; thick arrows indicate synovitis. Ultrasonography (left side of image) in the (a) longitudinal and (b) the transverse planes shows both signs of destruction and inflammation. Axial T1-weighted magnetic resonance images were obtained (c) before and (d) after contrast administration, also demonstrating synovitis. Additionally, a coronal T1-weighted magnetic resonance image (e) before contrast administration visualizes the same bone erosion as shown in panels c and d.

## Differential diagnoses [edit]

Several other medical conditions can resemble RA, and usually need to be distinguished from it [57][58]

at the time of diagnosis:

- Crystal induced arthritis (gout, and pseudogout) – usually involves particular joints (knee, MTP1, heels) and can be distinguished with an aspiration of joint fluid if in doubt. Redness, asymmetric distribution of affected joints, pain occurs at night and the starting pain is less than an hour with gout.
- Osteoarthritis – distinguished with X-rays of the affected joints and blood tests, age (mostly older persons), starting pain less than an hour, asymmetric distribution of affected joints and pain worsens when using joint for longer periods.
- Systemic lupus erythematosus (SLE) – distinguished by specific clinical symptoms and blood tests (antibodies against double-stranded DNA)
- One of the several types of psoriatic arthritis resembles RA – nail changes and skin symptoms distinguish between them
- Lyme disease causes erosive arthritis and may closely resemble RA – it may be distinguished by blood test in endemic areas
- Reactive arthritis (previously Reiter's disease) – asymmetrically involves heel, sacroiliac joints and large joints of the leg. It is usually associated with urethritis, conjunctivitis, iritis, painless buccal ulcers, and keratoderma blennorrhagica.
- Ankylosing spondylitis – this involves the spine, although an RA-like symmetrical small-joint polyarthritis may occur in the context of this condition.
- Hepatitis C – RA-like symmetrical small-joint polyarthritis may occur in the context of this condition. Hepatitis C may also induce Rheumatoid Factor auto-antibodies

Rarer causes that usually behave differently but may cause joint pains:[57]

- Sarcoidosis, amyloidosis, and Whipple's disease can also resemble RA.
- Hemochromatosis may cause hand joint arthritis.
- Acute rheumatic fever can be differentiated from RA by a migratory pattern of joint involvement and evidence of antecedent streptococcal infection. Bacterial arthritis (such as by *Streptococcus*) is usually asymmetric, while RA usually involves both sides of the body symmetrically.
- Gonococcal arthritis (another bacterial arthritis) is also initially migratory and can involve tendons around the wrists and ankles.

### Monitoring progression [edit]

There are many tools available for monitoring remission in rheumatoid arthritis.

**DAS28**

*Disease Activity Score of 28 joints* (DAS28) is widely used as an indicator of RA disease activity and response to treatment, but is not always a reliable indicator of treatment effect.[59] The joints included in DAS28 are (bilaterally): proximal interphalangeal joints (10 joints), metacarpophalangeal joints (10), wrists (2), elbows (2), shoulders (2) and knees (2). When looking at these joints, both the number of joints with tenderness upon touching (TEN28) and swelling (SW28) are counted. In addition, the erythrocyte sedimentation rate (ESR) is measured. Also, the affected person makes a subjective assessment (SA) of disease activity during the preceding 7 days on a scale between 0 and 100, where 0 is "no activity" and 100 is "highest activity possible". With these parameters, DAS28 is calculated as:[60]

From this, the disease activity of the affected person can be classified as follows:[60]

| Current DAS28 | | DAS28 decrease from initial value | | |
|---|---|---|---|---|
| | | > 1.2 | > 0.6 but ≤ 1.2 | ≤ 0.6 |
| ≤ 3.2 | Inactive | Good improvement | Moderate improvement | No improvement |
| > 3.2 but ≤ 5.1 | Moderate | Moderate improvement | Moderate improvement | No improvement |
| > 5.1 | Very active | Moderate improvement | No improvement | No improvement |

One major limitation of use of the DAS28 score in clinical setting is low-grade synovitis may be missed.[*citation needed*]

**Other**

Other tools to monitor remission in rheumatoid arthritis are: ACR-EULAR Provisional Definition of Remission of Rheumatoid arthritis, Simplified Disease Activity Index (SDAI) and Clinical Disease Activity Index (CDAI).[61]

## Prevention [edit]

There is no known prevention for the condition other than the reduction of risk factors.[62]

## Management [edit]

There is no cure for RA, but treatments can improve symptoms and slow the progress of the disease. Disease-modifying treatment has the best results when it is started early and aggressively.[63]

The goals of treatment are to minimize symptoms such as pain and swelling, to prevent bone deformity (for example, bone erosions visible in X-rays), and to maintain day-to-day functioning.[64] This can often be achieved using two main classes of

medications: analgesics such as NSAIDs, and disease-modifying antirheumatic drugs (DMARDs).[65] RA should generally be treated with at least one specific anti-rheumatic medication.[63] The use of benzodiazepines (such as diazepam) to treat the pain is not recommended as it does not appear to help and is associated with risks.[66] Analgesics, other than NSAIDs, offer lesser, but some benefit with respect to pain whilst not causing the same level of gastrointestinal irritation.[3]

## Lifestyle [edit]

Regular exercise is recommended as both safe and useful to maintain muscles strength and overall physical function.[67] It is uncertain if specific dietary measures have an effect.[68] Physical activity is beneficial for persons with Rheumatoid arthritis complaining of fatigue.[69] Occupational therapy has a positive role to play in improving functional ability of persons with rheumatoid arthritis.[70]

## Disease modifying agents [edit]

Disease-modifying antirheumatic drugs (DMARDs) are the primary treatment for RA.[3] They are a diverse collection of drugs, grouped by use and convention. They have been found to improve symptoms, decrease joint damage, and improve overall functional abilities.[3] DMARDs should be started early in the disease as they result in disease remission in approximately half of people and improved outcomes overall.[71] The following drugs are considered as DMARDs: methotrexate, hydroxychloroquine, sulfasalazine, leflunomide, TNF-alpha inhibitors (certolizumab, infliximab and etanercept), abatacept, and anakinra. Rituximab and tocilizumab are monoclonal antibodies and are also DMARDs.

The most commonly used agent is methotrexate with other frequently used agents including sulfasalazine and leflunomide. Sodium aurothiomalate (gold) and cyclosporin are less commonly used due to more common adverse effects. Agents may be used in combinations.[3] Methotrexate is the most important and useful DMARD and is usually the first treatment.[64][65][72] Adverse effects should be monitored regularly with toxicity including gastrointestinal, hematologic, pulmonary, and hepatic.[72] Side effects such as nausea, vomiting or abdominal pain can be reduced by taking folic acid.[73] The most common undesirable effect is that it increases liver enzymes in almost 15% of people.[72] It is thus recommended that those who consistently demonstrate abnormal levels of liver enzymes or have a history of liver disease or alcohol use undergo liver biopsies.[74]

Biological agents should generally only be used if methotrexate and other conventional agents are not effective after a trial of three months.[75] They are associated with a higher rate of serious infections as compared to other DMARDs.[76] These agents used to treat rheumatoid arthritis include: tumor necrosis factor alpha (TNFα) blockers[3] such as infliximab; interleukin 1 blockers such as anakinra, monoclonal antibodies against B cells such as rituximab and tocilizumab,[77] T cell costimulation blocker such as abatacept among others. They are often used in combination with either methotrexate or leflunomide.[3] In those who are well controlled on TNF blockers decreasing the dose does not appear to affect overall function.[78] Persons should be screened for latent tuberculosis before starting any TNF blockers therapy to avoid reactivation.[14]

TNF blockers and methotrexate appear to have similar effectiveness when used alone and better results are obtained when used together. TNF blockers appear to have equivalent effectiveness with etanercept appearing to be the safest.[79] Abatacept appears effective for RA with 20% more people improving with treatment than without but long term safety studies are yet unavailable.[80] However, there is a lack of evidence to distinguish between the biologics available for RA.[81] Issues with the biologics include their high cost and association with infections including tuberculosis.[3]

## Anti-inflammatory agents [edit]

NSAIDs reduce both pain and stiffness in those with RA.[3] Generally they appear to have no effect on people's long term disease course and thus are no longer first line agents.[3][82] NSAIDs should be used with caution in those with gastrointestinal, cardiovascular, or kidney problems.[83][84][85] Use of methotrexate together with NSAIDS is safe, if adequate monitoring is done.[86]

COX-2 inhibitors, such as celecoxib, and NSAIDs are equally effective.[87] They have a similar gastrointestinal risk as an NSAIDs plus a proton pump inhibitor.[88] In the elderly there is less gastrointestinal intolerance to celecoxib than to NSAIDs alone.[89] There however is an increased risk of myocardial infarction with COX-2 inhibitors.[87] Anti-ulcer medications are not recommended routinely but only in those high risk of gastrointestinal problems.[90]

Glucocorticoids can be used in the short term for flare-ups, while waiting for slow-onset drugs to take effect.[3] Injection of glucocorticoids into individual joints is also effective.[3] While long-term use reduces joint damage it also results in osteoporosis and susceptibility to infections, and thus is not recommended.[3]

## Surgery [edit]

In early phases of the disease, an arthroscopic or open synovectomy may be performed. It consists of the removal of the inflamed synovia and prevents a quick destruction of the affected joints. Severely affected joints may require joint replacement surgery, such as knee replacement.[3] Postoperatively, physiotherapy is always necessary.

## Alternative medicine [edit]

In general, there is not enough evidence to support any complementary health approaches for RA, with safety concerns for some of them. Some mind and body practices and dietary supplements may help people with symptoms and therefore may be beneficial additions to conventional treatments, but there is not enough evidence to draw conclusions.[6] A systematic review of CAM modalities (excluding fish oil) found that " The available evidence does not support their current use in the management of RA.".[91] Studies showing beneficial effects in RA on a wide variety of CAM modalities are often affected by publication bias and are generally not high quality evidence such as randomized controlled trials (RCTs).[5]

A 2005 Cochrane review states that low level laser therapy can be tried to improve pain and morning stiffness due to rheumatoid arthritis as there are few side-effects.[92]

There is some evidence that Tai Chi improves the range of motion of a joint in persons with rheumatoid arthritis.[93] The evidence for acupuncture is inconclusive[94] with it appearing to be equivalent to sham acupuncture.[95]

## Dietary supplements [edit]

### Omega-3

Some evidence supports omega-3 fatty acids and gamma-linolenic acid in RA.[96] The benefit from omega-3 appears modest but consistent,[97] though the current evidence is not strong enough to determine that supplementation with omega-3 polyunsaturated fatty acids (found in fish oil) is an effective treatment for RA.[98] Gamma-linolenic acid, which may reduce pain, tender joint count and stiffness, is generally safe.[99]

### Herbal

The American College of Rheumatology states that no herbal medicines have health claims supported by high-quality evidence and thus they do not recommend their use.[100] There is no scientific basis to suggest that herbal supplements advertised as "natural" are safer for use than conventional medications as both are chemicals. Herbal medications, although labelled "natural", may be toxic or fatal if consumed.[100]

Due to the false belief that herbal supplements are always safe, there is sometimes a hesitancy to report their use which may increase the risk of adverse reaction.[5]

The following are under investigation for treatments for RA, based on preliminary promising results (not recommended for clinical use yet): boswellic acid,[101] curcumin,[102] devil's claw,[103][104] Euonymus alatus,[105] and thunder god vine (*Tripterygium wilfordii*).[106] NCCIH has noted that, "In particular, the herb thunder god vine (Tripterygium wilfordii) can have serious side effects."[6]

There is conflicting evidence on the role of erythropoiesis-stimulating agents for treatment of anemia in persons with rheumatoid arthritis.[107]

## Pregnancy [edit]

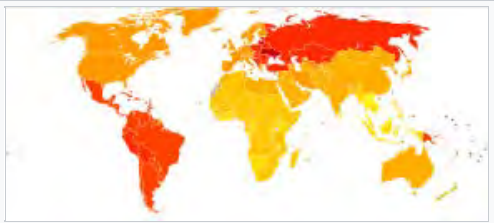
More than 75% of people with rheumatoid arthritis have symptoms improve during pregnancy but might have worsenings after delivery.[14] Methotrexate and leflunomide are teratogenic (harmful to foetus) and not used in pregnancy. It is recommended women of childbearing age should use contraceptives to avoid pregnancy and to discontinue its use if pregnancy is planned.[64][72] Low dose of prednisolone, hydroxychloroquine and sulfasalazine are considered safe in pregnant persons with rheumatoid arthritis.

## Vaccinations [edit]

People with RA have an increased risk of infections and mortality and recommended vaccinations can reduce these risks.[108] The inactivated influenza vaccine should be received annually.[109] The pneumococcal vaccine should be administered twice for people under the age 65 and once for those over 65.[110] Lastly, the live-attenuated zoster vaccine should be administered once after the age 60, but is not recommended in people on a tumor necrosis factor alpha blocker.[111]

# Prognosis [edit]

The course of the disease varies greatly. Some people have mild short-term symptoms, but in most the disease is progressive for life. Around 20%–30% will have subcutaneous nodules (known as rheumatoid nodules); this is associated with a poor prognosis.[*citation needed*]



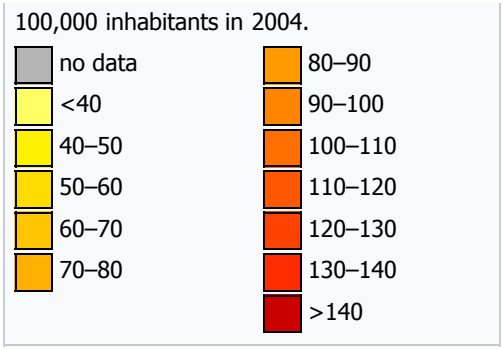
Disability-adjusted life year for RA per [112]

## Prognostic factors [edit]

Poor prognostic factors include,

- Persistent synovitis

Early erosive disease
- Extra-articular findings (including subcutaneous rheumatoid nodules)
- Positive serum RF findings
- Positive serum anti-CCP autoantibodies
- Carriership of HLA-DR4 "Shared Epitope" alleles
- Family history of RA
- Poor functional status
- Socioeconomic factors
- Elevated acute phase response (erythrocyte sedimentation rate [ESR], C-reactive protein [CRP])
- Increased clinical severity.

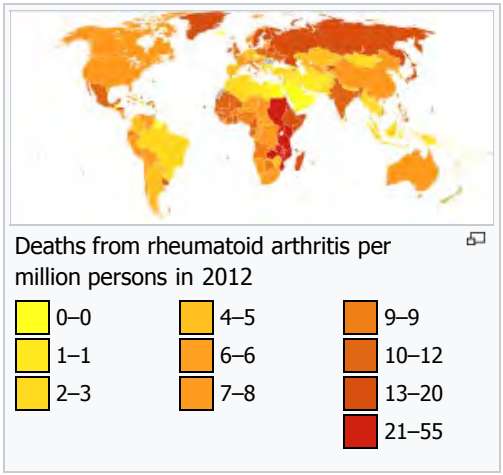


## Mortality [edit]

RA reduces lifespan on average from three to twelve years.[64] According to the UK's National Rheumatoid Arthritis Society, Young age at onset, long disease duration, the concurrent presence of other health problems (called co-morbidity), and characteristics of severe RA—such as poor functional ability or overall health status, a lot of joint damage on x-rays, the need for hospitalisation or involvement of organs other than the joints—have been shown to associate with higher mortality".[113] Positive responses to treatment may indicate a better prognosis. A 2005 study by the Mayo Clinic noted that RA sufferers suffer a doubled risk of heart disease,[114] independent of other risk factors such as diabetes, alcohol abuse, and elevated cholesterol, blood pressure and body mass index. The mechanism by which RA causes this increased risk remains unknown; the presence of chronic inflammation has been proposed as a contributing factor.[115] It is possible that the use of new biologic drug therapies extend the lifespan of people with RA and reduce the risk and progression of atherosclerosis.[116] This is based on cohort and registry studies, and still remains hypothetical. It is still uncertain whether biologics improve vascular function in RA or not. There was an increase in total cholesterol and HDLc levels and no improvement of the atherogenic index.[117]

# Epidemiology [edit]

RA affects between 0.5 and 1% of adults in the developed world with between 5 and 50 per 100,000 people newly developing the condition each year.[3] In 2010 it resulted in about 49,000 deaths globally.[118]



Onset is uncommon under the age of 15 and from then on the incidence rises with age until the age of 80. Women are affected three to five times as often as men.[14]

The age at which the disease most commonly starts is in women between 40 and 50 years of age, and for men somewhat later.[119] RA is a chronic disease, and although rarely, a spontaneous remission may occur, the natural course is almost invariably one of the persistent symptoms, waxing and waning in intensity, and a progressive deterioration of joint structures leading to deformations and disability.

# History [edit]

The first known traces of arthritis date back at least as far as 4500 BC. A text dated 123 AD first describes symptoms very similar to RA.[*citation needed*] It was noted in skeletal remains of Native Americans found in Tennessee.[120] In Europe, the disease is vanishingly rare before the 17th century.[121] The first recognized description of RA in modern medicine was in 1800 by the French physician Dr Augustin Jacob Landré-Beauvais (1772–1840) who was based in the famed Salpêtrière Hospital in Paris.[8] The name "rheumatoid arthritis" itself was coined in 1859 by British rheumatologist Dr Alfred Baring Garrod.[122]

An anomaly has been noticed from the investigation of Pre-Columbian bones. The bones from the Tennessee site show no signs of tuberculosis even though it was prevalent at the time throughout the Americas.[123]

The art of Peter Paul Rubens may possibly depict the effects of RA. In his later paintings, his rendered hands show, in the opinion of some physicians, increasing deformity consistent with the symptoms of the disease.[124][125] RA appears to some to have been depicted in 16th-century paintings.[126] However, it is generally recognized in art historical circles that the painting of hands in the 16th and 17th century followed certain stylized conventions, most clearly seen in the Mannerist movement. It was conventional, for instance, to show the upheld right hand of Christ in what now appears a deformed posture. These conventions are easily misinterpreted as portrayals of disease.

Historic treatments for RA have also included: rest, ice, compression and elevation, apple diet, nutmeg, some light exercise every now and then, nettles, bee venom, copper bracelets, rhubarb diet, extractions of teeth, fasting, honey, vitamins, insulin, magnets, and electroconvulsive therapy (ECT).[127] The Prosorba column blood filtering device (removing IgG) was approved by the FDA in 1999 for treatment of RA[128] However it was discontinued at the end of 2006.[129]

[edit]

## Etymology

Rheumatoid arthritis is derived from the Greek word *ῥεύμα-rheuma (nom.), ῥεύματος-rheumatos (gen.)* ("flow, current"). The suffix *-oid* ("resembling") gives the translation as *joint inflammation that resembles rheumatic fever*. Rhuma which means watery discharge might refer to the fact that the joints are swollen or that the disease may be made worse by wet weather.[9]

# Sarcoidosis

From Wikipedia, the free encyclopedia

**Sarcoidosis** is a disease involving abnormal collections of inflammatory cells that form lumps known as granulomas.[1] The disease usually begins in the lungs, skin, or lymph nodes. Less commonly affected are the eyes, liver, heart, and brain. Any organ, however, can be affected. The signs and symptoms depend on the organ involved. Often there are no, or only mild, symptoms.[1] When it affects the lungs there may be wheezing, cough, shortness of breath, or chest pain.[2] Some may have Löfgren's syndrome in which there is fever, large lymph nodes, arthritis, and a rash known as erythema nodosum.[1]

The cause of sarcoidosis is unknown.[1] Some believe it may be due to an immune reaction to a trigger such as an infection or chemicals in those who are genetically predisposed.[3][4] Those with affected family members are at greater risk.[5] Diagnosis is partly based on signs and symptoms, which may be supported by biopsy. Findings that make it likely include large lymph nodes at the root of the lung on both sides, high blood calcium with a normal parathyroid hormone level, or elevated levels of angiotensin converting enzyme (ACE) in the blood. The diagnosis should only be made after excluding other possible causes of similar symptoms such as tuberculosis.[6]

Many people clear up without any treatment within a few years.[1][7] However some may have long term or severe disease.[7] Some symptoms may be improved with the use of anti-inflammatory drugs such as ibuprofen.[8] In cases where the condition causes significant health problems steroids such as prednisone are indicated. Alternatively, medications such as methotrexate, chloroquine, or azathioprine may occasionally be used in an effort to decrease the side effects of steroids.[9] The risk of death is between one and seven percent.[7] There is a less than five percent chance of the disease returning in someone who has had it previously.[1]

In 2013 pulmonary sarcoidosis and interstitial lung disease affected 595,000 people globally.[10] These two diseases resulted in 471,000 deaths.[11] It is most common in Scandinavians but occurs in all parts of the world. In the United States risk is greater among black as opposed to white people.[12] It usually begins between the ages of 20–50.[5] It occurs more often in women than men.[5]

Sarcoidosis was first described in 1877 by the English doctor Jonathan Hutchinson as a non painful skin

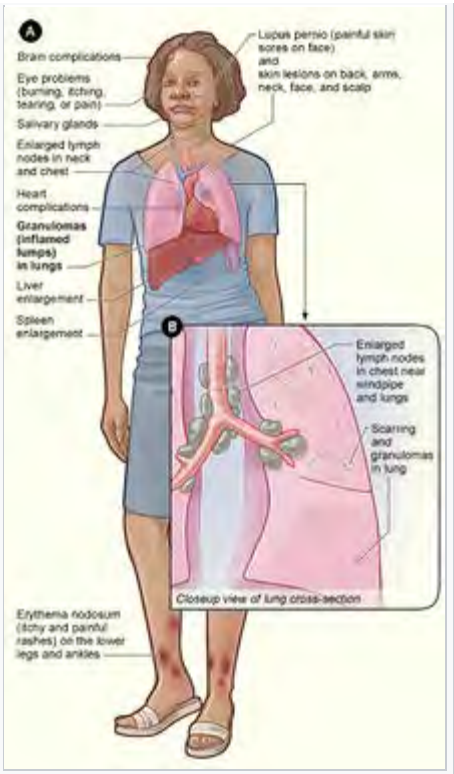
## Signs and symptoms [edit]

Sarcoidosis is a systemic inflammatory disease that can affect any organ, although it can be asymptomatic and is discovered by accident in about 5% of cases.[15] Common symptoms, which tend to be vague, include fatigue (unrelieved by sleep; occurs in 66% of cases), lack of energy, weight loss, joint aches and pains (which occur in about 70% of cases),[16] arthritis (14–38% of persons), dry eyes, swelling of the knees, blurry vision, shortness of breath, a dry, hacking cough, or skin lesions.[17][18][19][20] Less commonly, people may cough up blood.[17] The cutaneous symptoms vary, and range from rashes and noduli (small bumps) to erythema nodosum, granuloma annulare, or lupus pernio. Sarcoidosis and cancer may mimic one another, making the distinction difficult.[21]

The combination of erythema nodosum, bilateral hilar lymphadenopathy, and joint pain is called Löfgren syndrome, which has a relatively good prognosis.[17] This form of the disease occurs significantly more often in Scandinavian patients than in those of non-Scandinavian origin.[22]



Signs and symptoms of sarcoidosis.[14]

## Respiratory tract [edit]

Localization to the lungs is by far the most common manifestation of sarcoidosis.[23] At least 90% of affected persons experience lung involvement.[24] Overall, about 50% develop permanent pulmonary abnormalities, and 5 to 15% have progressive fibrosis of the lung parenchyma. Sarcoidosis of the lung is primarily an interstitial lung disease in which the inflammatory process involves the alveoli, small bronchi and small blood vessels.[25] In acute and subacute cases, physical examination usually reveals dry crackles.[24] At least 5% of persons will suffer pulmonary arterial hypertension.[24][26] Less commonly, the upper respiratory tract (including the larynx, pharynx, and sinuses) may be affected, which occurs in between 5 and 10% of cases.[27]

Sarcoid affecting the skin

There are four stages of pulmonary involvement based on radiological stage of the disease, which is helpful in prognosis:[28]

- Stage I: bilateral hilar lymphadenopathy (BHL) alone
- Stage II: BHL with pulmonary infiltrates
- Stage III: pulmonary infiltrates without BHL
- Stage IV: fibrosis.

Use of the Scadding scale only provides general information regarding the prognosis of the pulmonary disease over time. Caution is recommended as it only shows a general relation with physiological markers of the disease and the variation is such that it has limited applicability in individual assessments, including treatment decisions.[29]

## Skin [edit]

*Main article: Skin manifestations of sarcoidosis*

Sarcoidosis involves the skin in between 9 and 37% of persons and is more common in African Americans than in European Americans.[24] The skin is the second most commonly affected organ after the lungs.[30] The most common lesions are erythema nodosum, plaques, maculopapular eruptions, subcutaneous nodules, and lupus pernio.[30] Treatment is not required, since the lesions usually resolve spontaneously in two to four weeks. Although it may be disfiguring, cutaneous sarcoidosis rarely causes major problems.[24][31][32] Sarcoidosis of the scalp presents with diffuse or patchy hair loss.[33][34]

## Heart [edit]

The frequency of cardiac involvement varies and is significantly influenced by race; in Japan more than 25% of persons with sarcoidosis have symptomatic cardiac involvement, whereas in the US and Europe only about 5% of cases present with cardiac involvement.[24] Autopsy studies in the US have revealed a frequency of cardiac involvement of about 20–30%, whereas autopsy studies in Japan have shown a frequency of 60%.[19] The presentation of cardiac sarcoidosis can range from asymptomatic conduction abnormalities to fatal ventricular arrhythmia.[35][36] Conduction abnormalities are the most common cardiac manifestations of sarcoidosis in humans and can include complete heart block.[37] Second to conduction abnormalities, in frequency, are ventricular arrhythmias, which occurs in about 23% of persons with cardiac involvement.[37] Sudden cardiac death, either due to ventricular arrhythmias or complete heart block is a rare complication of cardiac sarcoidosis.[38][39] Cardiac sarcoidosis can cause fibrosis, granuloma formation, or the accumulation of fluid in the interstitium of the heart, or a combination of the former two.[40][41]

## Eye [edit]

Eye involvement occurs in about 10–90% of cases.[19] Manifestations in the eye include uveitis, uveoparotitis, and retinal inflammation, which may result in loss of visual acuity or blindness.[42] The most common ophthalmologic manifestation of sarcoidosis is uveitis.[19][43][44] The combination of anterior uveitis, parotitis, VII cranial nerve paralysis and fever is called uveoparotid fever or Heerfordt syndrome (D86.8). Development of scleral nodule associated with sarcoidosis has been observed.[45]

## Nervous system [edit]

*Main article: Neurosarcoidosis*

Any of the components of the nervous system can be involved.[46] Sarcoidosis affecting the nervous system is known as neurosarcoidosis.[46] Cranial nerves are most commonly affected, accounting for about 5–30% of neurosarcoidosis cases, and peripheral facial nerve palsy, often bilateral, is the most common neurological manifestation of sarcoidosis.[46][47][48] It occurs suddenly and is usually transient. The central nervous system involvement is present in 10–25% of sarcoidosis cases.[27] Other common manifestations of neurosarcoidosis include optic nerve dysfunction, papilledema, palate dysfunction, neuroendocrine changes, hearing abnormalities, hypothalamic and pituitary abnormalities, chronic meningitis, and peripheral neuropathy.[24] Myelopathy, that is spinal cord involvement, occurs in about 16–43% of neurosarcoidosis cases and is often associated with the poorest prognosis of the neurosarcoidosis subtypes.[46] Whereas facial nerve palsies and acute meningitis due to sarcoidosis tends to have the most favourable prognosis.[46] Another common finding in sarcoidosis with neurological involvement is autonomic or sensory small fiber neuropathy.[49][50] Neuroendocrine sarcoidosis accounts for about 5–10% of neurosarcoidosis cases and can lead to diabetes insipidus, changes in menstrual cycle and hypothalamic dysfunction.[46][48] The latter can lead to changes in body temperature, mood and prolactin (see the endocrine and exocrine section for details).[46]

## Endocrine and exocrine [edit]

Prolactin is frequently increased in sarcoidosis, between 3% and 32% of cases have hyperprolactinemia[51] this frequently leads to amenorrhea, galactorrhea, or nonpuerperal mastitis in women. It also frequently causes an increase in 1,25-dihydroxy vitamin D, the active metabolite of vitamin D, which is usually hydrolysed within the kidney, but in sarcoidosis patients hydroxylation of vitamin D can occur outside the kidneys, namely inside the immune cells found in the granulomas the condition produces. 1 alpha, 25(OH)2D3 is the main cause for hypercalcemia in sarcoidosis and overproduced by sarcoid granulomata. Gamma-interferon produced by activated lymphocytes and macrophages plays a major role in the synthesis of 1 alpha, 25(OH)2D3.[52] Hypercalciuria (excessive secretion of calcium in one's urine) and hypercalcemia (an excessively high amount of calcium in the blood) are seen in <10% of individuals and likely results from [53]

the increased 1,25-dihydroxy vitamin D production. Thyroid dysfunction is seen in 4.2–4.6% of cases.[54][55]

Parotid enlargement occurs in about 5–10% of persons.[16] Bilateral involvement is the rule. The gland is usually not tender, but firm and smooth. Dry mouth can occur; other exocrine glands are affected only rarely.[24] The eyes, their glands, or the parotid glands are affected in 20–50% of cases.[56]

## Gastrointestinal and genitourinary [edit]

Symptomatic GI involvement occurs in less than 1% of persons (note that this is if one excludes the liver), and most commonly the stomach is affected, although the small or large intestine may also be affected in a small portion of cases.[16][57] Studies at autopsy have revealed GI involvement in less than 10% of people.[48] These cases would likely mimic Crohn's disease, which is a more commonly intestine-affecting granulomatous disease.[16] About 1–3% of people have evidence of pancreatic involvement at autopsy.[48] Symptomatic kidney involvement occurs in just 0.7% of cases, although evidence of kidney involvement at autopsy has been reported in up to 22% of people and occurs exclusively in cases of chronic disease.[16][19][48] Symptomatic kidney involvement is usually nephrocalcinosis, although granulomatous interstitial nephritis that presents with reduced creatinine clearance and little proteinuria is a close second.[16][48] Less commonly, the epididymis, testicles, prostate, ovaries, fallopian tubes, uterus, or the vulva may be affected, the latter may cause vulva itchiness.[19][58][59] Testicular involvement has been reported in about 5% of people at autopsy.[48][59] In males, sarcoidosis may lead to infertility.[60]

Around 70% of people have granulomas in their livers, although only in about 20–30% of cases liver function test anomalies reflecting this fact are seen.[17][24] About 5–15% of persons exhibit hepatomegaly, that is an enlarged liver.[19] Only 5–30% of cases of liver involvement are symptomatic.[61] Usually, these changes reflect a cholestatic pattern and include raised levels of alkaline phosphatase (which is the most common liver function test anomaly seen in persons with sarcoidosis), while bilirubin and aminotransferases are only mildly elevated. Jaundice is rare.[16][24]

## Blood [edit]

Abnormal blood tests are frequent, accounting for over 50% of cases, but is not diagnostic.[24][27] Lymphopenia is the most common blood anomaly in sarcoidosis.[24] Anemia occurs in about 20% of people with sarcoidosis.[24] Leukopenia is less common and occurs in even fewer persons but is rarely severe.[24] Thrombocytopenia and hemolytic anemia are fairly rare.[16] In the absence of splenomegaly, leukopenia may reflect bone marrow involvement, but the most common mechanism is a redistribution of blood T cells to sites of disease.[62] Other nonspecific findings include monocytosis, occurring in the majority of sarcoidosis cases,[63] increased hepatic enzymes or alkaline phosphatase. People with sarcoidosis often have immunologic anomalies like allergies to test antigens such as *Candida* or purified protein derivative (PPD).[56] Polyclonal hypergammaglobulinemia is also a fairly common immunologic anomaly seen in sarcoidosis.[56]

Lymphadenopathy (swollen glands) is common in sarcoidosis and occurs in 15% of cases.[20] Intrathoracic nodes are enlarged in 75 to 90% of all people; usually this involves the hilar nodes, but the paratracheal nodes are commonly involved. Peripheral lymphadenopathy is very common, particularly involving the cervical (the most common head and neck manifestation of the disease), axillary, epitrochlear, and inguinal nodes.[64] Approximately 75% of cases show microscopic involvement of the spleen, although only in about 5–10% of cases does splenomegaly appear.[16][56]

## Bone, joints, and muscles [edit]

Sarcoidosis can be involved with the joints, bones and muscles. This causes a wide variety of musculoskeletal complaints that act through different mechanisms.[65] About 5–15% of cases affect the bones, joints, or muscles.[27]

Arthritic syndromes can be categorized in two ways: as acute or chronic.[65] Sarcoidosis patients suffering acute arthritis often also have bilateral Hilar lymphadenopathy and Erythema nodosum. These three associated syndromes often occur together in Löfgren syndrome.[65] The arthritis symptoms of Löfgren syndrome occur most frequently in the ankles, followed by the knees, wrists, elbows, and metacarpophalangeal joints.[65] Usually true arthritis is not present, but instead, periarthritis appears as a swelling in the soft tissue around the joints that can be seen by ultrasonographic methods.[65] These joint symptoms tend to precede or occur at the same time as erythema nodosum develops.[65] Even when erythema nodosum is absent, it is believed that the combination of hilar lymphadenopathy and ankle periarthritis can be considered as a variant of Löfgren syndrome.[65] Enthesitis also occurs in about one-third of patients with acute sarcoid arthritis, mainly affecting the Achilles tendon and heels.[65] Soft tissue swelling of the ankles can be prominent, and biopsy of this soft tissue reveals no granulomas but does show panniculitis that is similar to erythema nodosum.[65]

Chronic sarcoid arthritis usually occurs in the setting of more diffuse organ involvement.[65] The ankles, knees, wrists, elbows, and hands may all be affected in the chronic form and often this presents itself in a polyarticular pattern.[65] Dactylitis similar to that seen in Psoriatic arthritis, that is associated with pain, swelling, overlying skin erythema, and underlying bony changes may also occur.[65] Development of Jaccoud arthropathy (a nonerosive deformity) is very rarely seen.[65]

Bone involvement in sarcoidosis has been reported in 1–13% of cases.[48] The most frequent sites of involvement are the hands and feet, whereas the spine is less commonly affected.[65] Half of the patients with bony lesions experience pain and stiffness, whereas the other half remain asymptomatic.[65] Periostitis is rarely seen in Sarcoidosis and has been found to present itself at the femoral bone.[66][67]

## Cause [edit]

The exact cause of sarcoidosis is not known.[1] The current working hypothesis is, in genetically susceptible individuals, sarcoidosis is caused through alteration to the immune response after exposure to an environmental, occupational, or infectious agent.[68] Some cases may be caused by treatment with TNF inhibitors like etanercept.[69]

### Genetics [edit]

The heritability of sarcoidosis varies according to race, about 20% of African Americans with sarcoidosis have a family member with the condition, whereas the same figure for whites is about 5%.[22] Investigations of genetic susceptibility yielded many candidate genes, but only few were confirmed by further investigations and no reliable genetic markers are known. Currently, the most interesting candidate gene is *BTNL2*; several *HLA-DR* risk alleles are also being investigated.[70][71] In persistent sarcoidosis, the HLA haplotype *HLA-B7-DR15* are either cooperating in disease or another gene between these two loci is associated. In nonpersistent disease, there is a strong genetic association with HLA DR3-DQ2.[72][73] Cardiac sarcoid has been connected to TNFA variants.[74]

### Infectious agents [edit]

Several infectious agents appear to be significantly associated with sarcoidosis, but none of the known associations is specific enough to suggest a direct causative role.[75] The major implicated infectious agents include: mycobacteria, fungi, borrelia, and rickettsia.[76] A meta-analysis investigating the role of mycobacteria in sarcoidosis found it was present in 26.4% of cases, but they also detected a possible publication bias, so the results need further confirmation.[77][78] *Mycobacterium tuberculosis* catalase-peroxidase has been identified as a possible antigen catalyst of sarcoidosis.[79] The disease has also been reported by transmission via organ transplants.[80]

### Autoimmune [edit]

Association of autoimmune disorders has been frequently observed. The exact mechanism of this relation is not known, but some evidence supports the hypothesis that this is a consequence of Th1 lymphokine prevalence.[54][81] Tests of delayed cutaneous hypersensitivity have been used to measure progression.[82]

## Pathophysiology [edit]

Granulomatous inflammation is characterized primarily by accumulation of monocytes, macrophages, and activated T-lymphocytes, with increased production of key inflammatory mediators, TNF, IFN-γ, IL-2, IL-8, IL-10, IL-12, IL-18, IL-23 and TGF-β, indicative of a Th1-mediated immune response.[76][83] Sarcoidosis has paradoxical effects on inflammatory processes; it is characterized by increased macrophage and CD4 helper T-cell activation, resulting in accelerated inflammation, but immune response to antigen challenges such as tuberculin is suppressed. This paradoxic state of simultaneous hyper- and hypoactivity is suggestive of a state of anergy. The anergy may also be responsible for the increased risk of infections and cancer.

The regulatory T-lymphocytes in the periphery of sarcoid granulomas appear to suppress IL-2 secretion, which is hypothesized to cause the state of anergy by preventing antigen-specific memory responses.[84] Schaumann bodies seen in sarcoidosis are calcium and protein inclusions inside of Langhans giant cells as part of a granuloma.

While TNF is widely believed to play an important role in the formation of granulomas (which is further supported by the finding that in animal models of mycobacterial granuloma formation inhibition of either TNF or IFN-γ production inhibits granuloma formation), sarcoidosis can and does still develop in persons being treated with TNF antagonists like etanercept.[85] B cells also likely play a role in the pathophysiology of sarcoidosis.[22] Serum levels of soluble HLA class I antigens and ACE are higher in persons with sarcoidosis.[22] Likewise the ratio of CD4/CD8 T cells in bronchoalveolar lavage is usually higher in persons with pulmonary sarcoidosis (usually >3.5), although it can be normal or even abnormally low in some cases.[22] Serum ACE levels have been found to usually correlate with total granuloma load.[76]

Cases of sarcoidosis have also been reported as part of the immune reconstitution syndrome of HIV, that is, when people receive treatment for HIV their immune system rebounds and the result is that it starts to attack the antigens of opportunistic infections caught prior to said rebound and the resulting immune response starts to damage healthy tissue.[83]

## Diagnosis [edit]

Diagnosis of sarcoidosis is a matter of exclusion, as there is no specific test for the condition. To exclude sarcoidosis in a case presenting with pulmonary symptoms might involve a chest

CT scan of the chest showing lymphadenopathy (arrows) in the mediastinum due to sarcoidosis

radiograph, CT scan of chest, PET scan, CT-guided biopsy, mediastinoscopy, open lung biopsy, bronchoscopy with biopsy, endobronchial ultrasound, and endoscopic ultrasound with fine-needle aspiration of mediastinal lymph nodes (EBUS FNA). Tissue from biopsy of lymph nodes is subjected to both flow cytometry to rule out cancer and special stains (acid fast bacilli stain and Gömöri methenamine silver stain) to rule out microorganisms and fungi.[86][87][88][89]

Serum markers of sarcoidosis, include: serum amyloid A, soluble interleukin 2 receptor, lysozyme, angiotensin converting enzyme, and the glycoprotein KL-6.[90] Angiotensin-converting enzyme blood levels are used in the monitoring of sarcoidosis.[90] A bronchoalveolar lavage can show an elevated (of at least 3.5) CD4/CD8 T cell ratio, which is indicative (but not proof) of pulmonary sarcoidosis.[22] In at least one study the induced sputum ratio of CD4/CD8 and level of TNF was correlated to those in the lavage fluid.[90] A sarcoidosis-like lung disease called Granulomatous–lymphocytic interstitial lung disease can be seen in patients with Common variable immunodeficiency (CVID) and therefore serum antibody levels should be measured to exclude CVID.

Differential diagnosis includes metastatic disease, lymphoma, septic emboli, rheumatoid nodules, granulomatosis with polyangiitis, varicella infection, tuberculosis, and atypical infections, such as *Mycobacterium avium* complex, cytomegalovirus, and cryptococcus.[91] Sarcoidosis is confused most commonly with neoplastic diseases, such as lymphoma, or with disorders characterized also by a mononuclear cell granulomatous inflammatory process, such as the mycobacterial and fungal disorders.[24]

Chest radiograph changes are divided into four stages:[92]

1. bihilar lymphadenopathy
2. bihilar lymphadenopathy and reticulonodular infiltrates
3. bilateral pulmonary infiltrates
4. fibrocystic sarcoidosis typically with upward hilar retraction, cystic and bullous changes

Although people with stage 1 radiographs tend to have the acute or subacute, reversible form of the disease, those with stages 2 and 3 often have the chronic, progressive disease; these patterns do not represent consecutive "stages" of sarcoidosis. Thus, except for epidemiologic purposes, this categorization is mostly of historic interest.[24]

In sarcoidosis presenting in the Caucasian population, hilar adenopathy and erythema nodosum are the most common initial symptoms. In this population, a biopsy of the gastrocnemius muscle is a useful tool in correctly diagnosing the person. The presence of a noncaseating epithelioid granuloma in a gastrocnemius specimen is definitive evidence of sarcoidosis, as other tuberculoid and fungal diseases extremely rarely present histologically in this muscle.[93]

## Classification [edit]

Sarcoidosis may be divided into the following types:[33]

- Annular sarcoidosis
- Erythrodermic sarcoidosis
- Ichthyosiform sarcoidosis
- Hypopigmented sarcoidosis
- Löfgren syndrome
- Lupus pernio
- Morpheaform
- Mucosal sarcoidosis
- Neurosarcoidosis
- Papular sarcoid
- Scar sarcoid
- Subcutaneous sarcoidosis
- Systemic sarcoidosis
- Ulcerative sarcoidosis

# Treatment [edit]

Treatments for sarcoidosis vary greatly depending on the patient.[94] At least half of patients require no systemic therapy.[95] Most persons (>75%) only require symptomatic treatment with non-steroidal anti-inflammatory drugs (NSAIDs) like ibuprofen or aspirin.[96] For persons presenting with lung symptoms, unless the respiratory impairment is devastating, active pulmonary sarcoidosis is observed usually without therapy for two to three months; if the inflammation does not subside spontaneously, therapy is instituted.[24]

Major categories of drug interventions include glucocorticoids, antimetabolites, biologic agents especially monoclonal anti-tumor necrosis factor antibodies, and more recently, specific antibiotic combinations and mesenchymal stem cells.[95] If drug intervention is indicated, a step-wise approach is often used to explore alternatives in order of increasing side effects and to monitor potentially toxic effects.[95]

Corticosteroids, most commonly prednisone or prednisolone, have been the standard treatment for many years.[16] In some people, this treatment can slow or reverse the course of the disease, but other people do not respond to steroid therapy. The use of corticosteroids in mild disease is controversial because in many cases the disease remits spontaneously.[97][98]

## Antimetabolites [edit]

Antimetabolites, also categorized as steroid-sparing agents, such as azathioprine, methotrexate, mycophenolic acid, and leflunomide[99][100] are often used as alternatives to corticosteroids.[16][101] Of these, methotrexate is most widely used and studied.[101][102] Methotrexate is considered a first-line treatment in neurosarcoidosis, often in conjunction with corticosteroids.[46][101] Long-term treatment with methotrexate is associated with liver damage in about 10% of people and hence may be a significant concern in people with liver involvement and requires regular liver function test monitoring.[16] Methotrexate can also lead to pulmonary toxicity (lung damage), although this is fairly uncommon and more commonly it can confound the leukopenia caused by sarcoidosis.[16] Due to these safety concerns it is often recommended that methotrexate is combined with folic acid in order to prevent toxicity.[16] Azathioprine treatment can also lead to liver damage.[102] Leflunomide is being used as a replacement for methotrexate, possibly due to its purportedly lower rate of pulmonary toxicity.[102] Mycophenolic acid has been used successfully in uveal sarcoidosis,[103] neurosarcoidosis (especially CNS sarcoidosis; minimally effective in sarcoidosis myopathy),[104] and pulmonary sarcoidosis.[105][106]

## Immunosuppressants [edit]

As the granulomas are caused by collections of immune system cells, particularly T cells, there has been some success using immunosuppressants (like cyclophosphamide, cladribine,[107] chlorambucil, and cyclosporine), immunomodulatory (pentoxifylline and thalidomide), and anti-tumor necrosis factor treatment[108][109] (such as infliximab, etanercept, golimumab, and adalimumab).[96][110][111]

In a clinical trial cyclosporine added to prednisone treatment failed to demonstrate any significant benefit

over prednisone alone in people with pulmonary sarcoidosis, although there was evidence of increased toxicity from the addition of cyclosporine to the steroid treatment including infections, malignancies (cancers), hypertension, and kidney dysfunction.[102] Likewise chlorambucil and cyclophosphamide are seldom used in the treatment of sarcoidosis due to their high degree of toxicity, especially their potential for causing malignancies.[112] Infliximab has been used successfully to treat pulmonary sarcoidosis in clinical trials in a number of persons.[102] Etanercept, on the other hand, has failed to demonstrate any significant efficacy in people with uveal sarcoidosis in a couple of clinical trials.[102] Likewise golimumab has failed to show any benefit in persons with pulmonary sarcoidosis.[102] One clinical trial of adalimumab found treatment response in about half of subjects, which is similar to that seen with infliximab, but as adalimumab has better tolerability profile it may be preferred over infliximab.[102]

## Specific organ treatments [edit]

Ursodeoxycholic acid has been used successfully as a treatment for cases with liver involvement.[113] Thalidomide has also been tried successfully as a treatment for treatment-resistant lupus pernio in a clinical trial, which may stem from its anti-TNF activity, although it failed to exhibit any efficacy in a pulmonary sarcoidosis clinical trial.[83][110] Cutaneous disease may be successfully managed with antimalarials (such as chloroquine and hydroxychloroquine) and the tetracycline antibiotic, minocycline.[24][110] Antimalarials have also demonstrated efficacy in treating sarcoidosis-induced hypercalcemia and neurosarcoidosis.[16] Long-term use of antimalarials is limited, however, by their potential to cause irreversible blindness and hence the need for regular ophthalmologic screening.[112] This toxicity is usually less of a problem with hydroxychloroquine than with chloroquine, although hydroxychloroquine can disturb the glucose homeostasis.[112]

Recently selective phosphodiesterase 4 (PDE4) inhibitors like apremilast (a thalidomide derivative), roflumilast, and the less subtype-selective PDE4 inhibitor, pentoxifylline, have been tried as a treatment for sarcoidosis, with successful results being obtained with apremilast in cutaneous sarcoidosis in a small open-label study.[114][115] Pentoxifylline has been used successfully to treat acute disease although its use is greatly limited by its gastrointestinal toxicity (mostly nausea, vomiting, and diarrhea).[100][102][112] Case reports have supported the efficacy of rituximab, an anti-CD20 monoclonal antibody and a clinical trial investigating atorvastatin as a treatment for sarcoidosis is under-way.[116][117] ACE inhibitors have been reported to cause remission in cutaneous sarcoidosis and improvement in pulmonary sarcoidosis, including improvement in pulmonary function, remodeling of lung parenchyma and prevention of pulmonary fibrosis in separate case series'.[118][119][120] Nicotine patches have been found to possess anti-inflammatory effects in sarcoidosis patients, although whether they had disease-modifying effects requires further investigation.[121] Antimycobacterial treatment (drugs that kill off mycobacteria, the causative agents behind tuberculosis and leprosy) has also proven itself effective in treating chronic cutaneous (that is, it affects the skin) sarcoidosis in one clinical trial.[122] Quercetin has also been tried as a treatment for pulmonary sarcoidosis with some early success in one small trial.[123]

Because of its uncommon nature, the treatment of male reproductive tract sarcoidosis is controversial. Since the differential diagnosis includes testicular cancer, some recommend orchiectomy, even if evidence of sarcoidosis in other organs is present. In the newer approach, testicular, epididymal biopsy and resection of the largest lesion has been proposed.[60]

## Symptoms [edit]

People with sarcoidosis may have a range of symptoms that do not correspond with objective physical evidence of disease but that still decrease quality of life.[124]

Physical therapy, rehabilitation, and counseling can help avoid deconditioning,[124]:733 and improve social participation, psychological well-being, and activity levels. Key aspects are avoiding exercise intolerance and muscle weakness.[124]:734

Low or moderate-intensity physical training has been shown to improve fatigue, psychological health, and

physical functioning in people sarcoidosis without adverse effects.[125][126] Inspiratory muscle training has also decreased severe fatigue perception in subjects with early stages of sarcoidosis, as well as improving functional and maximal exercise capacity and respiratory muscle strength.[127] The duration, frequency, and physical intensity of exercise needs to accommodate impairments such as joint pain, muscle pain, and fatigue.[124]:734 [126][128]

Neurostimulants such as methylphenidate and modafinil have shown some effectiveness as an adjunct for treatment of sarcoidosis fatigue.[124]:733[129]

Counseling have also benefitted sarcoidosis patients and helped them manage their own conditions.[125]

Treatments for symptomatic neuropathic pain in sarcoidosis patients is similar to that for other causes, and include antidepressants, anticonvulsants and prolonged-release opioids, however only 30-60% of patients experience limited pain relief.[124]:733

## Prognosis [edit]

The disease can remit spontaneously or become chronic, with exacerbations and remissions. In some persons, it can progress to pulmonary fibrosis and death. About half of cases resolve without treatment or can be cured within 12–36 months, and most within five years. Some cases, however, may persist several decades.[16] Two-thirds of people with the condition achieve a remission within 10 years of the diagnosis.[130] When the heart is involved, the prognosis is generally less favourable, although, corticosteroids appear effective in improving AV conduction.[131][132] The prognosis tends to be less favourable in African Americans, compared to white Americans.[22]

Persons with sarcoidosis appear to be at significantly increased risk for cancer, in particular lung cancer, lymphomas,[133] and cancer in other organs known to be affected in sarcoidosis.[134][135] In sarcoidosis-lymphoma syndrome, sarcoidosis is followed by the development of a lymphoproliferative disorder such as non-Hodgkin lymphoma.[136] This may be attributed to the underlying immunological abnormalities that occur during the sarcoidosis disease process.[137] Sarcoidosis can also follow cancer[138][139] or occur concurrently with cancer.[140][141] There have been reports of hairy cell leukemia,[142] acute myeloid leukemia,[143] and acute myeloblastic leukemia[144] associated with sarcoidosis. Sometimes, sarcoidosis, even untreated, can complicated by opportunistic infections.[145][146]

Gross pathology image showing sarcoidosis with honeycombing: Prominent honeycombing is present in the lower lobes accompanied by fibrosis and some honeycombing in the upper lungs. Honeycombing consists of cystically dilated airways separated by scar tissue resembling the honeycomb of bees. It is a nonspecific end stage of many types of interstitial lung disease.

## Epidemiology [edit]

Sarcoidosis most commonly affects young adults of both sexes, although studies have reported more cases in females. Incidence is highest for individuals younger than 40 and peaks in the age-group from 20 to 29 years; a second peak is observed for women over 50.[16][131]

Sarcoidosis occurs throughout the world in all races with an average incidence of 16.5 per 100,000 in men and 19 per 100,000 in women. The disease is most common in Northern European countries and the highest annual incidence of 60 per 100,000 is found in Sweden and Iceland. In the United Kingdom the prevalence is 16 in 100,000.[147] In the United States, sarcoidosis is more common in people of African descent than Caucasians, with annual incidence reported as 35.5 and 10.9 per 100,000, respectively.[148] Sarcoidosis is less commonly reported in South America, Spain, India, Canada, and the Philippines. There may be a higher susceptibility to sarcoidosis in those with celiac disease. An association between the two

disorders has been suggested.[149]

There also has been a seasonal clustering observed in sarcoidosis-affected individuals.[150] In Greece about 70% of diagnoses occur between March and May every year, in Spain about 50% of diagnoses occur between April and June, and in Japan it is mostly diagnosed during June and July.[150]

The differing incidence across the world may be at least partially attributable to the lack of screening programs in certain regions of the world, and the overshadowing presence of other granulomatous diseases, such as tuberculosis, that may interfere with the diagnosis of sarcoidosis where they are prevalent.[131] There may also be differences in the severity of the disease between people of different ethnicities. Several studies suggest the presentation in people of African origin may be more severe and disseminated than for Caucasians, who are more likely to have asymptomatic disease.[62] Manifestation appears to be slightly different according to race and sex. Erythema nodosum is far more common in men than in women and in Caucasians than in other races. In Japanese persons, ophthalmologic and cardiac involvement are more common than in other races.[16]

It is more common in certain occupations, namely firefighters, educators, military personnel, persons who work in industries where pesticides are used, law enforcement, and healthcare personnel.[151] In the year after the September 11 attacks, the rate of sarcoidosis incidence went up four-fold (to 86 cases per 100,000).[27][151]

## History [edit]

It was first described in 1877 by Dr. Jonathan Hutchinson, a dermatologist as a condition causing red, raised rashes on the face, arms, and hands.[13] In 1888 the term Lupus pernio was coined by Dr. Ernest Besnier, another dermatologist.[152] Later in 1892 lupus pernio's histology was defined.[152] In 1902 bone involvement was first described by a group of three doctors.[152] Between 1909 and 1910 uveitis in sarcoidosis was first described, and later in 1915 it was emphasised, by Dr. Schaumann, that it was a systemic condition.[152] This same year lung involvement was also described.[152] In 1937 uveoparotid fever was first described and likewise in 1941 Löfgren syndrome was first described.[152] In 1958 the first international conference on sarcoidosis was called in London, likewise the first USA sarcoidosis conference occurred in Washington, DC in the year 1961.[152] It has also been called Besnier-Boeck disease or Besnier-Boeck-Schaumann disease.[153]

### Etymology [edit]

The word "sarcoidosis" comes from Greek [σάρκο-] *sarco-* meaning "flesh", the suffix *-(e)ido* (from the Greek εἶδος -eidos [usually omitting the initial e in English as the diphthong epsilon-iota in Classic Greek stands for a long "i" = English ee]) meaning "type", " resembles" or "like", and *-sis*, a common suffix in Greek meaning "condition". Thus the whole word means "a condition that resembles crude flesh". The first cases of sarcoïdosis, which were recognised as a new pathological entity, in Scandinavia, at the end of the 19th century exhibited skin nodules resembling cutaneous sarcomas, hence the name initially given.

## Society and culture [edit]

The World Association of Sarcoidosis and Other Granulomatous Disorders (WASOG) is an organisation of physicians involved in the diagnosis and treatment of sarcoidosis and related conditions.[154] WASOG publishes the journal *Sarcoidosis, Vasculitis and Diffuse Lung Diseases*.[155] Additionally, the Foundation for Sarcoidosis Research (FSR) is devoted to supporting research into sarcoidosis and its possible treatments.[156] Online communities provide support for those affected by sarcoidosis.[157]

There have been concerns that World Trade Center rescue workers are at a heightened risk for sarcoidosis.[158][159]

Comedian & actor Bernie Mac suffered from sarcoidosis. In 2005, he mentioned that the disease was in remission.[160] His death on August 9, 2008 was caused by complications from pneumonia, which was precipitated by pulmonary scarring attributed to his sarcoidosis.

In 2014, in a letter to the British medical journal The Lancet, it was suggested that the French Revolution leader Maximilien Robespierre suffered from sarcoidosis, and suggested that the condition caused him a notable impairment during his time as the head of the Reign of Terror.[161]

## Pregnancy [edit]

Sarcoidosis generally does not prevent successful pregnancy and delivery; the increase in estrogen levels during pregnancy may even have a slightly beneficial immunomodulatory effect. In most cases, the course of the disease is unaffected by pregnancy, with improvement in a few cases and worsening of symptoms in very few cases, although it is worth noting that a number of the immunosuppressants (such as methotrexate, cyclophosphamide, and azathioprine) used in corticosteroid-refractory sarcoidosis are known teratogens.[162]

# Sciatica

From Wikipedia, the free encyclopedia

**Sciatica** is a medical condition characterized by pain going down the leg from the lower back.[1] This pain may go down the back, outside, or front of the leg. Typically, symptoms are only on one side of the body. Certain causes, however, may result in pain on both sides. Lower back pain is sometimes but not always present. Weakness or numbness may occur in various parts of the affected leg and foot.[2]

About 90% of the time sciatica is due to a spinal disc herniation pressing on one of the lumbar or sacral nerve roots.[3] Other problems that may result in sciatica include spondylolisthesis, spinal stenosis, piriformis syndrome, pelvic tumors, and compression by a baby's head during pregnancy. The straight leg-raising test is often helpful in diagnosis. The test is positive if, when the leg is raised while a person is lying on their back, pain shoots below the knee.[2] In most cases medical imaging is not needed. Exceptions to this are when bowel or bladder function is affected, there is significant loss of feeling or weakness, symptoms are long standing, or there is a concern of a tumor or infection.[4] Conditions that may present similarly are diseases of the hip and early herpes zoster before the rash appears.[2]

Treatment initially is typically with pain medications.[4] It is generally recommended that people continue with activities to the best of their abilities.[2] Often all that is required is time: in about 90% of people the problem goes away in less than six weeks. If the pain is severe and lasts for more than six weeks then surgery may be an option.[4] While surgery often speeds pain improvement, long term benefits are unclear.[2] Surgery may be required if complications occur such as bowel or bladder problems.[4] Many treatments, including steroids, gabapentin, acupuncture, heat or ice, and spinal manipulation, have poor evidence for their use.[2][5]

Depending on how it is defined, 2% to 40% of people have sciatica at some point in time.[3] It is most common during people's 40s and 50s, and men are more frequently affected than women.[2][4] The condition has been known since ancient times.[2] The first known use of the word *sciatica* dates from 1451.[6]

## Definition [edit]

The term "sciatica" describes a symptom— pain along the sciatic nerve pathway— rather than a specific condition, illness, or disease. Some use it to mean any pain starting in the lower back and going down the leg. Others use the term more specifically to mean a nerve dysfunction caused by compression of one or more lumbar or sacral nerve roots from a spinal disc herniation. though in this second use it is a diagnosis (i.e., it indicates a cause and effect). Pain typically occurs in the distribution of a dermatome and goes below the knee to the foot. It may be associated with neurological dysfunction, such as weakness.[3] The pain is characteristically of a shooting type, quickly traveling along the course of the nerve.[7]

## Causes [edit]

### Spinal disc herniation [edit]

*Main article: Spinal disc herniation*

Spinal disc herniation pressing on one of the lumbar or sacral nerve roots is the most frequent cause of sciatica, being present in about 90% of cases.[3]

Sciatica caused by pressure from a disc herniation and swelling of surrounding tissue can spontaneously subside if the tear in the disc heals and the pulposus extrusion and inflammation cease.

### Spinal stenosis [edit]

*Main article: Lumbar spinal stenosis*

Other compressive spinal causes include lumbar spinal stenosis, a condition in which the spinal canal (the spaces the spinal cord runs through) narrows and compresses the spinal cord, cauda equina, or sciatic nerve roots. This narrowing can be caused by bone spurs, spondylolisthesis, inflammation, or a herniated disc, which decreases available space for the spinal cord, thus pinching and irritating nerves from the spinal cord that travel to the sciatic nerves.

### Piriformis syndrome [edit]

*Main article: Piriformis syndrome*

Piriformis syndrome is a controversial condition that, depending on the analysis, varies from a "very rare" cause to contributing to up to 8% of low back or buttock pain.[8] In 17% of the population, the sciatic nerve runs through the piriformis muscle rather than beneath it. When the muscle shortens or spasms due to trauma or overuse, it is posited that this causes compression of the sciatic nerve.[8] It has colloquially

been referred to as "wallet sciatica" since a wallet carried in a rear hip pocket compresses the buttock muscles and sciatic nerve when the bearer sits down. Piriformis syndrome causes sciatica when the nerve root itself remains normal and no herniation of a spinal disc is apparent.[9][10]

### Pregnancy [edit]

Sciatica may also occur during pregnancy as a result of the weight of the fetus pressing on the sciatic nerve during sitting or during leg spasms. While most cases do not directly harm the fetus or the mother, indirect harm may come from the numbing effect on the legs, which can cause loss of balance and falls. There is no standard treatment for pregnancy-induced sciatica.[11]

### Other [edit]

Sciatica can also be caused by tumors impinging on the spinal cord or the nerve roots.[3] Severe back pain extending to the hips and feet, loss of bladder or bowel control, or muscle weakness may result from spinal tumors or cauda equina syndrome. Trauma to the spine, such as from a car accident, may also lead to sciatica.

## Pathophysiology [edit]

Sciatica is generally caused by the compression of lumbar nerves L4, or L5 or sacral nerves S1, S2, or S3, or by compression of the sciatic nerve itself. When sciatica is caused by compression of a dorsal nerve root (radix), it is considered a lumbar radiculopathy (or radiculitis when accompanied with an inflammatory response). This can occur as a result of a spinal disk bulge or spinal disc herniation (a herniated intervertebral disc), or from roughening, enlarging, or misalignment (*spondylolisthesis*) of the vertebrae, or as a result of degenerated discs that can reduce the diameter of the lateral foramen (natural hole) through which nerve roots exit the spine. The intervertebral discs consist of an annulus fibrosus, which forms a ring surrounding the inner nucleus pulposus. When there is a tear in the anulus fibrosus, the nucleus pulposus (pulp) may extrude through the tear and press against spinal nerves within the spinal cord, cauda equina, or exiting nerve roots, causing inflammation, numbness, or excruciating pain. Inflammation of the spinal canal can also spread to adjacent facet joints and cause lower back pain and/or referred pain in the posterior thigh(s). Pseudosciatic pain can also be caused by compression of peripheral sections of the nerve, usually from soft tissue tension in the piriformis or related muscles.

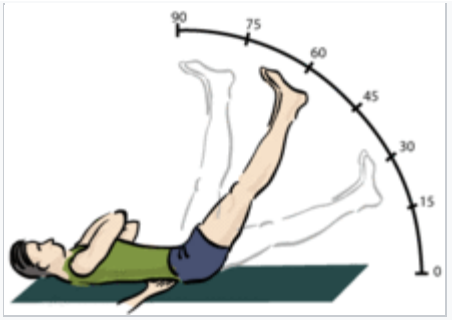
The spinal discs are composed of a tough spongiform ring of cartilage ("anulus fibrosus") with a more malleable center ("nucleus pulposus"). The discs separate the vertebrae, thereby allowing room for the nerve roots to properly exit through the spaces between the vertebrae. The discs cushion the spine from compressive forces, but are weak to pressure applied during rotational movements. That is why a person who bends to one side, at a bad angle to pick something up, may more likely herniate a spinal disc than a person jumping from a ladder and landing on their feet.

Herniation of a disc occurs when the liquid center of the disc bulges outwards, tearing the external ring of fibers, extrudes into the spinal canal, and compresses a nerve root against the lamina or pedicle of a vertebra, thus causing sciatica. This extruded liquid from the "nucleus pulposus" may cause inflammation and swelling of surrounding tissue, which may cause further compression of the nerve root in the confined space in the spinal canal. Many herniated discs themselves, however, cause no pain or discomfort: only occasionally does a disc herniation cause sciatica.

## Diagnosis [edit]

Sciatica is typically diagnosed by physical examination, and the history of the symptoms.[3] Generally if a person reports the typical radiating pain in one leg as well as one or more neurological indications of nerve root tension or neurological deficit, sciatica can be diagnosed.[12]

The most applied diagnostic test is the straight leg raise to produce



Straight Leg test sometimes used to help diagnose a lumbar herniated disc

Lasègue's sign, which is considered positive if pain in the distribution of the sciatic nerve is reproduced with passive flexion of the straight leg between 30 and 70 degrees.[13] While this test is positive in about 90% of people with sciatica, approximately 75% of people with a positive test do not have sciatica.[3]

Imaging tests such as computerised tomography or magnetic resonance imaging can help with the diagnosis of lumbar disc herniation.[14] The utility of MR neurography in the diagnoses of piriformis syndrome is controversial.[8]

## Management [edit]

When the cause of sciatica is lumbar disc herniation, most cases resolve spontaneously over weeks to months.[15] Initially treatment in the first 6–8 weeks should be conservative.[3] There does not appear to be a significant difference in outcomes between advice to stay active and recommendations of bed rest.[16] Similarly, physical therapy (directed exercise) has not been found better than bed rest.[17]

### Medication [edit]

Medicines are commonly prescribed for the treatment of sciatica, but evidence for pain medication is poor.[18] Specifically, low-quality evidence indicates that NSAIDs do not appear to improve immediate pain and all NSAIDs appear about equivalent.[18][19] Evidence is also lacking in use of opioids and muscle relaxants by usual means.[18] In those with sciatica due to piriformis syndrome, botulinum toxin injections may improve pain and or function.[20] There is little evidence for steroids, either epidural or by pill.[21][22] Low-quality evidence supports the use of gabapentin for acute pain relief in those with chronic sciatica.[18]

### Surgery [edit]

Surgery for unilateral sciatica involves the removal of part of the disc, which is known as a discectomy. While it results in short-term benefits, the long-term benefits appear to be equivalent to conservative care.[3][23] Treatment of the underlying cause of the compression is needed in cases of epidural abscess, epidural tumors, and cauda equina syndrome.

### Alternative medicine [edit]

Low to moderate-quality evidence suggests that spinal manipulation is an effective treatment for acute sciatica.[2][24] For chronic sciatica, the evidence is poor.[24] Spinal manipulation has been found generally safe for the treatment of disc-related pain; however, case reports have found an association with cauda equina syndrome[25] and it is contraindicated when there are progressive neurological deficits.[26]

## Epidemiology [edit]

Depending on how it is defined, 2% to 40% of people have sciatica at some point in time.[3] It is most common during people's 40s and 50s and men are more frequently affected than women.[2][4]

# Abortion

From Wikipedia, the free encyclopedia

*For other uses, see Abortion (disambiguation).*

**Abortion** is the ending of pregnancy by removing a fetus or embryo before it can survive outside the uterus.[note 1] An abortion which occurs spontaneously is also known as a miscarriage. An abortion may be caused purposely and is then called an induced abortion, or less frequently, "induced miscarriage". The word *abortion* is often used to mean only induced abortions. A similar procedure after the fetus could potentially survive outside the womb is known as a "late termination of pregnancy".[1]

When allowed by local law, abortion in the developed world is one of the safest procedures in medicine.[2][3] Modern methods use medication or surgery for abortions.[4] The drug mifepristone in combination with prostaglandin appears to be as safe and effective as surgery during the first and second trimester of pregnancy.[4][5] Birth control, such as the pill or intrauterine devices, can be used immediately following abortion.[5] When performed legally and safely, induced abortions do not increase the risk of long-term mental or physical problems.[6] In contrast, unsafe abortions cause 47,000 deaths and 5 million hospital admissions each year.[6][7] The World Health Organization recommends safe and legal abortions be available to all women.[8]

Around 56 million abortions occur each year in the world,[9] with a little under half done unsafely.[10] Abortion rates changed little between 2003 and 2008,[10] before which they decreased for at least two decades as access to family planning and birth control increased.[11] As of 2008, 40% of the world's women had access to legal abortions without limits as to reason.[12] Countries that permit abortions have different limits on how late in pregnancy abortion is allowed.[12]

Since ancient times, abortions have been done using herbal medicines, sharp tools, with force, or through other traditional methods.[13] Abortion laws and cultural or religious views of abortions are different around the world. In some areas abortion is legal only in specific cases such as rape, problems with the fetus, poverty, risk to a woman's health, or incest.[14] In many places there is much debate over the moral, ethical, and legal issues of abortion.[15][16] Those who oppose abortion often maintain that an embryo or fetus is a human with a right to life and may compare abortion to murder.[17][18] Those who favor the legality of abortion often hold that a woman has a right to make decisions about her own body.[19]

# Types

## Induced

Approximately 205 million pregnancies occur each year worldwide. Over a third are unintended and about a fifth end in induced abortion.[10][20] Most abortions result from unintended pregnancies.[21][22] In the United Kingdom, 1 to 2% of abortions are done due to genetic problems in the fetus.[6] A pregnancy can be intentionally aborted in several ways. The manner selected often depends upon the gestational age of the embryo or fetus, which increases in size as the pregnancy progresses.[23][24] Specific procedures may also be selected due to legality, regional availability, and doctor or a women's personal preference.

Reasons for procuring induced abortions are typically characterized as either therapeutic or elective. An abortion is medically referred to as a therapeutic abortion when it is performed to save the life of the pregnant woman; prevent harm to the woman's physical or mental health; terminate a pregnancy where indications are that the child will have a significantly increased chance of premature morbidity or mortality or be otherwise disabled; or to selectively reduce the number of fetuses to lessen health risks associated with multiple pregnancy.[25][26] An abortion is referred to as an elective or voluntary abortion when it is performed at the request of the woman for non-medical reasons.[26] Confusion sometimes arises over the term "elective" because "elective surgery" generally refers to all scheduled surgery, whether medically necessary or not.[27]

## Spontaneous

*Main article: Miscarriage*

Spontaneous abortion, also known as miscarriage, is the unintentional expulsion of an embryo or fetus before the 24th week of gestation.[28] A pregnancy that ends before 37 weeks of gestation resulting in a live-born infant is known as a "premature birth" or a "preterm birth".[29] When a fetus dies in utero after viability, or during delivery, it is usually termed "stillborn".[30] Premature births and stillbirths are generally

not considered to be miscarriages although usage of these terms can sometimes overlap.[31]

Only 30% to 50% of conceptions progress past the first trimester.[32] The vast majority of those that do not progress are lost before the woman is aware of the conception,[26] and many pregnancies are lost before medical practitioners can detect an embryo.[33] Between 15% and 30% of known pregnancies end in clinically apparent miscarriage, depending upon the age and health of the pregnant woman.[34] 80% of these spontaneous abortions happen in the first trimester.[35]

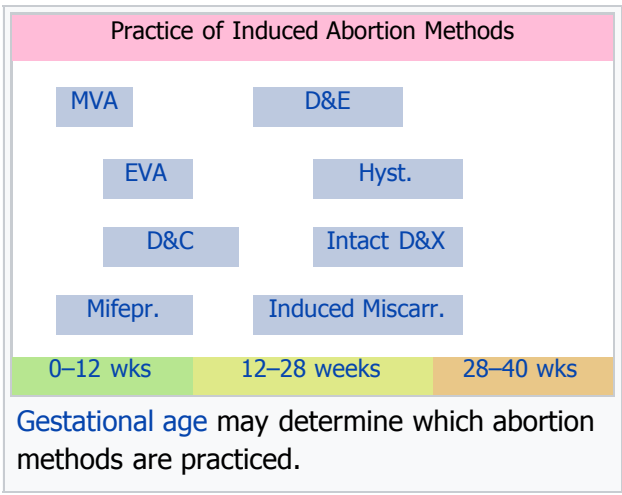
The most common cause of spontaneous abortion during the first trimester is chromosomal abnormalities of the embryo or fetus,[26][36] accounting for at least 50% of sampled early pregnancy losses.[37] Other causes include vascular disease (such as lupus), diabetes, other hormonal problems, infection, and abnormalities of the uterus.[36] Advancing maternal age and a women's history of previous spontaneous abortions are the two leading factors associated with a greater risk of spontaneous abortion.[37] A spontaneous abortion can also be caused by accidental trauma; intentional trauma or stress to cause miscarriage is considered induced abortion or feticide.[38]

# Methods

## Medical

*Main article: Medical abortion*

Medical abortions are those induced by abortifacient pharmaceuticals. Medical abortion became an alternative method of abortion with the availability of prostaglandin analogs in the 1970s and the antiprogestogen mifepristone (also known as RU-486) in the 1980s.[4][5][39][40][41]



Gestational age may determine which abortion methods are practiced.

The most common early first-trimester medical abortion regimens use mifepristone in combination with a prostaglandin analog (misoprostol or gemeprost) up to 9 weeks gestational age, methotrexate in combination with a prostaglandin analog up to 7 weeks gestation, or a prostaglandin analog alone.[39] Mifepristone–misoprostol combination regimens work faster and are more effective at later gestational ages than methotrexate–misoprostol combination regimens, and combination regimens are more effective than misoprostol alone.[40] This regime is effective in the second trimester.[42]

In very early abortions, up to 7 weeks gestation, medical abortion using a mifepristone–misoprostol combination regimen is considered to be more effective than surgical abortion (vacuum aspiration), especially when clinical practice does not include detailed inspection of aspirated tissue.[43] Early medical abortion regimens using mifepristone, followed 24–48 hours later by buccal or vaginal misoprostol are 98% effective up to 9 weeks gestational age.[44] If medical abortion fails, surgical abortion must be used to complete the procedure.[45]

Early medical abortions account for the majority of abortions before 9 weeks gestation in Britain,[46][47] France,[48] Switzerland,[49] and the Nordic countries.[50] In the United States, the percentage of early medical abortions is far lower.[51][52]

Medical abortion regimens using mifepristone in combination with a prostaglandin analog are the most common methods used for second-trimester abortions in Canada, most of Europe, China and India,[41] in contrast to the United States where 96% of second-trimester abortions are performed surgically by dilation and evacuation.[53]

## Surgical

Up to 15 weeks' gestation, suction-aspiration or vacuum aspiration are the most common surgical methods of induced abortion.[54] *Manual vacuum aspiration* (MVA) consists of removing the fetus or embryo, placenta, and membranes by suction using a manual syringe, while *electric vacuum aspiration* (EVA) uses an electric pump. These techniques differ in the mechanism used to apply suction, in how early in pregnancy they can be used, and in whether cervical dilation is necessary.

MVA, also known as "mini-suction" and "menstrual extraction", can be used in very early pregnancy, and does not require cervical dilation. Dilation and curettage (D&C), the second most common method of surgical abortion, is a standard gynecological procedure performed for a variety of reasons, including examination of the uterine lining for possible malignancy, investigation of abnormal bleeding, and abortion. Curettage refers to cleaning the walls of the uterus with a curette. The World Health Organization recommends this procedure, also called *sharp curettage,* only when MVA is unavailable.[55]

From the 15th week of gestation until approximately the 26th, other techniques must be used. Dilation and evacuation (D&E) consists of opening the cervix of the uterus and emptying it using surgical instruments and suction. After the 16th week of gestation, abortions can also be induced by intact dilation and extraction (IDX) (also called intrauterine cranial decompression), which requires surgical decompression of the fetus's head before evacuation. IDX is sometimes called "partial-birth abortion", which has been federally banned in the United States.

In the third trimester of pregnancy, induced abortion may be performed surgically by intact dilation and extraction or by hysterotomy. Hysterotomy abortion is a procedure similar to a caesarean section and is performed under general anesthesia. It requires a smaller incision than a caesarean section and is used during later stages of pregnancy.[56]

First-trimester procedures can generally be performed using local anesthesia, while second-trimester methods may require deep sedation or general anesthesia.[52]

## Labor induction abortion

In places lacking the necessary medical skill for dilation and extraction, or where preferred by practitioners, an abortion can be induced by first inducing labor and then inducing fetal demise if necessary.[57] This is sometimes called "induced miscarriage". This procedure may be performed from 13 weeks gestation to the third trimester. Although it is very uncommon in the United States, more than 80% of induced abortions throughout the second trimester are labor induced abortions in Sweden and other nearby countries.[58]

Only limited data are available comparing this method with dilation and extraction.[58] Unlike D&E, labor induced abortions after 18 weeks may be complicated by the occurrence of brief fetal survival, which may be legally characterized as live birth. For this reason, labor induced abortion is legally risky in the U.S.[58][59]

## Other methods

Historically, a number of herbs reputed to possess abortifacient properties have been used in folk medicine: tansy, pennyroyal, black cohosh, and the now-extinct silphium.[60] The use of herbs in such a manner can cause serious—even lethal—side effects, such as multiple organ failure, and is not recommended by physicians.[61]

Abortion is sometimes attempted by causing trauma to the abdomen. The degree of force, if severe, can cause serious internal injuries without necessarily succeeding in inducing miscarriage.[62] In Southeast Asia,

there is an ancient tradition of attempting abortion through forceful abdominal massage.[63] One of the bas reliefs decorating the temple of Angkor Wat in Cambodia depicts a demon performing such an abortion upon a woman who has been sent to the underworld.[63]

Reported methods of unsafe, self-induced abortion include misuse of misoprostol, and insertion of non-surgical implements such as knitting needles and clothes hangers into the uterus. These methods are rarely seen in developed countries where surgical abortion is legal and available.[64] All of these, and any other method to terminate pregnancy may be called "induced miscarriage".

# Safety

The health risks of abortion depend principally upon whether the procedure is performed safely or unsafely. The World Health Organization defines unsafe abortions as those performed by unskilled individuals, with hazardous equipment, or in unsanitary facilities.[65] Legal abortions performed in the developed world are among the safest procedures in medicine.[2][66] In the US, the risk of maternal death from abortion is 0.7 per 100,000 procedures,[3] making abortion about 13 times safer for women than childbirth (8.8 maternal deaths per 100,000 live births).[67][68] The risk of abortion-related mortality increases with gestational age, but remains lower than that of childbirth through at least 21 weeks' gestation.[69][70][71] Outpatient abortion is as safe and effective from 64 to 70 days' gestation as it is from 57 to 63 days.[72] In the United States from 2000 to 2009, abortion had a lower mortality rate than plastic surgery.[73]

Vacuum aspiration in the first trimester is the safest method of surgical abortion, and can be performed in a primary care office, abortion clinic, or hospital. Complications are rare and can include uterine perforation, pelvic infection, and retained products of conception requiring a second procedure to evacuate.[74] Infections account for one-third of abortion-related deaths in the United States.[75] The rate of complications of vacuum aspiration abortion in the first trimester is similar regardless of whether the procedure is performed in a hospital, surgical center, or office.[76] Preventive antibiotics (such as doxycycline or metronidazole) are typically given before elective abortion,[77] as they are believed to substantially reduce the risk of postoperative uterine infection.[52][78] Complications after second-trimester abortion are similar to those after first-trimester abortion, and depend somewhat on the method chosen.

There is little difference in terms of safety and efficacy between medical abortion using a combined regimen of mifepristone and misoprostol and surgical abortion (vacuum aspiration) in early first trimester abortions up to 9 weeks gestation.[43] Medical abortion using the prostaglandin analog misoprostol alone is less effective and more painful than medical abortion using a combined regimen of mifepristone and misoprostol or surgical abortion.[79][80]

Some purported risks of abortion are promoted primarily by anti-abortion groups, but lack scientific support.[81] For example, the question of a link between induced abortion and breast cancer has been investigated extensively. Major medical and scientific bodies (including the World Health Organization, the US National Cancer Institute, the American Cancer Society, the Royal College of Obstetricians and Gynaecologists and the American Congress of Obstetricians and Gynecologists) have concluded that abortion does not cause breast cancer,[82] although such a link continues to be studied[83][84] and promoted by anti-abortion groups.[81][85]

## Mental health

*Main article: Abortion and mental health*

There is no relationship between most induced abortions and mental-health problems[6][86] other than

those expected for any unwanted pregnancy.[87] The American Psychological Association has concluded that a woman's first abortion is not a threat to mental health when carried out in the first trimester, with such women no more likely to have mental-health problems than those carrying an unwanted pregnancy to term; the mental-health outcome of a woman's second or greater abortion is less certain.[87][88] Although some studies show negative mental-health outcomes in women who choose abortions after the first trimester because of fetal abnormalities,[89] more rigorous research would be needed to show this conclusively.[90] Some proposed negative psychological effects of abortion have been referred to by anti-abortion advocates as a separate condition called "post-abortion syndrome", which is not recognized by medical or psychological professionals in the United States.[91]

## Unsafe abortion

*Main article: Unsafe abortion*

Women seeking to terminate their pregnancies sometimes resort to unsafe methods, particularly when access to legal abortion is restricted. They may attempt to self-abort or rely on another person who does not have proper medical training or access to proper facilities. This has a tendency to lead to severe complications, such as incomplete abortion, sepsis, hemorrhage, and damage to internal organs.[92]

Soviet poster circa 1925, warning against midwives performing abortions. Title translation: "Abortions performed by either trained or self-taught midwives not only maim the woman, they also often lead to death."

Unsafe abortions are a major cause of injury and death among women worldwide. Although data are imprecise, it is estimated that approximately 20 million unsafe abortions are performed annually, with 97% taking place in developing countries.[2] Unsafe abortions are believed to result in millions of injuries.[2][93] Estimates of deaths vary according to methodology, and have ranged from 37,000 to 70,000 in the past decade;[2][7][94] deaths from unsafe abortion account for around 13% of all maternal deaths.[95] The World Health Organization believes that mortality has fallen since the 1990s.[96] To reduce the number of unsafe abortions, public health organizations have generally advocated emphasizing the legalization of abortion, training of medical personnel, and ensuring access to reproductive-health services.[97] However, the Dublin Declaration on Maternal Health, signed in 2012, notes that "the prohibition of abortion does not affect, in any way, the availability of optimal care to pregnant women".[98]

A major factor in whether abortions are performed safely or not is the legal standing of abortion. Countries with restrictive abortion laws have higher rates of unsafe abortion and similar overall abortion rates compared to those where abortion is legal and available.[7][10][97][99][100][101][102] For example, the 1996 legalization of abortion in South Africa had an immediate positive impact on the frequency of abortion-related complications,[103] with abortion-related deaths dropping by more than 90%.[104] A 2011 study concluded that in the United States, some state-level anti-abortion laws are correlated with lower rates of abortion in that state.[105] The analysis, however, did not take into account travel to other states without such laws to obtain an abortion.[106] In addition, a lack of access to effective contraception contributes to unsafe abortion. It has been estimated that the incidence of unsafe abortion could be reduced by up to 75% (from 20 million to 5 million annually) if modern family planning and maternal health services were readily available globally.[107] Rates of such abortions may be difficult to measure because they can be reported variously as miscarriage, "induced miscarriage", "menstrual regulation", "mini-abortion", and "regulation of a delayed/suspended menstruation".[108][109]

Forty percent of the world's women are able to access therapeutic and elective abortions within gestational limits,[12] while an additional 35 percent have access to legal abortion if they meet certain physical, mental, or socioeconomic criteria.[14] While maternal mortality seldom results from safe abortions, unsafe abortions result in 70,000 deaths and 5 million disabilities per year.[7] Complications of unsafe abortion account for

approximately an eighth of maternal mortalities worldwide,[110] though this varies by region.[111] Secondary infertility caused by an unsafe abortion affects an estimated 24 million women.[100] The rate of unsafe abortions has increased from 44% to 49% between 1995 and 2008.[10] Health education, access to family planning, and improvements in health care during and after abortion have been proposed to address this phenomenon.[112]

### Live birth

Although it is very uncommon, women undergoing surgical abortion after 18 weeks gestation sometimes give birth to a fetus that may survive briefly.[113][114][115] Longer term survival is possible after 22 weeks.[116]

If medical staff observe signs of life, they may be required to provide care: emergency medical care if the child has a good chance of survival and palliative care if not.[117][118][119] Induced fetal demise before termination of pregnancy after 20–21 weeks gestation is recommended to avoid this.[120][121][122][123][124]

Death following live birth which is caused by abortion is given the ICD-10 underlying cause description code of P96.4; data are identified as either fetus or newborn. Between 1999 and 2013, in the U.S., the CDC recorded 531 such deaths for newborns,[125] approximately 4 per 100,000 abortions.[126]

## Incidence

There are two commonly used methods of measuring the incidence of abortion:

- Abortion rate – number of abortions per 1000 women between 15 and 44 years of age
- Abortion percentage – number of abortions out of 100 known pregnancies (pregnancies include live births, abortions and miscarriages)

In many places, where abortion is illegal or carries a heavy social stigma, medical reporting of abortion is not reliable.[99] For this reason, estimates of the incidence of abortion must be made without determining certainty related to standard error.[10]

The number of abortions performed worldwide seems to have remained stable in recent years, with 41.6 million having been performed in 2003 and 43.8 million having been performed in 2008.[10] The abortion rate worldwide was 28 per 1000 women, though it was 24 per 1000 women for developed countries and 29 per 1000 women for developing countries.[10] The same 2012 study indicated that in 2008, the estimated abortion percentage of known pregnancies was at 21% worldwide, with 26% in developed countries and 20% in developing countries.[10]

On average, the incidence of abortion is similar in countries with restrictive abortion laws and those with more liberal access to abortion. However, restrictive abortion laws are associated with increases in the percentage of abortions which are performed unsafely.[12][127][128] The unsafe abortion rate in developing countries is partly attributable to lack of access to modern contraceptives; according to the Guttmacher Institute, providing access to contraceptives would result in about 14.5 million fewer unsafe abortions and 38,000 fewer deaths from unsafe abortion annually worldwide.[129]

The rate of legal, induced abortion varies extensively worldwide. According to the report of employees of Guttmacher Institute it ranged from 7 per 1000 women (Germany and Switzerland) to 30 per 1000 women (Estonia) in countries with complete statistics in 2008. The proportion of pregnancies that ended in induced abortion ranged from about 10% (Israel, the Netherlands and Switzerland) to 30% (Estonia) in the same group, though it might be as high as 36% in Hungary and Romania, whose statistics were deemed incomplete.[130][131]

The abortion rate may also be expressed as the average number of abortions a woman has during her reproductive years; this is referred to as *total abortion rate* (TAR).

### Gestational age and method

Abortion rates also vary depending on the stage of pregnancy and the method practiced. In 2003, the Centers for Disease Control and Prevention (CDC) reported that 26% of abortions in the United States were known to have been obtained at less than 6 weeks' gestation, 18% at 7 weeks, 15% at 8 weeks, 18% at 9 through 10 weeks, 9.7% at 11 through 12 weeks, 6.2% at 13 through 15 weeks, 4.1% at 16 through 20 weeks and 1.4% at more than 21 weeks. 90.9% of these were classified as having been done by "curettage" (suction-aspiration, dilation and curettage, dilation and evacuation), 7.7% by "medical" means (mifepristone), 0.4% by "intrauterine instillation" (saline or prostaglandin), and 1.0% by "other" (including hysterotomy and hysterectomy).[132]

According to the CDC, due to data collection difficulties the data must be viewed as tentative and some fetal deaths reported beyond 20 weeks may be natural deaths erroneously classified as abortions if the removal of the dead fetus is accomplished by the same procedure as an induced abortion.[133]

The Guttmacher Institute estimated there were 2,200 intact dilation and extraction procedures in the US during 2000; this accounts for 0.17% of the total number of abortions performed that year.[134] Similarly, in England and Wales in 2006, 89% of terminations occurred at or under 12 weeks, 9% between 13 and 19 weeks, and 1.5% at or over 20 weeks. 64% of those reported were by vacuum aspiration, 6% by D&E, and 30% were medical.[135] There are more second trimester abortions in developing countries such as China, India and Vietnam than in developed countries.[136]

# Motivation

## Personal

The reasons why women have abortions are diverse and vary across the world.[133][137]

Some of the most common reasons are to postpone childbearing to a more suitable time or to focus energies and resources on existing children. Others include being unable to afford a child either in terms of the direct costs of raising a child or the loss of income while caring for the child, lack of support from the father, inability to afford additional children, desire to provide schooling for existing children, disruption of one's own education, relationship problems with their partner, a perception of being too young to have a child, unemployment, and not being willing to raise a child conceived as a result of rape or incest, among others.[137][138]

A bar chart depicting selected data from a 1998 AGI meta-study on the reasons women stated for having an abortion.

## Societal

Some abortions are undergone as the result of societal pressures. These might include the preference for children of a specific sex or race,[139] disapproval of single or early motherhood, stigmatization of people with disabilities, insufficient economic support for families, lack of access to or rejection of contraceptive methods, or efforts toward population control (such as China's one-child policy). These factors can sometimes result in compulsory abortion or sex-selective abortion.[140]

An American study in 2002 concluded that about half of women having abortions were using a form of

contraception at the time of becoming pregnant. Inconsistent use was reported by half of those using condoms and three-quarters of those using the birth-control pill; 42% of those using condoms reported failure through slipping or breakage.[141] The Guttmacher Institute estimated that "most abortions in the United States are obtained by minority women" because minority women "have much higher rates of unintended pregnancy."[142]

## Maternal and fetal health

An additional factor is risk to maternal or fetal health, which was cited as the primary reason for abortion in over a third of cases in some countries and as a significant factor in only a single-digit percentage of abortions in other countries.[133][137]

In the U.S., the Supreme Court decisions in *Roe vs Wade* and *Doe vs Bolton*: "ruled that the state's interest in the life of the fetus became compelling only at the point of viability, defined as the point at which the fetus can survive independently of its mother. Even after the point of viability, the state cannot favor the life of the fetus over the life or health of the pregnant woman. Under the right of privacy, physicians must be free to use their "medical judgment for the preservation of the life or health of the mother." On the same day that the Court decided Roe, it also decided Doe v. Bolton, in which the Court defined health very broadly: "The medical judgment may be exercised in the light of all factors—physical, emotional, psychological, familial, and the woman's age—relevant to the well-being of the patient. All these factors may relate to health. This allows the attending physician the room he needs to make his best medical judgment."[143]:1200–1201

Public opinion shifted in America following television personality Sherri Finkbine's discovery during her fifth month of pregnancy that she had been exposed to thalidomide, unable to abort in the United States she traveled to Sweden. From 1962-65 there was an outbreak of German measles that left 15,000 babies with severe birth defects. In 1967, the American Medical Association publicly supported liberalization of abortion laws. A National Opinion Research Center poll in 1965 showed 73% supported abortion when the mothers life was at risk, 57% when birth defects were present and 59% for pregnancies resulting from rape or incest. [144]

## Cancer

The rate of cancer during pregnancy is 0.02–1%, and in many cases, cancer of the mother leads to consideration of abortion to protect the life of the mother, or in response to the potential damage that may occur to the fetus during treatment. This is particularly true for cervical cancer, the most common type which occurs in 1 of every 2000-13000 pregnancies, for which initiation of treatment "cannot co-exist with preservation of fetal life (unless neoadjuvant chemotherapy is chosen)." Very early stage cervical cancers (I and IIa) may be treated by radical hysterectomy and pelvic lymph node dissection, radiation therapy, or both, while later stages are treated by radiotherapy. Chemotherapy may be used simultaneously. Treatment of breast cancer during pregnancy also involves fetal considerations, because lumpectomy is discouraged in favor of modified radical mastectomy unless late-term pregnancy allows follow-up radiation therapy to be administered after the birth.[145]

Exposure to a single chemotherapy drug is estimated to cause a 7.5–17% risk of teratogenic effects on the fetus, with higher risks for multiple drug treatments. Treatment with more than 40 Gy of radiation usually causes spontaneous abortion. Exposure to much lower doses during the first trimester, especially 8 to 15 weeks of development, can cause intellectual disability or microcephaly, and exposure at this or subsequent stages can cause reduced intrauterine growth and birth weight. Exposures above 0.005–0.025 Gy cause a dose-dependent reduction in IQ.[145] It is possible to greatly reduce exposure to radiation with abdominal shielding, depending on how far the area to be irradiated is from the fetus.[146][147]

The process of birth itself may also put the mother at risk. "Vaginal delivery may result in dissemination of neoplastic cells into lymphovascular channels, haemorrhage, cervical laceration and implantation of malignant cells in the episiotomy site, while abdominal delivery may delay the initiation of non-surgical treatment."[148]

# History and religion

*Main article: History of abortion*

Since ancient times abortions have been done using herbal medicines, sharp tools, with force, or through other traditional methods.[13] Induced abortion has long history, and can be traced back to civilizations as varied as China under Shennong (c. 2700 BCE), Ancient Egypt with its Ebers Papyrus (c. 1550 BCE), and the Roman Empire in the time of Juvenal (c. 200 CE).[13] There is evidence to suggest that pregnancies were terminated through a number of methods, including the administration of abortifacient herbs, the use of sharpened implements, the application of abdominal pressure, and other techniques. One of the earliest known artistic representations of abortion is in a bas relief at Angkor Wat (c. 1150). Found in a series of friezes that represent judgment after death in Hindu and Buddhist culture, it depicts the technique of abdominal abortion.[63]

Bas-relief at Angkor Wat, Cambodia, c. 1150, depicting a demon inducing an abortion by pounding the abdomen of a pregnant woman with a pestle.[63][149]

Some medical scholars and abortion opponents have suggested that the Hippocratic Oath forbade Ancient Greek physicians from performing abortions;[13] other scholars disagree with this interpretation,[13] and state the medical texts of Hippocratic Corpus contain descriptions of abortive techniques right alongside the Oath.[150] The physician Scribonius Largus wrote in 43 CE that the Hippocratic Oath prohibits abortion, as did Soranus, although apparently not all doctors adhered to it strictly at the time. According to Soranus' 1st or 2nd century CE work *Gynaecology*, one party of medical practitioners banished all abortives as required by the Hippocratic Oath; the other party —to which he belonged— was willing to prescribe abortions, but only for the sake of the mother's health.[151][152]

FRENCH PERIODICAL PILLS.

Warranted to have the desired effect in all cases.

THESE Pills contain a portion of the only article in the whole materia medica, which can regulate the system and produce the monthly turns of females that can be taken, without hazarding life, and this article is not to be found in any of the pills or nostrums which are pictured forth so largely in the papers of the day. It has frequently occurred that the unhappy patient has by the use of these pills and nostrums given nature such a shock that they have never since enjoyed health, and they never can. It seems that they are got up and advertised merely for the object of making money, regardless of the consequences, and the venders are usually considered beneath responsibility, by all who know them.

The French Periodical Pills are the result of the combined knowledge and experience of some of the oldest and most distinguished physicians of Europe, and have been used by females embracing the gentility and most of the nobility of France, for the last twenty-three years. To eulogize their virtues would not add to their merits. We will only say TRY THEM, and if they do not prove to be what they are here represented to be, your money shall be refunded.

They contain no medicine detrimental to the constitution, but restore all debilitated constitutions to their wonted energy and healthfulness by removing from the system every impurity.

The only precaution necessary to be observed is ladies married should not take them if they have reason to believe they are en ciente, as they are sure to produce a miscarriage, almost without the knowledge of the patient, so gentle yet active are they.

Aristotle, in his treatise on government *Politics* (350 BCE), condemns infanticide as a means of population control. He preferred abortion in such cases, with the restriction[153] "[that it] must be practised on it before it has developed sensation and life; for the line between lawful and unlawful abortion will be marked by the fact of having sensation and being alive."[154] In Christianity, Pope Sixtus V (1585–90) was the first Pope to declare that abortion is homicide regardless of the stage of pregnancy;[155] the Catholic Church had previously been divided on whether it believed that abortion was murder, and did not begin vigorously opposing abortion until the 19th century.[13] Islamic tradition has traditionally permitted abortion until a point in time when Muslims believe the soul enters the fetus,[13] considered by various theologians to be at conception, 40 days after conception, 120 days after conception, or quickening.[156] However, abortion is largely heavily restricted or forbidden in areas of high Islamic faith such as the Middle East and North Africa.[157]

In Europe and North America, abortion techniques advanced starting in the 17th century. However, conservatism by most physicians with regards to sexual matters prevented the wide expansion of safe abortion techniques.[13] Other medical practitioners in addition to some physicians advertised their services, and they were not widely regulated until the 19th century, when the practice (sometimes called *restellism*)[158] was banned in both the United States and the United Kingdom.[13] Church groups as well as physicians were highly influential in anti-abortion movements.[13] In the US, abortion was more dangerous than childbirth until about 1930 when incremental improvements in abortion procedures relative to

childbirth made abortion safer.[note 2] Soviet Russia (1919), Iceland (1935) and Sweden (1938) were among the first countries to legalize certain or all forms of abortion.[159] In 1935 Nazi Germany, a law was passed permitting abortions for those deemed "hereditarily ill", while women considered of German stock were specifically prohibited from having abortions.[160] Beginning in the second half of the twentieth century, abortion was legalized in a greater number of countries.[13] A bill passed by the state legislature of New York legalizing abortion was signed by Governor Nelson Rockefeller in April 1970.[161]

## Abortion debate

*Main article: Abortion debate*

Induced abortion has long been the source of considerable debate. Ethical, moral, philosophical, biological, religious and legal issues surrounding abortion are related to value systems. Opinions of abortion may be about fetal rights, governmental authority, and women's rights.

In both public and private debate, arguments presented in favor of or against abortion access focus on either the moral permissibility of an induced abortion, or justification of laws permitting or restricting abortion.[162] The World Medical Association Declaration on Therapeutic Abortion notes that "circumstances bringing the interests of a mother into conflict with the interests of her unborn child create a dilemma and raise the question as to whether or not the pregnancy should be deliberately terminated".[163] Abortion debates, especially pertaining to abortion laws, are often spearheaded by groups advocating one of these two positions. Anti-abortion groups who favor greater legal restrictions on abortion, including complete prohibition, most often describe themselves as "pro-life" while abortion rights groups who are against such legal restrictions describe themselves as "pro-choice".[164] Generally, the former position argues that a human fetus is a human person with a right to live, making abortion morally the same as murder. The latter position argues that a woman has certain reproductive rights, especially the choice whether or not to carry a pregnancy to term.

## Modern abortion law

*Main article: Abortion law*
*See also: History of abortion law debate*

Current laws pertaining to abortion are diverse. Religious, moral, and cultural sensibilities continue to influence abortion laws throughout the world. The right to life, the right to liberty, the right to security of person, and the right to reproductive health are major issues of human rights that are sometimes used as justification for the existence or absence of laws controlling abortion.

In jurisdictions where abortion is legal, certain requirements must often be met before a woman may obtain a safe, legal abortion (an abortion performed without the woman's consent is considered feticide). These requirements usually depend on the age of the fetus, often using a trimester-based system to regulate the window of legality, or as in the U.S., on a doctor's evaluation of the fetus' viability. Some jurisdictions require a waiting period before the procedure, prescribe the distribution of information on fetal development, or require that parents be contacted if their minor daughter requests an

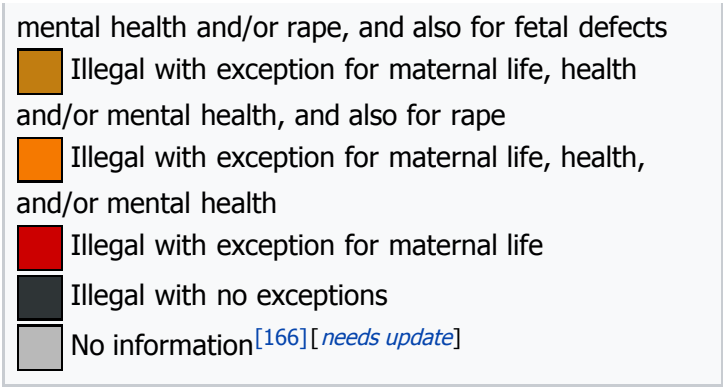
Legal on request

Legal for maternal life, health, mental health, rape and/or fetal defects, and also for socioeconomic factors

Illegal with exception for maternal life, health,

abortion.[167] Other jurisdictions may require that a woman obtain the consent of the fetus' father before aborting the fetus, that abortion providers inform women of health risks of the procedure—sometimes including "risks" not supported by the medical literature—and that multiple medical authorities certify that the abortion is either medically or socially necessary. Many restrictions are waived in emergency situations. China, which has ended their[168] one-child policy, and now has a two child policy.[169] [170] has at times incorporated mandatory abortions as part of their population control strategy.[171]



Other jurisdictions ban abortion almost entirely. Many, but not all, of these allow legal abortions in a variety of circumstances. These circumstances vary based on jurisdiction, but may include whether the pregnancy is a result of rape or incest, the fetus' development is impaired, the woman's physical or mental well-being is endangered, or socioeconomic considerations make childbirth a hardship.[14] In countries where abortion is banned entirely, such as Nicaragua, medical authorities have recorded rises in maternal death directly and indirectly due to pregnancy as well as deaths due to doctors' fears of prosecution if they treat other gynecological emergencies.[172][173] Some countries, such as Bangladesh, that nominally ban abortion, may also support clinics that perform abortions under the guise of menstrual hygiene.[174] This is also a terminology in traditional medicine.[175] In places where abortion is illegal or carries heavy social stigma, pregnant women may engage in medical tourism and travel to countries where they can terminate their pregnancies.[176] Women without the means to travel can resort to providers of illegal abortions or attempt to perform an abortion by themselves.[177]

## Sex-selective abortion

*Main article: Sex-selective abortion*

Sonography and amniocentesis allow parents to determine sex before childbirth. The development of this technology has led to sex-selective abortion, or the termination of a fetus based on sex. The selective termination of a female fetus is most common.

Sex-selective abortion is partially responsible for the noticeable disparities between the birth rates of male and female children in some countries. The preference for male children is reported in many areas of Asia, and abortion used to limit female births has been reported in Taiwan, South Korea, India, and China.[178] This deviation from the standard birth rates of males and females occurs despite the fact that the country in question may have officially banned sex-selective abortion or even sex-screening.[179][180][181][182] In China, a historical preference for a male child has been exacerbated by the one-child policy, which was enacted in 1979.[183]

Many countries have taken legislative steps to reduce the incidence of sex-selective abortion. At the International Conference on Population and Development in 1994 over 180 states agreed to eliminate "all forms of discrimination against the girl child and the root causes of son preference",[184] conditions which were also condemned by a PACE resolution in 2011.[185] The World Health Organization and UNICEF, along with other United Nations agencies, have found that measures to reduce access to abortion are much less effective at reducing sex-selective abortions than measures to reduce gender inequality.[184]

## Anti-abortion violence

*Main article: Anti-abortion violence*

In a number of cases, abortion providers and these facilities have been subjected to various forms of violence, including murder, attempted murder, kidnapping, stalking, assault, arson, and bombing. Anti-abortion violence is classified by both governmental and scholarly sources as terrorism.[186][187] Only a

small fraction of those opposed to abortion commit violence.

In the United States, four physicians who performed abortions have been murdered: David Gunn (1993), John Britton (1994), Barnett Slepian (1998), and George Tiller (2009). Also murdered, in the U.S. and Australia, have been other personnel at abortion clinics, including receptionists and security guards such as James Barrett, Shannon Lowney, Lee Ann Nichols, and Robert Sanderson. Woundings (e.g., Garson Romalis) and attempted murders have also taken place in the United States and Canada. Hundreds of bombings, arsons, acid attacks, invasions, and incidents of vandalism against abortion providers have occurred.[188][189] Notable perpetrators of anti-abortion violence include Eric Robert Rudolph, Scott Roeder, Shelley Shannon, and Paul Jennings Hill, the first person to be executed in the United States for murdering an abortion provider.[190]

Legal protection of access to abortion has been brought into some countries where abortion is legal. These laws typically seek to protect abortion clinics from obstruction, vandalism, picketing, and other actions, or to protect women and employees of such facilities from threats and harassment.

Far more common than physical violence is psychological pressure. In 2003, Chris Danze organized pro-life organizations throughout Texas to prevent the construction of a Planned Parenthood facility in Austin. The organizations released the personal information online, of those involved with construction, sending them up to 1200 phone calls a day and contacting their churches.[191] Some protestors record women entering clinics on camera.[191]

## Other animals

*Further information: Miscarriage*

Spontaneous abortion occurs in various animals. For example, in sheep, it may be caused by crowding through doors, or being chased by dogs.[192] In cows, abortion may be caused by contagious disease, such as brucellosis or *Campylobacter*, but can often be controlled by vaccination.[193] Eating pine needles can also induce abortions in cows.[194][195] In horses, a fetus may be aborted or resorbed if it has lethal white syndrome (congenital intestinal aganglionosis). Foal embryos that are homozygous for the dominant white gene (WW) are theorized to also be aborted or resorbed before birth.[196]

Viral infection can cause abortion in dogs.[197] Cats can experience spontaneous abortion for many reasons, including hormonal imbalance. A combined abortion and spaying is performed on pregnant cats, especially in Trap-Neuter-Return programs, to prevent unwanted kittens from being born.[198][199][200] Female rodents may terminate a pregnancy when exposed to the smell of a male not responsible for the pregnancy, known as the Bruce effect.[201]

Abortion may also be induced in animals, in the context of animal husbandry. For example, abortion may be induced in mares that have been mated improperly, or that have been purchased by owners who did not realize the mares were pregnant, or that are pregnant with twin foals.[202] Feticide can occur in horses and zebras due to male harassment of pregnant mares or forced copulation,[203][204][205] although the frequency in the wild has been questioned.[206] Male gray langur monkeys may attack females following male takeover, causing miscarriage.[207]

Drawing on the information available on the accuracy and precision of abortion estimates that were used to develop the subregional, regional, and worldwide rates, we computed intervals of certainty around these rates (webappendix). We computed wider intervals for unsafe abortion rates than for safe abortion rates. The basis for these intervals included published and unpublished assessments of abortion reporting in countries with liberal laws, recently published studies of national unsafe abortion, and high and low estimates of the numbers of unsafe abortion developed by WHO."

What is the effect of feticide on labor induction abortion outcome? Deliberately causing demise of the fetus before labor induction abortion is performed primarily to avoid transient fetal survival after expulsion; this approach may be for the comfort of both the woman and the staff, to avoid futile resuscitation efforts. Some providers allege that feticide also facilitates delivery, although little data support this claim. Transient fetal survival is very unlikely after intraamniotic installation of saline or urea, which are directly feticidal. Transient survival with misoprostol for labor induction abortion at greater than 18 weeks ranges from 0% to 50% and has been observed in up to 13% of abortions performed with high-dose oxytocin. Factors associated with a higher likelihood of transient fetal survival with labor induction abortion include increasing gestational age, decreasing abortion interval and the use of nonfeticidal inductive agents such as the PGE1 analogues."

## Notes

1. ^ Definitions of abortion, as with many words, vary from source to source. Language used to define abortion often reflects societal and political opinions (not only scientific knowledge). The following is a partial list of definitions as stated by obstetrics and gynecology (OB/GYN) textbooks, dictionaries, and other sources:

   **Major OB/GYN textbooks**

   - The National Center for Health Statistics defines an "abortus" as "[a] fetus or embryo removed or expelled from the uterus during the first half of gestation—20 weeks or less, or in the absence of accurate dating criteria, born weighing < 500 g." They also define "birth" as "[t]he complete expulsion or extraction from the mother of a fetus after 20 weeks' gestation. ... in the absence of accurate dating criteria, fetuses weighing <500 g are usually not considered as births, but rather are termed abortuses for purposes of vital statistics." Cunningham, FG; Leveno, KJ; Bloom, SL; et al., eds. (2010). "1. Overview of Obstetrics". *Williams Obstetrics* (23 ed.). McGraw-Hill Medical. ISBN 978-0-07-149701-5.
   - "[T]he standard medical definition of abortion [is] termination of a pregnancy when the fetus is not viable". Annas, George J.; Elias, Sherman (2007). "51.    **Other OB/GYN textbooks**

   - "Termination of pregnancy before 20 weeks' gestation calculated from date of onset of last menses. An alternative definition is delivery of a fetus with a weight of less than 500 g. If abortion occurs before 12 weeks' gestation, it is called early; from 12 to 20 weeks it is called late." Katz, Vern L. (2007). "16. Spontaneous and Recurrent Abortion – Etiology, Diagnosis, Treatment". In Katz, Vern L.; Lentz, Gretchen M.; Lobo, Rogerio A.; et al. *Katz: Comprehensive Gynecology* (5 ed.). Mosby. ISBN 978-0-323-02951-3.
   - "Abortion is the spontaneous or induced termination of pregnancy before fetal viability. Because popular use of the word abortion implies a deliberate pregnancy termination, some prefer the word miscarriage to refer to spontaneous fetal loss before viability ... The National Center for Health Statistics, the Centers for Disease Control and Prevention (CDC), and the World Health Organization (WHO) define abortion as pregnancy termination prior to 20 weeks' gestation or a fetus born weighing less than 500 g. Despite this, definitions vary widely according to state laws." Schorge, John O.; Schaffer, Joseph I.; Halvorson, Lisa M.; Hoffman, Barbara L.; Bradshaw, Karen D.; Cunningham, F. Gary, eds. (2008).    - "Expulsion from the uterus an embryo or fetus prior to the stage of viability (20 weeks' gestation or fetal weight <500g). A distinction made between [abortion] and premature birth: premature infants are those born after the

stage of viability but prior to 37 weeks." *Stedman's Medical Dictionary* (27 ed.). Lippincott Williams & Wilkins. ISBN 0-683-40008-8.

- "An abortion refers to the termination of a pregnancy. It can be *induced* (see Definitions, Terminology, and Reference Resources) through a pharmacological or a surgical procedure, or it may be spontaneous (also called miscarriage)." "Definitions of abortion vary across and within countries as well as among different institutions. Language used to refer to abortion often also reflects societal and political opinions and not only scientific knowledge (Grimes and Gretchen 2010). Popular use of the word abortion implies a deliberate pregnancy termination, whereas a miscarriage is used to refer to spontaneous fetal loss when the fetus is not viable (i.e., not yet unable to survive independently outside the womb)." **Major English dictionaries (general-purpose)**

- "1. a. The expulsion or removal from the womb of a developing embryo or fetus, spec. (Med.) in the period before it is capable of independent survival, occurring as a result either of natural causes (more fully spontaneous abortion) or of a deliberate act (more fully induced abortion); the early or premature termination of pregnancy with loss of the fetus; an instance of this." - "[Abortion] is commonly misunderstood outside medical circles. In general terms, the word 'abortion' simply means the failure of something to reach fulfilment or maturity. Medically, abortion means loss of the fetus, for any reason, before it is able to survive outside the womb. The term covers accidental or spontaneous ending, or miscarriage, of pregnancy as well as deliberate termination. The terms 'spontaneous abortion' and 'miscarriage' are synonymous and are defined as loss of the fetus before the twenty-eighth week of pregnancy. This definition implies a legal perception of the age at which a fetus can survive out of the womb. With great advances in recent years in the ability to keep very premature babies alive, this definition is in need of revision." **Journal articles about terminology**

- "Abortion can be performed up to viability; thereafter, according to standard dictionaries, other terms should be used for uterine evacuation. "Late" is an acceptable descriptor for abortion; "late-term" is not. Gestational age should be expressed in completed cardinal days, weeks or months; ordinal numbers (and trimesters) should be avoided. "Intact D&E" should be used instead of the oxymoronic "partial-birth abortion" or the mysterious "D&X." " (internal citations removed) Grimes, DA; Stuart, G (2010). # Breastfeeding

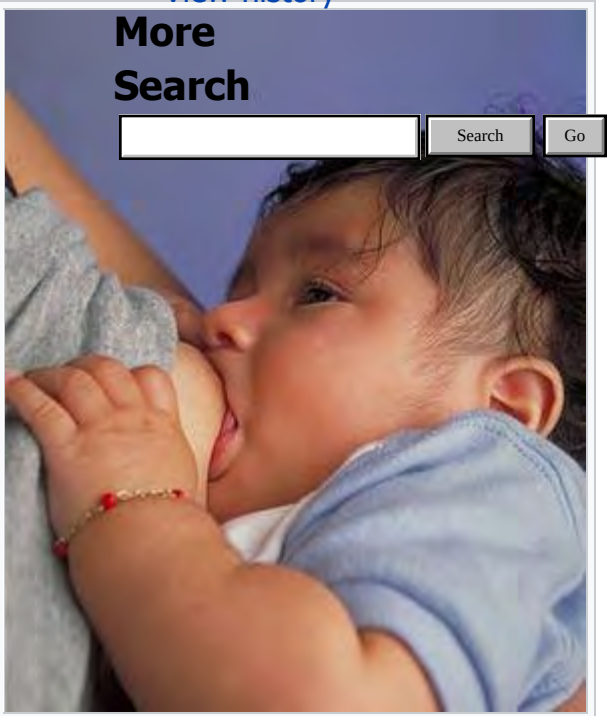
From Wikipedia, the free encyclopedia

*"Suckling" redirects here. For other uses, see Suckling (disambiguation).*

**Breastfeeding**, also known as **nursing**, is the feeding of babies and young children with milk from a woman's breast.[1] Health professionals recommend that breastfeeding begin within the first hour of a baby's life and continue as often and as much as the baby wants.[2][3] During the first few weeks of life babies may nurse roughly every two to three hours. The duration of a feeding is usually ten to fifteen minutes on each breast.[4] Older children feed less often.[5] Mothers may pump milk so that it can be used later when breastfeeding is not possible.[1] Breastfeeding has a number of benefits to both mother and baby, which infant formula lacks.[3][6]



A baby breastfeeding

Deaths of an estimated 820,000 children under the age of five could be prevented globally every year with increased breastfeeding.[7] Breastfeeding decreases the risk of respiratory tract infections and diarrhea, both in developing and developed countries.[2][3] Other benefits include lower risks of asthma, food allergies, celiac disease, type 1 diabetes, and leukemia.[3] Breastfeeding may also improve cognitive development and decrease the risk of obesity in adulthood.[2] Mothers may feel pressure to breastfeed; however in the developed world children generally grow up normally when bottle feed.[8]

Benefits for the mother include less blood loss following delivery, better uterus shrinkage, weight loss, and less postpartum depression. Breastfeeding delays the return of menstruation and fertility, a phenomenon known as lactational amenorrhea. Long term benefits for the mother include decreased risk of breast cancer, cardiovascular disease, and rheumatoid arthritis.[3][7] Breastfeeding is often less expensive than infant formula.[9][10]

Health organizations, including the World Health Organization (WHO), recommend breastfeeding exclusively for six months.[2][11] This means that no other foods or drinks other than possibly vitamin D are typically given.[12] After the introduction of foods at six months of age, recommendations include continued breastfeeding until at least one to two years of age.[2][3] Globally about 38% of infants are only breastfed during their first six months of life.[2] In the United States, about 75% of women begin breastfeeding and about 13% only breastfeed until the age of six months.[3] Medical conditions that do not allow breastfeeding are rare.[3] Mothers who take certain recreational drugs and medications should not breastfeed.[13] Smoking, limited intake of alcohol, and coffee are not reasons to avoid breastfeeding.[14][15][16]

# Lactation [edit]

*Main article: Lactation*

The endocrine system drives milk production during pregnancy and the first few days after the birth. From the twenty-fourth week of pregnancy (the second and third trimesters), a woman's body produces hormones that stimulate the growth of the breast's milk duct system. Progesterone influences the growth in size of alveoli and lobes; high levels of progesterone, estrogen, prolactin and other hormones inhibit lactation before birth; hormone levels drop after birth, triggering milk production.[17] After birth, the hormone oxytocin contracts the smooth muscle layer of cells surrounding the alveoli to squeeze milk into the duct system. Oxytocin is also necessary for the milk ejection reflex, or *let-down* to occur. Let-down occurs in response to the baby's suckling, though it also may be a conditioned response, e.g. to the cry of the baby. Lactation can also be induced by a combination of physical and psychological stimulation, by drugs or by a combination of these methods.[18][19]

Two 25ml samples of human breast milk. The sample on the left is foremilk, the watery milk coming from a full breast. To the right is hindmilk, the creamy milk coming from a nearly empty breast.[20]

Not all of breast milk's properties are understood, but its nutrient content is relatively consistent. Breast milk is made from nutrients in the mother's bloodstream and bodily stores. Breast milk has an optimal balance of fat, sugar, water, and protein that is needed for a baby's growth and development.[21] Breastfeeding triggers biochemical reactions which allows for the enzymes, hormones, growth factors and immunologic substances to effectively defend against infectious diseases for the infant. The breastmilk also has long-chain polyunsaturated fatty acids which help with normal retinal and neural development.[22] Because breastfeeding requires an average of 500 calories a day, it helps the mother lose weight after giving birth.[23]

The composition of breast milk changes depending on how long the baby nurses at each session, as well as on the child's age.[24] The first type, produced during the first days after childbirth, is called *colostrum*. Colostrum is easy to digest although it is more concentrated than mature milk. It has a laxative effect that helps the infant to pass early stools, aiding in the excretion of excess bilirubin, which helps to prevent jaundice. It also helps to seal the infants gastrointestional tract from foreign substances, which may sensitize the baby to foods that the mother has eaten. Although the baby has received some antibodies through the placenta, colostrum contains a substance which is new to the newborn, secretory immunoglobulin A (IgA). IgA works to attack germs in the mucous membranes of the throat, lungs, and intestines, which are most likely to come under attack from germs.[25]

Breasts begin producing mature milk around the third or fourth day after birth. Early in a nursing session, the breasts produce *foremilk*, a thinner milk containing many proteins and vitamins. If the baby keeps nursing, then *hindmilk* is produced. Hindmilk has a creamier color and texture because it contains more fat.[26] The American Academy of Pediatrics (AAP) states that "tobacco smoking by mothers is not a contraindication to breastfeeding."[27] In addition, AAP states that while breastfeeding mothers "should avoid the use of alcoholic beverages", an "occasional celebratory single, small alcoholic drink is acceptable, but breastfeeding should be avoided for 2 hours after the drink."[27] A 2014 review found that "even in a theoretical case of binge drinking, the children would not be subjected to clinically relevant amounts of alcohol [through breastmilk]", and would have no adverse effects on children as long as drinking is "occasional".[28]

## Process [edit]

### Commencement [edit]

Breastfeeding can begin immediately after birth. The baby is placed on the mother and feeding starts as soon as the baby shows interest.

According to some authorities, increasing evidence suggests that early

Newborn rests as caregiver checks breath sounds

skin-to-skin contact (also called kangaroo care) between mother and baby stimulates breastfeeding behavior in the baby.[29] Newborns who are immediately placed on their mother's skin have a natural instinct to latch on to the breast and start nursing, typically within one hour of birth. Immediate skin-to-skin contact may provide a form of imprinting that makes subsequent feeding significantly easier. In addition to more successful breastfeeding and bonding, immediate skin-to-skin contact reduces crying and warms the baby.

According to studies cited by UNICEF, babies naturally follow a process which leads to a first breastfeed. Initially after birth the baby cries with its first breaths. Shortly after, it relaxes and makes small movements of the arms, shoulders and head. The baby crawls towards the breast and begins to feed. After feeding, it is normal for a baby to remain latched to the breast while resting. This is sometimes mistaken for lack of appetite. Absent interruptions, all babies follow this process. Rushing or interrupting the process, such as removing the baby to weigh him/her, may complicate subsequent feeding.[30] Activities such as weighing, measuring, bathing, needle-sticks, and eye prophylaxis wait until after the first feeding."[27]

Children who are born preterm have difficulty in initiating breast feeds immediately after birth. By convention, such children are often fed on expressed breast milk or other supplementary feeds through tubes or bottles until they develop satisfactory ability to suck breast milk. Tube feeding, though commonly used, is not supported by scientific evidence as of October 2016.[31] It has also been reported in the same systematic review that by avoiding bottles and using cups instead to provide supplementary feeds to preterm children, a greater extent of breast feeding for a longer duration can subsequently be achieved.[31]

## Timing [edit]

Newborn babies typically express demand for feeding every 1 to 3 hours (8-12 times in 24 hours) for the first two to four weeks.[32] A newborn has a very small stomach capacity. At one-day old it is 5 to 7 ml, about the size of a marble; at day three it is 0.75-1 oz, about the size of a "shooter" marble; and at day seven it is 1.5-2 oz, or about the size of a ping-pong ball. The amount of breast milk that is produced is timed to meet the infant's needs in that the first milk, colostrum, is concentrated but produced in only very small amounts, gradually increasing in volume to meet the expanding size of the infant's stomach capacity.[25]

According to La Leche League International, "Experienced breastfeeding mothers learn that the sucking patterns and needs of babies vary. While some infants' sucking needs are met primarily during feedings, other babies may need additional sucking at the breast soon after a feeding even though they are not really hungry. Babies may also nurse when they are lonely, frightened or in pain....Comforting and meeting sucking needs at the breast is nature's original design. Pacifiers (dummies, soothers) are a substitute for the mother when she cannot be available. Other reasons to pacify a baby primarily at the breast include superior oral-facial development, prolonged lactational amenorrhea, avoidance of nipple confusion, and stimulation of an adequate milk supply to ensure higher rates of breastfeeding success."[33]

During the newborn period, most breastfeeding sessions take from 20 to 45 minutes.[32] After one breast is empty, the mother may offer the other breast.

## Location [edit]

Most US states now have laws that allow a mother to breastfeed her baby anywhere. In hospitals, rooming-in care permits the baby to stay with the mother and simplifies the process. Some commercial establishments provide breastfeeding rooms, although laws generally specify that mothers may breastfeed anywhere, without requiring a

Rooming-in bassinet

special area. Breastfeeding in public remains controversial in many developed countries.

In 2014, newly elected Pope Francis drew world-wide commentary when he encouraged mothers to breastfeed babies in church. During a papal baptism, he said that mothers "should not stand on ceremony" if their children were hungry. "If they are hungry, mothers, feed them, without thinking twice," he said, smiling. "Because they are the most important people here."[34]

## Position [edit]

Correct positioning and technique for latching on are necessary to prevent nipple soreness and allow the baby to obtain enough milk.[35]

Babies can successfully latch on to the breast from multiple positions. Each baby may prefer a particular position. The "football" hold places the baby's legs next to the mother's side with the baby facing the mother. Using the "cradle" or "cross-body" hold, the mother supports the baby's head in the crook of her arm. The "cross-over" hold is similar to the cradle hold, except that the mother supports the baby's head with the opposite hand. The mother may choose a reclining position on her back or side with the baby laying next to her.[36]

## Latching on [edit]

The "rooting reflex" is the baby's natural tendency to turn towards the breast with the mouth open wide; mothers sometimes make use of this by gently stroking the baby's cheek or lips with their nipple to induce the baby to move into position for a breastfeeding session, then quickly moving the baby onto the breast while its mouth is wide open.[37] To prevent nipple soreness and allow the baby to get enough milk, a large part of the breast and areola need to enter the baby's mouth.[38][39] Failure to latch on is one of the main reasons for ineffective feeding and can lead to infant health concerns.

## Weaning [edit]

*Main article: Weaning*

Weaning is the process of replacing breast milk with other foods; the infant is fully weaned after the replacement is complete. Psychological factors affect the weaning process for both mother and infant, as issues of closeness and separation are very prominent.[40] If the baby is less than a year old substitute bottles are necessary; an older baby may accept milk from a cup. Unless a medical emergency necessitates abruptly stopping breastfeeding, it is best to gradually cut back on feedings to allow the breasts to adjust to the decreased demands without becoming engorged. La Leche League advises: "The nighttime feeding is usually the last to go. Make a bedtime routine not centered around breastfeeding. A good book or two will eventually become more important than a long session at the breast."[41]

If breastfeeding is suddenly stopped a woman's breasts are likely to become engorged with milk. Pumping small amounts to relieve discomfort helps to gradually train the breasts to produce less milk. There is

presently no safe medication to prevent engorgement, but cold compresses and ibuprofen may help to relieve pain and swelling. Pain should go away in one to five days. If symptoms continue and comfort measures are not helpful a woman should consider the possibility that a blocked milk duct or infection may be present and seek medical intervention.[42]

When weaning is complete the mother's breasts return to their previous size after several menstrual cycles. If the mother was experiencing lactational amenorrhea her periods will return along with the return of her fertility. When no longer breastfeeding she will need to adjust her diet to avoid weight gain.[43]

## Methods [edit]

### Exclusive [edit]

Exclusive breastfeeding is defined as "an infant's consumption of human milk with no supplementation of any type (no water, no juice, no nonhuman milk and no foods) except for vitamins, minerals and medications."[27] Exclusive breastfeeding till six months of age helps to protect an infant from gastrointestinal infections in both developing and industrialized countries. The risk of death due to diarrhea and other infections increases when babies are either partially breastfed or not breastfed at all.[2]

Measuring how many calories a breastfed baby consumes is complex, although babies normally attempt to meet their own requirements.[44] Babies that fail to eat enough may exhibit symptoms of failure to thrive.[45]

La Leche League says that mothers' most often asked question is, "How can I tell if my baby is getting enough milk?" They advise that for the first few days, while the baby is receiving mostly colostrum, one or two wet diapers per day is normal. Once the mother starts producing milk, usually on the third or fourth day, the baby should have 6-8 wet cloth diapers (5-6 wet disposable diapers) per day. In addition, most young babies have at least two to five bowel movements every 24 hours for the first several months.[46]

La Leache League offers the following additional signs that indicate a baby is receiving enough milk:

- Averages at least 8-12 feedings per 24-hour period.
- Determines the duration of feeding, which may be 10 to 20 minutes per breast or longer.
- Swallowing sounds are audible.
- Gains at least 4-7 ounces per week after the fourth day.
- Is alert and active, appears healthy, has good color, firm skin and is growing in length and head circumference.[46]

### Mixed feeding [edit]

Predominant or mixed breastfeeding means feeding breast milk along with infant formula, baby food and even water, depending on the child's age.[47]

Formula and pumped breastmilk, side-by-side. Note that the formula is of uniform consistency and color, while the

### Expressed milk [edit]

A mother can "express" (produce) her milk for storage and later use. Expression occurs with massage or a breast pump. It can be stored in freezer storage bags, containers made specifically for breastmilk, a supplemental nursing system, or a bottle ready for use. Using someone other than the mother/wet nurse to deliver the bottle maintains the baby's association of nursing with the mother/wet nurse and bottle feeding with other people.

Breast milk may be kept at room temperature for up to six hours, refrigerated for up to eight days or frozen for six to twelve months.[48]

milk exhibits properties of an organic solution, separating into the creamline layer of fat at the top, milk and a watery blue layer at the bottom.

Research suggests that the antioxidant activity in expressed breast milk decreases over time, but remains at higher levels than in infant formula.[49]

Mothers express milk for multiple reasons. Expressing breast milk can maintain a mother's milk supply when she and her child are apart. A sick baby who is unable to nurse can take expressed milk through a nasogastric tube. Some babies are unable or unwilling to nurse. Expressed milk is the feeding method of choice for premature babies.[50] Viral disease transmission can be prevented by expressing breast milk and subjecting it to Holder pasteurisation.[51] Some women donate expressed breast milk (EBM) to others, either directly or through a milk bank. This allows mothers who cannot breastfeed to give their baby the benefits of breast milk.

Manual breast pump

Babies feed differently with artificial nipples than from a breast. With the breast, the infant's tongue massages the milk out rather than sucking, and the nipple does not go as far into the mouth. Drinking from a bottle takes less effort and the milk may come more rapidly, potentially causing the baby to lose desire for the breast. This is called *nursing strike, nipple strike* or *nipple confusion*. To avoid this, expressed milk can be given by means such as spoons or cups.[47]

"Exclusively expressing", "exclusively pumping", and "EPing" are terms for a mother who exclusively feeds her baby expressed milk. With good pumping habits, particularly in the first 12 weeks while establishing the milk supply, it is possible to express enough milk to feed the baby indefinitely. With the improvements in breast pumps, many women exclusively feed expressed milk, expressing milk at work. Women can leave their infants in the care of others while traveling, while maintaining a supply of breast milk.[52]

## Shared nursing [edit]

*Main article: Wet nurse*

Expressed breast milk or infant formula can be fed by bottle

Wet nursing was common throughout history. It remains popular in some developing nations, including those in Africa, for more than one woman to breastfeed a child. Shared breastfeeding is a risk factor for HIV infection in infants.[53] A woman who is engaged to breastfeed another's baby is known as a wet nurse. Shared nursing can sometimes provoke negative reactions in the Anglosphere.[54][55]

## Tandem nursing [edit]

Feeding two children at the same time who are not twins or multiples is called *tandem nursing*. Appetite and feeding habits of each baby may differ, so they may feed at the same or different times, which may involve feeding them simultaneously, one on each breast.

Breastfeeding triplets or larger broods is a challenge given babies' varying appetites. Breasts can respond to the demand and produce larger milk quantities; mothers have breastfed triplets successfully.[56][57][58]

Tandem nursing occurs when a woman gives birth while breastfeeding an older child. During the late stages of pregnancy, the milk changes to colostrum. While some children continue to breastfeed even with this change, others may wean. Breastfeeding a child while pregnant with another may be considered a form of tandem feeding for the nursing mother, as she provides nutrition for two.[59]

## Induced lactation [edit]

Induced lactation, also called *adoptive lactation*, is the process of starting breastfeeding in a woman who did not give birth.[60] This usually requires the adoptive mother to take hormones and other drugs to stimulate breast development and promote milk production. In some cultures, breastfeeding an adoptive child creates milk kinship that built community bonds across class and other hierarchal bonds.[60]

### Re-lactation [edit]

Re-lactation is the process of restarting breastfeeding.[60] In developing countries, mothers may restart breastfeeding after a weaning as part of an oral rehydration treatment for diarrhea. In developed countries, re-lactation is common after early medical problems are resolved, or because a mother changes her mind about breastfeeding.

Re-lactation is most easily accomplished with a newborn or with a baby that was previously breastfeeding; if the baby was initially bottle-fed, the baby may refuse to suckle. If the mother has recently stopped breastfeeding, she is more likely to be able to re-establish her milk supply, and more likely to have an adequate supply. Although some women successfully re-lactate after months-long interruptions, success is higher for shorter interruptions.[60]

Techniques to promote lactation use frequent attempts to breastfeed, extensive skin-to-skin contact with the baby, and frequent, long pumping sessions.[60] Suckling may be encouraged with a tube filled with infant formula, so that the baby associates suckling at the breast with food. A dropper or syringe without the needle may be used to place milk onto the breast while the baby suckles. The mother should allow the infant to suckle at least ten times during 24 hours, and more times if he or she is interested. These times can include every two hours, whenever the baby seems interested, longer at each breast, and when the baby is sleepy when he or she might suckle more readily. In keeping with increasing contact between mother and child, including increasing skin-to-skin contact, grandmothers should pull back and help in other ways. Later on, grandmothers can again provide more direct care for the infant.[61]

These techniques require the mother's commitment over a period of weeks or months. However, even when lactation is established, the supply may not be large enough to breastfeed exclusively. A supportive social environment improves the likelihood of success.[60] As the mother's milk production increases, other feeding can decrease. Parents and other family members should watch the baby's weight gain and urine output to assess nutritional adequacy.[61]

A WHO manual for physicians and senior health workers citing a 1992 source states: "If a baby has been breastfeeding sometimes, the breastmilk supply increases in a few days. If a baby has stopped breastfeeding, it may take 1-2 weeks or more before much breastmilk comes."[61]

### Extended [edit]

*Main article: Extended breastfeeding*

Extended breastfeeding means breastfeeding after the age of 12 or 24 months, depending on the source. Worldwide, infants are weaned on average between ages two and four. Breast-feeding continues until children are six or seven years old in some cultures but in other countries extended breast-feeding is less common. In Western countries such as the United States, Canada, and Great Britain, extended breastfeeding is relatively uncommon and can provoke criticism.[62][63]

In the United States, 22.4% of babies are breastfed for 12 months, the minimum amount of time advised by the American Academy of Pediatrics. In India, mothers commonly breastfeed for 2 to 3 years.[64]

## Health effects [edit]

Breastfeeding decreases the risk of a number of diseases in both mothers and babies.[65] The US Preventive Services Task Force recommends efforts to promote breastfeeding.[66]

## Baby [edit]

Early breastfeeding is associated with fewer nighttime feeding problems.[67] Early skin-to-skin contact between mother and baby improves breastfeeding outcomes, increases cardio-respiratory stability and decreases infant crying.[68] Reviews from 2007 found numerous benefits. Breastfeeding aids general health, growth and development in the infant. Infants who are not breastfed are at mildly increased risk of developing acute and chronic diseases, including lower respiratory infection, ear infections, bacteremia, bacterial meningitis, botulism, urinary tract infection and necrotizing enterocolitis.[69][70] Breastfeeding may protect against sudden infant death syndrome,[71] insulin-dependent diabetes mellitus, Crohn's disease, ulcerative colitis, lymphoma, allergic diseases, digestive diseases and may enhance cognitive development.[27]

## Growth [edit]

The average breastfed baby doubles its birth weight in 5 to 6 months. By one year, a typical breastfed baby weighs about 2½ times its birth weight. At one year, breastfed babies tend to be leaner than formula-fed babies, which improves long-run health.[72]

The Davis Area Research on Lactation, Infant Nutrition and Growth (DARLING) study reported that breastfed and formula-fed groups had similar weight gain during the first 3 months, but the breastfed babies began to drop below the median beginning at 6 to 8 months and were significantly lower weight than the formula-fed group between 6 and 18 months. Length gain and head circumference values were similar between groups, suggesting that the breastfed babies were leaner.[73]

### Infections [edit]

Breast milk contains several anti-infective factors such as bile salt stimulated lipase (protecting against amoebic infections) and lactoferrin (which binds to iron and inhibits the growth of intestinal bacteria).[74][75]

Infants who are exclusively breastfed for the first six months are less likely to die of gastrointestinal infections than infants who switched from exclusive to partial breastfeeding at three to four months.[76]

During breastfeeding, approximately 0.25–0.5 grams per day of secretory IgA antibodies pass to the baby via milk.[77][78] This is one of the important features of colostrum.[79] The main target for these antibodies are probably microorganisms in the baby's intestine. The rest of the body displays some uptake of IgA,[80] but this amount is relatively small.[81]

Maternal vaccinations while breastfeeding is safe for almost all vaccines. Additionally, the mother's immunity obtained by vaccination against tetanus, diphtheria, whooping cough and influenza can protect the baby from these diseases, and breastfeeding can reduce fever rate after infant immunization. However, smallpox and yellow fever vaccines increase the risk of infants developing vaccinia and encephalitis.[82][83]

## Mortality [edit]

Babies who are not breastfed are almost six times more likely to die by the age of one month than those who receive at least some breastmilk.[84]

### Diabetes [edit]

Infants exclusively breastfed have less chance of developing diabetes mellitus type 1 than those with a shorter duration of breastfeeding.[70] Breastfed infants appear to have a lower likelihood of developing diabetes mellitus type 2 later in life.[69][70][85] Breastfeeding is also associated with a lower risk of type 2 diabetes among mothers who practice it.[86]

### Childhood obesity [edit]

The protective effect of breastfeeding against obesity is consistent, though small, across many studies.[69][70][87] A 2013 longitudinal study reported less obesity at ages two and four years among infants who were breastfed for at least four months.[88]

### Allergic diseases [edit]

In children who are at risk for developing allergic diseases (defined as at least one parent or sibling having atopy), atopic syndrome can be prevented or delayed through 4-month exclusive breastfeeding, though these benefits may not persist.[89]

### Other health effects [edit]

Breastfeeding may reduce the risk of necrotizing enterocolitis (NEC).[70]

Breastfeeding or introduction of gluten while breastfeeding don't protect against celiac disease among at-risk children. Breast milk of healthy human mothers who eat gluten-containing foods presents high levels of non-degraded gliadin (the main gluten protein). Early introduction of traces of gluten in babies to potentially induce tolerance doesn't reduce the risk of developing celiac disease. Delaying the introduction of gluten does not prevent, but is associated with a delayed onset of the disease.[90][91]

About 19% of leukemia cases may be prevented by breastfeeding for six months or longer.[92]

Breastfeeding may decrease the risk of cardiovascular disease in later life, as indicated by lower cholesterol and C-reactive protein levels in breastfed adult women.[69] Breastfed infants have somewhat lower blood pressure later in life, but it is unclear how much practical benefit this provides.[69][70]

A 1998 study suggested that breastfed babies have a better chance of good dental health than formula-fed infants because of the developmental effects of breastfeeding on the oral cavity and airway. It was thought that with fewer malocclusions, breastfed children may have a reduced need for orthodontic intervention. The report suggested that children with a well rounded, "U-shaped" dental arch, which is found more commonly in breastfed children, may have fewer problems with snoring and sleep apnea in later life.[93] A 2016 review found that breastfeeding protected against malocclusions.[94]

### Intelligence [edit]

It is unclear whether breastfeeding improves intelligence later in life. Several studies found no relationship after controlling for confounding factors like maternal intelligence (smarter mothers were more likely to breastfeed their babies).[70][95] However, other studies concluded that breastfeeding was associated with increased cognitive development in childhood, although the cause may be increased mother–child interaction rather than nutrition.[69]

## Mother [edit]

Breastfeeding aids maternal physical and emotional health. Breastfeeding and depression in the mother are associated.[96] Mothers who successfully breastfeed are less likely to develop postpartum depression.[97]

## Maternal bond [edit]

Hormones released during breastfeeding help to strengthen the maternal bond.[21] Teaching partners how to manage common difficulties is associated with higher breastfeeding rates.[98] Support for a breastfeeding mother can strengthen familial bonds and help build a paternal bond.[21][99]

## Fertility [edit]

*Main article: Postpartum infertility*

Exclusive breastfeeding usually delays the return of fertility through lactational amenorrhea, although it does not provide reliable birth control. Breastfeeding may delay the return to fertility for some women by

suppressing ovulation. Mothers may not ovulate, or have regular periods, during the entire lactation period. The non-ovulating period varies by individual. This has been used as natural contraception, with greater than 98% effectiveness during the first six months after birth if specific nursing behaviors are followed.[100]

### Hormonal [edit]

Breastfeeding releases beneficial hormones into the mother's body.[78] Oxytocin and prolactin hormones relax the mother and increase her nurturing response.[101] This hormone release can help to enable sleep. Breastfeeding soon after birth increases the mother's oxytocin levels, making her uterus contract more quickly and reducing bleeding. Pitocin, a synthetic hormone used to make the uterus contract during and after labour, is structurally modelled on oxytocin. Syntocinon, another synthetic oxytocic, is commonly used in Australia and the UK rather than Pitocin.[102]

### Weight loss [edit]

It is unclear whether breastfeeding causes mothers to lose weight after giving birth.[70]

### Reduced cancer risk [edit]

For breastfeeding women, long-term health benefits include reduced risk of breast cancer, ovarian cancer, and endometrial cancer.[27][70][103]

## Decision factors [edit]

*Main article: Breastfeeding difficulties*

The majority of mothers intend to breastfeed at birth. Many factors can disrupt this intent. Research done in the U.S. shows that information about breastfeeding is rarely provided by a women's obstetricians during their prenatal visits and some health professionals incorrectly believe that due to recent improvements commercially prepared formula is equal to breast milk in terms of its health benefits.[104] Many hospitals have instituted practices that encourage breastfeeding, however a 2012 survey in the U.S. found that 24% of maternity services were still providing supplements of commercial infant formula as a general practice in the first 48 hours after birth.[3] *The Surgeon General's Call to Action to Support Breastfeeding* attempts to educate practitioners.[105]

### Social support [edit]

Work is the most commonly cited reason for not breastfeeding.[106] In 2012 Save the Children examined maternity leave laws, ranking 36 industrialized countries according to their support for breastfeeding. Norway ranked first, while the United States came in last.[107] Maternity leave in the US varies widely, including by state, despite the Family Medical Leave Act (FMLA), which guarantees most mothers up to 12 weeks unpaid leave. The majority of US mothers resume work earlier.

- Mother – Adolescence is a risk factor for low breastfeeding rates, although classes, books and personal counseling (professional or lay) can help compensate.[108] Some women fear that breastfeeding will negatively impact the look of their breasts. However, a 2008 study found that breastfeeding had no effect on a woman's breasts, other factors did contribute to "drooping" of the breasts, such as advanced age, number of pregnancies and smoking behavior.[109]
- Partner – Partners may lack knowledge of breastfeeding and their role in the practice.

### Healthcare [edit]

Infants that are otherwise healthy uniformly benefit from breastfeeding. "No known disadvantages" stem from breastfeeding.[110] However, extra precautions should be taken or breastfeeding be avoided in circumstances including

certain infectious diseases, or use of certain medications.[111] In some cases it may not be feasible for the mother to continue breastfeeding.[112]

A number of hospital-employed procedures have been found to interfere with breastfeeding, including routine mother/baby separation, delayed initiation, vigorous routine suctioning, medications and mode of delivery.[113]

Pain caused from mis-positioning the baby on the breast or a tongue-tie in the infant can cause pain in the mother and discourage her. These problems are generally easy to correct (by re-positioning or clipping the tongue-tie).[114]

Breast surgery, including breast implants or breast reduction surgery, reduces the chances that a woman will have sufficient milk to breastfeed.[115] Women whose pregnancies are unintended are less likely to breast feed their babies.[116]

## Maternal infections [edit]

*Main article: Breastfeeding by HIV infected mothers*

The central concern about breastfeeding in the presence of maternal HIV is risks of the child becoming infected. Factors such as the viral load in the mother's milk complicate breastfeeding recommendations for HIV-positive mothers.[117]

In mothers who are treated with antiretroviral drugs the risk of HIV transmission with breastfeeding is 1 to 2%.[2] Therefore, of breastfeeding is still recommended in areas of the world with death from infectious diseases is common.[2] Infant formula should only be given if this can be safely done.[2]

WHO recommends that national authorities in each country decide which infant feeding practice should be promoted by their maternal and child health services to best avoid HIV transmission from mother to child.[118] Other maternal infection of concern include active untreated tuberculosis or human T-lymphotropic virus.

## Medications [edit]

Breastfeeding mothers should inform their healthcare provider about all of the medications they are taking, including herbal products. Nursing mothers can safely take many over-the-counter drugs and prescription drugs and receive immunizations, but certain drugs, including painkillers and psychiatric drugs, may pose a risk.

The U.S. National Library of Medicine publishes "LactMed", an up-to-date online database of information on drugs and lactation. Geared to both healthcare practitioners and nursing mothers, LactMed contains over 450 drug records with information such as potential drug effects and alternate drugs to consider.[83][119]

Some pollutants in the mother's food and drink are passed to the baby through breast milk, including mercury (found in some carnivorous fish),[120] caffeine,[121] and bisphenol A.[122][123]

## Socioeconomic status [edit]

Race, ethnicity and socioeconomic status affect choice and duration in the United States. A 2011 study found that on average, US women who breastfed had higher levels of education, were older and were more likely to be white.[124]

The reasons for the persistently lower rates of breastfeeding among African American mothers are not well understood, but employment may play a role. They tend to return to work sooner than white mothers, and are more likely to work in unsupportive environments.

Although return to work is associated with early discontinuation, a supportive work environment may encourage mothers to continue.

Low-income mothers are more likely to have unintended pregnancies.[124] Mothers whose pregnancies are unintended are less likely to breastfeed.[116]

## Social acceptance [edit]

*Main article: Breastfeeding in public*

Negative perception of breastfeeding in social settings has led some women to feel discomfort when breastfeeding in public.[125] Public breastfeeding is forbidden in some places, not addressed by law in others, and a granted legal right in others. Even given a legal right, some mothers are reluctant to breastfeed,[126][127] while others may object to the practice.[128] Some public places and workplaces, rooms for mothers to nurse in private have been designated.

The invention of formula was hypothesized as a way for western culture to adapt to negative perceptions of breastfeeding.[129] The breast pump offered a way for mothers to supply breast milk with most of formula feeding's convenience and without enduring possible disapproval of nursing.[130]

Western society tends to perceive breasts in sexual terms instead of for their biological purpose.[131] This view led many to object to breastfeeding because of the implicit association between infant feeding and sex.[132] Many women feel embarrassed to breast-feed in public.[126] These negative cultural connotations may reduce breastfeeding duration.[126][133][134] Maternal guilt and shame is often affected by how a mother feeds her infant. These feelings result from her inability to behave according to her definition of a "good mother". These feelings occur in both bottle- and breast- feeding mothers, although for different reasons. Bottle feeding mothers may feel that they should be breastfeeding.[135] Conversely, breastfeeding mothers may feel forced to feed in uncomfortable circumstances. Some may see breastfeeding as, "indecent, disgusting, animalistic, sexual, and even possibly a perverse act."[131] Advocates use "nurse-ins" to show support for breastfeeding in public.[125] Some advocates emphasize providing women with education on breastfeeding's benefits as well as problem-solving skills.[135]

If someone criticizes breastfeeding in public, the La Leche League offers a few ways to respond:

- Ignore the comment or change the subject.
- Share information on breastfeeding with the other person.
- Make a joke about the situation or yourself to lighten the mood.
- Show that you are recognizing the person's viewpoint by asking further questions without agreeing or responding to the criticism.
- Be empathetic — show that you understand the other person's feeling and meaning.[136]

# Prevalence [edit]

Globally about 38% of babies are just breastfeed during their first six months of life.[2] In the United States as of 2012, 75% of women started breastfeeding, 43% breastfeed for six months though only 13% exclusively breastfed, and 23%

breastfeed for twelve months.[3][138]

Breastfeeding rates in different parts of China vary considerably.[139]

Breastfeeding rates in the United Kingdom were the lowest in the world in 2015 with only 0.5% of mothers still breastfeeding at a year, while in Germany 23% are doing so, 56% in Brazil and 99% in Senegal.[140]

In Australia for children born in 2004, more than 90% were initially breastfed.[141] In Canada for children born in 2005-06, more than 50% were only breastfed and more than 15% received both breastmilk and other liquids, by the age of 3 months.[142]

## History [edit]

*Main article: History and culture of breastfeeding*

In the Egyptian, Greek and Roman empires, women usually fed only their own children. However, breastfeeding began to be seen as something too common to be done by royalty, and wet nurses were employed to breastfeed the children of the royal families. This extended over time, particularly in western Europe, where noble women often made use of wet nurses. Lower-class women breastfed their infants and used a wet nurse only if they were unable to feed their own infant. Attempts were made in 15th-century Europe to use cow or goat milk, but these attempts were not successful. In the 18th century, flour or cereal mixed with broth were introduced as substitutes for breastfeeding, but this was also unsuccessful.

During the early 1900s, breastfeeding started to be viewed negatively by Western societies, especially Canada and the US. These societies considered it a low class and uncultured practice.[143] This coincided with the appearance of improved infant formulas in the mid 19th century and its increased use, which accelerated after World War II. From the 1960s onwards, breastfeeding experienced a revival which continued into the 2000s, though negative attitudes towards the practice were still entrenched up to 1990s.[143]

## Society and culture [edit]

### Financial considerations [edit]

Breastfeeding is cheaper than alternatives, but is not free of cost. The mother generally must eat more food than otherwise. In the US, the extra money spent on food (about US$13 each week) is usually about half as much money as the cost of infant formula.[144]

Breastfeeding represents an opportunity cost, as the mother must spend hours each day breastfeeding instead of other activities, such as paid

work or home production (such as growing food). In general, the higher the mother's earning power, the less likely she is to save money by breastfeeding.[145]

Breastfeeding reduces health care costs and the cost of caring for sick babies. Parents of breastfed babies are less likely to miss work and lose income because their babies are sick.[144] Looking at three of the most common infant illnesses, lower respiratory tract illnesses, otitis media, and gastrointestinal illness, one study compared infants that had been exclusively breastfed for at least three months to those who had not. It found that in the first year of life there were 2033 excess office visits, 212 excess days of hospitalization, and 609 excess prescriptions for these three illnesses per 1000 never-breastfed infants compared with 1000 infants exclusively breastfed for at least 3 months.[146]

## Recommendations [edit]

Support for breastfeeding is universal among major health and children's organizations. WHO states, "Breast milk is the ideal food for the healthy growth and development of infants; breastfeeding is also an integral part of the reproductive process with important implications for the health of mothers.".[147] WHO's guidelines recommend "continue[d] frequent, on-demand breastfeeding until two years of age or beyond."[148][149]

The European Commission,[150][151] the US Centers for Disease Control and Prevention[152] (CDC), UNICEF, AAP,[3] Save The Children and the UK National Health Service[153] (NHS), Australian Department of Health,[154] Health Canada, Canadian Paediatric Society, Dietitians of Canada, and Breastfeeding Committee for Canada,[155] recommend exclusive breastfeeding for six months following birth and continued nursing for an additional eighteen months or more.[2][156] Save the Children states, "Six months of exclusive breastfeeding increases a child's chance of survival at least six-fold."[157]

Authorities generally advise avoiding bottle feeding until the baby is 4–6 weeks old and is nursing successfully.[158]

## Advocacy [edit]

International board certified lactation consultants (IBCLCs) are health care professionals certified in lactation management. They work with mothers to solve breastfeeding problems and educate families and health professionals. Exclusive and partial breastfeeding are more common among mothers who gave birth in IBCLC-equipped hospitals.[160]

There are also controversies and ethical considerations surrounding the means used by public campaigns which attempt to increase breastfeeding rates, relating to pressure put on women, and potential feeling of guilt and shame of women who fail to breastfeed; and social condemnation of women who use formula.[161][162] [163][164] In addition to this, there is also the moral question as to what degree the state or medical community can interfere with the self-determination of a woman: for example in the United Arab Emirates the law requires a woman to breastfeed her baby for at least 2 years and allows her husband to sue her if she does not do so.[165][166]

"See It", a project dedicated to promoting the awareness of breastfeeding in the capital city of Iceland in 2011, by Fiann Paul.[159]

## Infant formula [edit]

Advocates oppose marketing of infant formula, especially in developing countries. They are concerned that mothers who use formula will stop breastfeeding and become dependent upon substitutes that are unaffordable or less safe.[167][168] Through efforts including the Nestlé boycott, they have advocated for bans on free samples of infant formula and for the adoption of pro-breastfeeding codes such as the International Code of Marketing of Breast-milk Substitutes by the World Health Assembly in 1981 and the Innocenti Declaration by WHO and UNICEF policy-makers in August 1990.[167]

## LGBTQ [edit]

Parents who identify as LGBTQ may encounter unique challenges and opportunities with breastfeeding or chestfeeding.

### Chestfeeding [edit]

Many transmasculine, gender non-binary, and gender nonconforming individuals prefer the gender-neutral term "chestfeeding."[169][170] Even if they have had chest masculinization surgery as part of their transition, some trans men choose to chestfeed their infants,[171] which may require use of a supplemental nursing system (SNS) if they do not have a full milk supply.[172] Individuals who have taken or are currently on hormone replacement therapy to develop male secondary sex characteristics may still chestfeed safely and successfully.[171]

### Induced lactation [edit]

Trans women who choose to breastfeed their children have successfully induced lactation.[173] Similarly, lesbian mothers have co-nursed their infants, either by inducing lactation or by using a supplemental nursing system.[174]

## Research [edit]

Breastfeeding research currently focuses on diverse aspects such as prevalence, HIV transmission, pharmacology, costs, benefits, immunology, contraindications, and comparisons to synthetic breast milk substitutes.[175][176] Factors related to the mental health of the nursing mother in the perinatal period have been studied. While cognitive behavior therapy may be the treatment of choice, medications are sometimes used. The use of therapy rather than medication reduces the infant's exposure to medication that may be transmitted through the milk.[177]

# Childbirth

From Wikipedia, the free encyclopedia

*This article is about birth in humans. For birth in other mammals, see birth.*

**Childbirth**, also known as **labour and delivery**, is the ending of a pregnancy by one or more babies leaving a woman's uterus.[1] In 2015 there were about 135 million births globally.[2] About 15 million were born before 37 weeks of gestation,[3] while between 3 and 12% were born after 42 weeks.[4] In the developed world most deliveries occur in hospital,[5][6] while in the developing world most births take place at home with the support of a traditional birth attendant.[7]

The most common way of childbirth is a vaginal delivery.[8] It involves three stages of labour: the shortening and opening of the cervix, descent and birth of the baby, and the pushing out of the placenta.[9] The first stage typically lasts twelve to nineteen hours, the second stage twenty minutes to two hours, and the third stage five to thirty minutes.[10] The first stage begins with crampy abdominal or back pains that last around half a minute and occur every ten to thirty minutes.[9] The crampy pains become stronger and closer together over time.[10] During the second stage pushing with contractions may occur.[10] In the third stage delayed clamping of the umbilical cord is generally recommended.[11] A number of methods can help with pain such as relaxation techniques, opioids, and spinal blocks.[10]

Most babies are born head first; however about 4% are born feet or buttock first, known as breech.[10][12] During labour a women can generally eat and move around as she likes, pushing is not recommended during the first stage or during delivery of the head, and enemas are not recommended.[13] While making a cut to the opening of the vagina is common, known as an episiotomy, it is generally not needed.[10] In 2012, about 23 million deliveries occurred by a surgical procedure known as Caesarean section.[14] Caesarean sections may be recommended for twins, signs of distress in the baby, or breech position.[10] This method of delivery can take longer to heal from.[10]

Each year complications from pregnancy and childbirth result in about 500,000 maternal deaths, 7 million women have serious long term problems, and 50 million women have health negative outcomes following delivery.[15] Most of these occur in the developing world.[15] Specific complications include obstructed labour, postpartum bleeding, eclampsia, and postpartum infection.[15] Complications in the baby include birth asphyxia.[16]

## Signs and symptoms [edit]

The most prominent sign of labour is strong repetitive uterine contractions. The distress levels reported by labouring women vary widely. They appear to be influenced by fear and anxiety levels, experience with prior childbirth, cultural ideas of childbirth and pain,[17][18] mobility during labour, and the support received during labour. Personal expectations, the amount of support from caregivers, quality of the caregiver-patient relationship, and involvement in decision-making are more important in women's overall satisfaction with the experience of childbirth than are other factors such as age, socioeconomic status, ethnicity, preparation, physical environment, pain, immobility, or medical interventions.[19]

### Descriptions [edit]

Pain in contractions has been described as feeling similar to very strong menstrual cramps. Women are often encouraged to refrain from screaming, but moaning and grunting may be encouraged to help lessen pain. Crowning may be experienced as an intense stretching and burning. Even women who show little reaction to labour pains, in comparison to other women, show a substantially severe reaction to crowning.

Back labour is a term for specific pain occurring in the lower back, just above the tailbone, during childbirth.[20]

### Psychological [edit]

Childbirth can be an intense event and strong emotions, both positive and negative, can be brought to the surface. Abnormal and persistent fear of childbirth is known as tokophobia.

During the later stages of gestation there is an increase in abundance of oxytocin, a hormone that is known to evoke feelings of contentment, reductions in anxiety, and feelings of calmness and security around the mate.[21] Oxytocin is further released during labour when the fetus stimulates the cervix and vagina, and it is believed that it plays a major role in the bonding of a mother to her infant and in the establishment of maternal behavior. The act of nursing a child also causes a release of oxytocin.[22]

Between 70% and 80% of mothers in the United States report some feelings of sadness or "baby blues" after giving birth. The symptoms normally occur for a few minutes up to few hours each day and they should lessen and disappear within two weeks after delivery. Postpartum depression may develop in some women; about 10% of mothers in the United States are diagnosed with this condition. Preventive group therapy has proven effective as a prophylactic treatment for postpartum depression.[23][24]

## Normal birth [edit]

*Further information: Vaginal delivery*

Humans are bipedal with an erect stance. The erect posture causes the weight of the abdominal contents to thrust on the

pelvic floor, a complex structure which must not only support this weight but allow, in women, three channels to pass through it: the urethra, the vagina and the rectum. The infant's head and shoulders must go through a specific sequence of maneuvers in order to pass through the ring of the mother's pelvis.

Six phases of a typical vertex (head-first presentation) delivery:

1. **Engagement** of the fetal head in the transverse position. The baby's head is facing across the pelvis at one or other of the mother's hips.
2. **Descent and flexion** of the fetal head.
3. **Internal rotation**. The fetal head rotates 90 degrees to the occipito-anterior position so that the baby's face is towards the mother's rectum.
4. **Delivery by extension**. The fetal head passes out of the birth canal. Its head is tilted forwards so that the crown of its head leads the way through the vagina.
5. **Restitution**. The fetal head turns through 45 degrees to restore its normal relationship with the shoulders, which are still at an angle.
6. **External rotation**. The shoulders repeat the corkscrew movements of the head, which can be seen in the final movements of the fetal head.

**Station** refers to the relationship of the fetal presenting part to the level of the ischial spines. When the presenting part is at the ischial spines the station is 0 (synonymous with engagement). If the presenting fetal part is above the spines, the distance is measured and described as minus stations, which range from −1 to −4 cm. If the presenting part is below the ischial spines, the distance is stated as plus stations ( +1 to +4 cm). At +3 and +4 the presenting part is at the perineum and can be seen.[25]

The fetal head may temporarily change shape substantially (becoming more elongated) as it moves through the birth canal. This change in the shape of the fetal head is called *molding* and is much more prominent in women having their first vaginal delivery.[26]

## Onset of labour [edit]

There are various definitions of the onset of labour, including:

- Regular uterine contractions at least every six minutes with evidence of change in cervical dilation or cervical effacement between consecutive digital examinations.[27]
- Regular contractions occurring less than 10 min apart and progressive cervical dilation or cervical effacement.[28]
- At least 3 painful regular uterine contractions during a 10-minute period, each lasting more than 45 seconds.[29]

In order to avail for more uniform terminology, the first stage of labour is divided into "latent" and "active" phases, where the latent phase is sometimes included in the definition of labour,[30] and sometimes not.[31]

Some reports note that the onset of term labour more commonly takes place in the late night and early morning hours. This may be a result of a synergism between the nocturnal increase in melatonin and oxytocin.[32]

## First stage: latent phase [edit]

The latent phase of labour is also called the quiescent phase, prodromal labour, or pre-labour. It is a subclassification of the first stage.[33]

The latent phase is generally defined as beginning at the point at which the woman perceives regular uterine contractions.[34] In contrast, Braxton Hicks contractions, which are contractions that may start around 26 weeks gestation and are sometimes called "false labour", should be infrequent, irregular, and involve only mild cramping.[35] The signaling mechanisms responsible for uterine coordination are complex. Electrical propagation is the primary mechanism used for signaling up to several centimeters. Over longer distances, however, signaling may involve a mechanical mechanism.[36]

Cervical effacement, which is the thinning and stretching of the cervix, and cervical dilation occur during the closing weeks of pregnancy and is usually complete or near complete, by the end of the latent phase.[*citation needed*] The degree of cervical effacement may be felt during a vaginal examination. A 'long' cervix implies that effacement has not yet occurred. Latent phase ends with the onset of active first stage, and this transition is defined retrospectively.

## First stage: active phase [edit]

The active stage of labour (or "active phase of first stage" if the previous phase is termed "latent phase of first stage") has geographically differing definitions. In the US, the definition of active labour was changed from 3 to 4 cm, to 5 cm of cervical dilation for multiparous women, mothers who had given birth previously, and at 6 cm for nulliparous women, those who had not given birth before.[37] This has been done in an effort to increase the rates of vaginal delivery.[38]

A definition of active labour in a British journal was having contractions more frequent than every 5 minutes, in addition to either a cervical dilation of 3 cm or more or a cervical effacement of 80% or more.[39]

In Sweden, the onset of the active phase of labour is defined as when two of the following criteria are met:[40]

- three to four contractions every ten minutes
- rupture of membranes
- cervical dilation of 3 to 4 cm

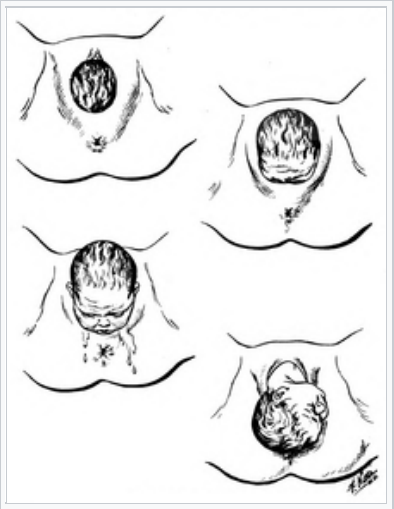
Health care providers may assess a labouring mother's progress in labour by performing a cervical exam to evaluate the cervical dilation, effacement, and station. These factors form the Bishop score. The Bishop score can also be used as a means to predict the success of an induction of labour.

During effacement, the cervix becomes incorporated into the lower segment of the uterus. During a contraction, uterine muscles contract causing shortening of the upper segment and drawing upwards of the lower segment, in a gradual expulsive motion.[*citation needed*] The presenting fetal part then is permitted to descend. Full dilation is reached when the cervix has widened enough to allow passage of the baby's head, around 10 cm dilation for a term baby.

The duration of labour varies widely, but the active phase averages some 8 hours[41] for women giving birth to their first child ("primiparae") and shorter for women who have already given birth ("multiparae"). Active phase prolongation is defined as in a primigravid woman as the failure of the cervix to dilate at a rate of 1.2 cm/h over a period of at least two hours. This definition is based on Friedman's Curve, which plots the typical rate of cervical dilation and fetal descent during active labour.[42] Some practitioners may diagnose "Failure to Progress", and consequently, propose interventions to optimize chances for healthy outcome.[43]

## Second stage: fetal expulsion [edit]

The expulsion stage (stimulated by prostaglandins and oxytocin) begins when the cervix is fully dilated, and ends when the baby is born. As pressure on the cervix increases, women may have the sensation of pelvic pressure and an urge to begin pushing. At the beginning of the normal second stage, the head is fully engaged in the pelvis; the widest diameter of the head has passed below the level of the pelvic inlet. The fetal head then continues descent into the pelvis, below the pubic arch and out through the vaginal introitus (opening). This is assisted by the additional maternal efforts of "bearing down" or pushing. The appearance of the fetal head at the vaginal orifice is termed the "crowning". At this point, the woman will feel an intense burning or stinging sensation.



Stages in the birth of the baby's head.

When the amniotic sac has not ruptured during labour or pushing, the infant can be born with the membranes intact. This is referred to as "delivery en caul".

Complete expulsion of the baby signals the successful completion of the second stage of labour.

The second stage of birth will vary by factors including parity (the number of children a woman has had), fetal size, anesthesia, and the presence of infection. Longer labours are associated with declining rates of spontaneous vaginal delivery and increasing rates of infection, perineal laceration, and obstetric hemorrhage, as well as the need for intensive care of the neonate.[44]

## Third stage: placenta delivery [edit]

*Further information: Umbilical cord and Placental expulsion*

The period from just after the fetus is expelled until just after the placenta is expelled is called the *third stage of labour* or the *involution stage*. Placental expulsion begins as a physiological separation from the wall of the uterus. The average time from delivery of the baby until complete expulsion of the placenta is estimated to be 10–12 minutes dependent on whether active or expectant management is employed[45] In as many as 3% of all

A newborn baby with umbilical cord ready to be clamped

vaginal deliveries, the duration of the third stage is longer than 30 minutes and raises concern for retained placenta.[46]

Placental expulsion can be managed actively or it can be managed expectantly, allowing the placenta to be expelled without medical assistance. Active management is described as the administration of a uterotonic drug within one minute of fetal delivery, controlled traction of the umbilical cord and fundal massage after delivery of the placenta, followed by performance of uterine massage every 15 minutes for two hours.[47] In a joint statement, World Health Organization, the International Federation of Gynaecology and Obstetrics and the International Confederation of Midwives recommend active management of the third stage of labour in all vaginal deliveries to help to prevent postpartum hemorrhage.[48][49][50]

Delaying the clamping of the umbilical cord until at least one minute after birth improves outcomes as long as there is the ability to treat jaundice if it occurs.[51] In some birthing centers, this may be delayed by 5 minutes or more, or omitted entirely. Delayed clamping of the cord decreases the risk of anemia but may increase risk of jaundice. Clamping is followed by cutting of the cord, which is painless due to the absence of nerves.

## Fourth stage [edit]

*Further information: Postnatal*

Newborn rests as caregiver checks breath sounds

The "fourth stage of labour" is the period beginning immediately after the birth of a child and extending for about six weeks. The terms postpartum and postnatal are often used to describe this period.[52] It is the time in which the mother's body, including hormone levels and uterus size, return to a non-pregnant state and the newborn adjusts to life outside the mother's body. The World Health Organization (WHO) describes the postnatal period as the most critical and yet the most neglected phase in the lives of mothers and babies; most deaths occur during the postnatal period.[53]

Following the birth, if the mother had an episiotomy or a tearing of the perineum, it is stitched. The mother should have regular assessments for uterine contraction and fundal height,[54] vaginal bleeding, heart rate and blood pressure, and temperature, for the first 24 hours after birth. The first passing of urine should be documented within 6 hours.[53] Afterpains (pains similar to menstrual cramps), contractions of the uterus to prevent excessive blood flow, continue for several days. Vaginal discharge, termed "lochia", can be expected to continue for several weeks; initially bright red, it gradually becomes pink, changing to brown, and finally to yellow or white.[55]

A 30 minute old infant receiving routine care.

Most authorities suggest the infant be placed in skin-to-skin contact with the mother for 1 –2 hours immediately after birth, putting routine cares off till later.

Until recently babies born in hospitals were removed from their mothers shortly after birth and brought to the mother only at feeding times. Mothers were told that their newborn would be safer in the nursery and that the separation would offer the mother more time to rest. As attitudes began to change, some hospitals offered a "rooming in" option wherein after a period of routine hospital procedures and observation, the infant could be allowed to share the mother's room. However, more recent information has begun to question the standard practice of removing the newborn immediately postpartum for routine postnatal procedures before being returned to the mother. Beginning around 2000, some authorities began to suggest that early skin-to-skin contact (placing the naked baby on the mother's chest) may benefit both mother and infant. Using animal studies that have shown that the intimate contact inherent in skin-to-skin contact promotes neurobehaviors that result in the fulfillment of basic biological needs as a model, recent studies have been done to assess what, if any, advantages may be associated with early skin-to-skin contact for human mothers and their babies. A 2011 medical review looked at existing studies and found that early skin-to-skin contact, sometimes called kangaroo care, resulted in improved breastfeeding outcomes, cardio-respiratory stability, and a decrease in infant crying. [56][57][58] A 2007 Cochrane review of studies found that skin-to-skin contact at birth reduced crying, kept the baby warmer, improved mother-baby interaction, and improved the chances for successful breastfeeding.[59]

As of 2014, early postpartum skin-to-skin contact is endorsed by all major organizations that are responsible for the well-[60]

being of infants, including the American Academy of Pediatrics. The World Health Organization (WHO) states that "the process of childbirth is not finished until the baby has safely transferred from placental to mammary nutrition." They advise that the newborn be placed skin-to-skin with the mother, postponing any routine procedures for at least one to two hours. The WHO suggests that any initial observations of the infant can be done while the infant remains close to the mother, saying that even a brief separation before the baby has had its first feed can disturb the bonding process. They further advise frequent skin-to-skin contact as much as possible during the first days after delivery, especially if it was interrupted for some reason after the delivery.[61] The National Institute for Health and Care Excellence also advises postponing procedures such as weighing, measuring, and bathing for at least 1 hour to insure an initial period of skin-to-skin contact between mother and infant. [62]

## Management [edit]

Deliveries are assisted by a number of professions include: obstetricians, family physicians and midwives. For low risk pregnancies all three result in similar outcomes.[63]

### Preparation [edit]

Eating or drinking during labour is an area of ongoing debate. While some have argued that eating in labour has no harmful effects on outcomes,[64] others continue to have concern regarding the increased possibility of an aspiration event (choking on recently eaten foods) in the event of an emergency delivery due to the increased relaxation of the esophagus in pregnancy, upward pressure of the uterus on the stomach, and the possibility of general anesthetic in the event of an emergency cesarean.[65] A 2013 Cochrane review found that with good obstetrical anaesthesia there is no change in harms from allowing eating and drinking during labour in those who are unlikely to need surgery. They additionally acknowledge that not eating does not mean there is an empty stomach or that its contents are not as acidic. They therefore conclude that "women should be free to eat and drink in labour, or not, as they wish."[66]

At one time shaving of the area around the vagina, was common practice due to the belief that hair removal reduced the risk of infection, made an episiotomy (a surgical cut to enlarge the vaginal entrance) easier, and helped with instrumental deliveries. It is currently less common, though it is still a routine procedure in some countries. A 2009 Cochrane review found no evidence of any benefit with perineal shaving. The review did find side effects including irritation, redness, and multiple superficial scratches from the razor.[67][*needs update*] Another effort to prevent infection has been the use of the antiseptic chlorhexidine or providone-iodine solution in the vagina. Evidence of benefit with chlorhexidine is lacking.[68] A decreased risk is found with providone-iodine when a cesarean section is to be performed.[69]

### Active management [edit]

Active management of labour consists of a number of care principles, including frequent assessment of cervical dilatation. If the cervix is not dilating, oxytocin is offered. This management results in a slightly reduced number of caesarean births, but does not change how many women have assisted vaginal births. 75% of women report that they are very satisfied with either active management or normal care.[70]

### Labour induction and elective cesarean [edit]

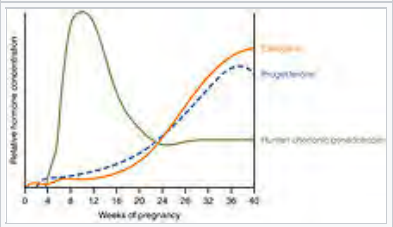
In many cases and with increasing frequency, childbirth is achieved through induction of labour or caesarean section. Caesarean section is the removal of the neonate through a surgical incision in the abdomen, rather than through vaginal birth.[71] Childbirth by C-Sections increased 50% in the U.S. from 1996 to 2006, and comprise nearly 32% of births in the U.S. and Canada.[71][72] Induced births and elective cesarean before 39 weeks can be harmful to the neonate as well as harmful or without benefit to the mother. Therefore, many guidelines recommend against non-medically required induced births and elective cesarean before 39 weeks.[73] The rate of labour induction in the United States is 22%, and has more than doubled from 1990 to 2006.[74][75]

Health conditions that may warrant induced labour or cesarean delivery include gestational or chronic hypertension, preeclampsia, eclampsia, diabetes, premature rupture of membranes, severe fetal growth restriction, and post-term pregnancy. Cesarean section too may be of benefit to both the mother and baby for certain indications including maternal HIV/AIDS, fetal abnormality, breech position, fetal distress, multiple gestations, and maternal medical conditions which would be worsened by labour or vaginal birth.

Pitocin is the most commonly used agent for induction in the United States, and is used to induce uterine contractions. Other methods of inducing labour include stripping of the amniotic membrane, artificial rupturing of the amniotic sac (called amniotomy), or nipple stimulation. Ripening of the cervix can be accomplished with the placement of a Foley [74]

The child as it is passing out through the vagina must pass through the lesser pelvis.

catheter or the use of synthetic prostaglandins such as misoprostol. A large review of methods of induction was published in 2011.[76]



The hormones initiating labour.

The American Congress of Obstetricians and Gynecologists (ACOG) guidelines recommend a full evaluation of the maternal-fetal status, the status of the cervix, and at least a 39 completed weeks (full term) of gestation for optimal health of the newborn when considering elective induction of labour. Per these guidelines, the following conditions may be an indication for induction, including:

- Abruptio placentae
- Chorioamnionitis
- Fetal compromise such as isoimmunization leading to hemolytic disease of the newborn or oligohydramnios
- Fetal demise
- Gestational hypertension
- Maternal conditions such as gestational diabetes or chronic kidney disease
- Preeclampsia or eclampsia
- Premature rupture of membranes
- Postterm pregnancy

Induction is also considered for logistical reasons, such as the distance from hospital or psychosocial conditions, but in these instances gestational age confirmation must be done, and the maturity of the fetal lung must be confirmed by testing.

The ACOG also note that contraindications for induced labour are the same as for spontaneous vaginal delivery, including vasa previa, complete placenta praevia, umbilical cord prolapse or active genital herpes simplex infection.[77]

## Pain control [edit]

### Non pharmaceutical [edit]

Some women prefer to avoid analgesic medication during childbirth. Psychological preparation may be beneficial.[78] A recent Cochrane overview of systematic reviews on non-drug interventions found that relaxation techniques, immersion in water, massage, and acupuncture may provide pain relief. Acupuncture and relaxation were found to decrease the number of caesarean sections required.[79] Immersion in water has been found to relieve pain during the first stage of labor and to reduce the need for anesthesia and shorten the duration of labor, however the safety and efficacy of immersion during birth, water birth, has not been established or associated with maternal or fetal benefit.[80]

Some women like to have someone to support them during labour and birth; such as a midwife, nurse, or doula; or a lay person such as the father of the baby, a family member, or a close friend. Studies have found that continuous support during labor and delivery reduce the need for medication and a caesarean or operative vaginal delivery, and result in an improved Apgar score for the infant.[81] [82]

The injection of small amounts of sterile water into or just below the skin at several points on the back has been a method tried to reduce labour pain, but no good evidence shows that it actually helps.[83]

### Pharmaceutical [edit]

Different measures for pain control have varying degrees of success and side effects to the woman and her baby. In some countries of Europe, doctors commonly prescribe inhaled nitrous oxide gas for pain control, especially as 53% nitrous oxide, 47% oxygen, known as Entonox; in the UK, midwives may use this gas without a doctor's prescription. Opioids such as fentanyl may be used, but if given too close to birth there is a risk of respiratory depression in the infant.

Popular medical pain control in hospitals include the regional anesthetics epidurals (EDA), and spinal anaesthesia. Epidural analgesia is a generally safe and effective method of relieving pain in labour, but is associated with longer labour, more operative intervention (particularly instrument delivery), and increases in cost.[84] Generally, pain and stress hormones rise throughout labour for women without epidurals, while pain, fear, and stress hormones decrease upon administration of epidural analgesia, but rise again later.[85] Medicine administered via epidural can cross the placenta and enter the bloodstream of the fetus.[86] Epidural analgesia has no statistically significant impact on the risk of caesarean section, and does not appear to have an immediate effect on neonatal status as determined by Apgar scores.[87]

## Augmentation [edit]

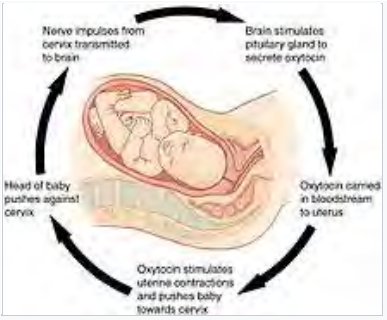
Augmentation is the process of facilitating further labour. Oxytocin has been used to increase the rate of vaginal delivery in those with a slow progress of labour.[88]

Administration of antispasmodics (e.g. hyoscine butylbromide) is not formally regarded as augmentation of labour; however, there is weak evidence that they may shorten labour.[89] There is not enough evidence to make conclusions about unwanted effects in

mothers or babies.[89]

## Episiotomy [edit]

*Further information: Episiotomy*



Oxytocin facilitates labour and will follow a positive feedback loop.

Vaginal tears can occur during childbirth, most often at the vaginal opening as the baby's head passes through, especially if the baby descends quickly. Tears can involve the perineal skin or extend to the muscles and the anal sphincter and anus. The midwife or obstetrician may decide to make a surgical cut to the perineum (episiotomy) to make the baby's birth easier and prevent severe tears that can be difficult to repair. A 2012 Cochrane review compared episiotomy as needed (restrictive) with routine episiotomy to determine the possible benefits and harms for mother and baby. The review found that restrictive episiotomy policies appeared to give a number of benefits compared with using routine episiotomy. Women experienced less severe perineal trauma, less posterior perineal trauma, less suturing and fewer healing complications at seven days with no difference in occurrence of pain, urinary incontinence, painful sex or severe vaginal/perineal trauma after birth, however they found that women experienced more anterior perineal damage with restrictive episiotomy.[90]

## Instrumental delivery [edit]

Obstetric forceps or ventouse may be used to facilitate childbirth.

## Multiple births [edit]

*Main article: Multiple birth*

In cases of a cephalic presenting twin (first baby head down), twins can often be delivered vaginally. In some cases twin delivery is done in a larger delivery room or in an operating theatre, in the event of complication e.g.

- Both twins born vaginally—this can occur both presented head first or where one comes head first and the other is breech and/or helped by a forceps/ventouse delivery
- One twin born vaginally and the other by caesarean section.
- If the twins are joined at any part of the body—called conjoined twins, delivery is mostly by caesarean section.

## Support [edit]

*See also: Men's role in childbirth*

Historically women have been attended and supported by other women during labour and birth. However currently, as more women are giving birth in a hospital rather than at home, continuous support has become the exception rather than the norm. When women became pregnant any time before the 1950s the husband would not be in the birthing room. It did not matter if it was a home birth; the husband was waiting downstairs or in another room in the home. If it was in a hospital then the husband was in the waiting room. "Her husband was attentive and kind, but, Kirby concluded, Every good woman needs a companion of her own sex."[91] Obstetric care frequently subjects women to institutional routines, which may have adverse effects on the progress of labour. Supportive care during labour may involve emotional support, comfort measures, and information and advocacy which may promote the physical process of labour as well as women's feelings of control and competence, thus reducing the need for obstetric intervention. The continuous support may be provided either by hospital staff such as nurses or midwives, doulas, or by companions of the woman's choice from her social network. There is increasing evidence to show that the participation of the child's father in the birth leads to better birth and also post-birth outcomes, providing the father does not exhibit excessive anxiety.[92]

A recent Cochrane review involving more than 15,000 women in a wide range of settings and circumstances found that "Women who received continuous labour support were more likely to give birth 'spontaneously', i.e. give birth with neither caesarean nor vacuum nor forceps. In addition, women were less likely to use pain medications, were more likely to be satisfied, and had slightly shorter labours. Their babies were less likely to have low five-minute Apgar scores."[81]

## Fetal monitoring [edit]

## External monitoring [edit]

For monitoring of the fetus during childbirth, a simple pinard stethoscope or doppler fetal monitor ("*doptone*") can be used. A

method of external (noninvasive) fetal monitoring (EFM) during childbirth is cardiotocography, using a *cardiotocograph* that consists of two sensors: The *heart* (cardio) sensor is an ultrasonic sensor, similar to a Doppler fetal monitor, that continuously emits ultrasound and detects motion of the fetal heart by the characteristic of the reflected sound. The pressure-sensitive *contraction* transducer, called a *tocodynamometer* (toco) has a flat area that is fixated to the skin by a band around the belly. The pressure required to flatten a section of the wall correlates with the internal pressure, thereby providing an estimate of contraction[93] Monitoring with a cardiotocograph can either be intermittent or continuous.

### Internal monitoring [edit]

A mother's water has to break before internal (invasive) monitoring can be used. More invasive monitoring can involve a fetal scalp electrode to give an additional measure of fetal heart activity, and/or intrauterine pressure catheter (IUPC). It can also involve fetal scalp pH testing.

## Collecting stem cells [edit]

It is currently possible to collect two types of stem cells during childbirth: amniotic stem cells and umbilical cord blood stem cells.[94] They are being studied as possible treatments of a number of conditions.[94]

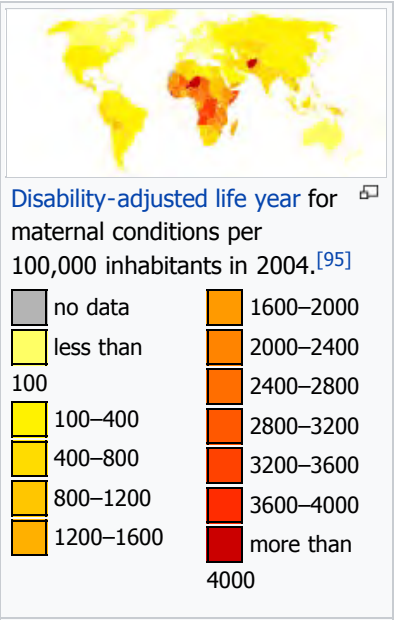
## Complications [edit]

*See also: Birth trauma (physical) and Childbirth-related posttraumatic stress disorder*

The "natural" maternal mortality rate of childbirth—where nothing is done to avert maternal death—has been estimated at 1500 deaths per 100,000 births.[96] (See main articles: neonatal death, maternal death). Each year about 500,000 women die due to pregnancy, 7 million have serious long term complications, and 50 million have negative outcomes following delivery.[15]

Modern medicine has decreased the risk of childbirth complications. In Western countries, such as the United States and Sweden, the current maternal mortality rate is around 10 deaths per 100,000 births.[96]:p.10 As of June 2011, about one third of American births have some complications, "many of which are directly related to the mother's health."[97]

Birthing complications may be maternal or fetal, and long term or short term.



Disability-adjusted life year for maternal conditions per 100,000 inhabitants in 2004.[95]

### Pre-term [edit]

Newborn mortality at 37 weeks may be 2.5 times the number at 40 weeks, and was elevated compared to 38 weeks of gestation. These "early term" births were also associated with increased death during infancy, compared to those occurring at 39 to 41 weeks ("full term").[73] Researchers found benefits to going full term and "no adverse effects" in the health of the mothers or babies.[73]

Medical researchers find that neonates born before 39 weeks experienced significantly more complications (2.5 times more in one study) compared with those delivered at 39 to 40 weeks. Health problems among babies delivered "pre-term" included respiratory distress, jaundice and low blood sugar.[73][98] The American Congress of Obstetricians and Gynecologists and medical policy makers review research studies and find increased incidence of suspected or proven sepsis, RDS, Hypoglycemia, need for respiratory support, need for NICU admission, and need for hospitalization > 4 – 5 days. In the case of cesarean sections, rates of respiratory death were 14 times higher in pre-labour at 37 compared with 40 weeks gestation, and 8.2 times higher for pre-labour cesarean at 38 weeks. In this review, no studies found decreased neonatal morbidity due to non-medically indicated (elective) delivery before 39 weeks.[73]

Disability-adjusted life year for perinatal conditions per 100,000 inhabitants in 2004.[95]

### Labour complications [edit]

The second stage of labour may be delayed or lengthy due to:

- malpresentation (breech birth (i.e. buttocks or feet first), face, brow, or other)
- failure of descent of the fetal head through the pelvic brim or the interspinous diameter
- poor uterine contraction strength
- active phase arrest
- cephalo-pelvic disproportion (CPD)
- shoulder dystocia

4000

Secondary changes may be observed: swelling of the tissues, maternal exhaustion, fetal heart rate abnormalities. Left untreated, severe complications include death of mother and/or baby, and genitovaginal fistula.

## Obstructed labour [edit]

*Main article: Obstructed labour*

Obstructed labour, also known as labor dystocia, is when, even though the uterus is contracting normally, the baby does not exit the pelvis during childbirth due to being physically blocked.[99] Prolonged obstructed labor can result in obstetric fistula, a complication of childbirth where tissue death preforates the rectum or bladder.

## Maternal complications [edit]

**Vaginal birth injury** with visible tears or episiotomies are common. Internal tissue tearing as well as nerve damage to the pelvic structures lead in a proportion of women to problems with prolapse, incontinence of stool or urine and sexual dysfunction. Fifteen percent of women become incontinent, to some degree, of stool or urine after normal delivery, this number rising considerably after these women reach menopause. Vaginal birth injury is a necessary, but not sufficient, cause of all non hysterectomy related prolapse in later life. Risk factors for significant vaginal birth injury include:

- A baby weighing more than 9 pounds.
- The use of forceps or vacuum for delivery. These markers are more likely to be signals for other abnormalities as forceps or vacuum are not used in normal deliveries.
- The need to repair large tears after delivery.

There is tentative evidence that antibiotics may help prevent wound infections in women with third or fourth degree tears.[100]

**Pelvic girdle pain**. Hormones and enzymes work together to produce ligamentous relaxation and widening of the symphysis pubis during the last trimester of pregnancy. Most girdle pain occurs before birthing, and is known as diastasis of the pubic symphysis. Predisposing factors for girdle pain include maternal obesity.

**Infection** remains a major cause of maternal mortality and morbidity in the developing world. The work of Ignaz Semmelweis was seminal in the pathophysiology and treatment of puerperal fever and saved many lives.

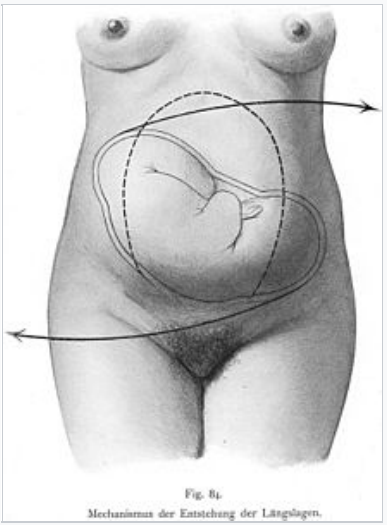
**Hemorrhage,** or heavy blood loss, is still the leading cause of death of birthing mothers in the world today, especially in the developing world. Heavy blood loss leads to hypovolemic shock, insufficient perfusion of vital organs and death if not rapidly treated. Blood transfusion may be life saving. Rare sequelae include Hypopituitarism Sheehan's syndrome.

The maternal mortality rate (MMR) varies from 9 per 100,000 live births in the US and Europe to 900 per 100,000 live births in Sub-Saharan Africa.[101] Every year, more than half a million women die in pregnancy or childbirth.[102]

## Fetal complications [edit]

### Mechanical fetal injury [edit]

Risk factors for fetal birth injury include fetal macrosomia (big baby), maternal obesity, the need for instrumental delivery, and an inexperienced attendant. Specific situations that can contribute to birth injury include breech presentation and shoulder dystocia. Most fetal birth injuries resolve without long term harm, but brachial plexus injury may lead to Erb's palsy or Klumpke's paralysis.[103]



Mechanical fetal injury may be caused by improper rotation of the fetus.

### Neonatal infection [edit]

*Main article: Neonatal infection*

Neonates are prone to infection in the first month of life. Some organisms such as S. agalactiae (Group B Streptococcus) or (GBS) are more prone to cause these occasionally fatal infections. Risk factors for GBS infection include:

- prematurity (birth before 37 weeks gestation)
- a sibling who has had a GBS infection
- prolonged labour or rupture of membranes

Untreated sexually transmitted infections are associated with congenital and perinatal infections in neonates, particularly in the areas where rates of infection remain high. The overall perinatal mortality rate associated with untreated syphilis, for example, is 30%.[105]

### Neonatal death [edit]

Infant deaths (*neonatal deaths* from birth to 28 days, or *perinatal deaths* if including fetal deaths at 28 weeks gestation and later) are around 1% in modernized countries.

The most important factors affecting mortality in childbirth are adequate nutrition and access to quality medical care ("access" is affected both by the cost of available care, and distance from health services).[*citation needed*]

A 1983–1989 study by the Texas Department of State Health Services highlighted the differences in neonatal mortality (NMR) between high risk and low risk pregnancies. NMR was 0.57% for doctor-attended high risk births, and 0.19% for low risk births attended by non-nurse midwives. Around 80% of pregnancies are low-risk. Factors that may make a birth high risk include prematurity, high blood pressure, gestational diabetes and a previous cesarean section.

### Intrapartum asphyxia [edit]

Intrapartum asphyxia is the impairment of the delivery of oxygen to the brain and vital tissues during the progress of labour. This may exist in a pregnancy already impaired by maternal or fetal disease, or may rarely arise *de novo* in labour. This can be termed *fetal distress*, but this term may be emotive and misleading. True intrapartum asphyxia is not as common as previously believed, and is usually accompanied by multiple other symptoms during the immediate period after delivery. Monitoring might show up problems during birthing, but the interpretation and use of monitoring devices is complex and prone to misinterpretation. Intrapartum asphyxia can cause long-term impairment, particularly when this results in tissue damage through encephalopathy.[106]

## Society and culture [edit]

*Further information: Ageing*

Childbirth routinely occurs in hospitals in much of Western society. Before the 20th century and in some countries to the present day it has more typically occurred at home.[107]

Medieval woman giving birth. France, 12th century

In Western and other cultures, age is reckoned from the date of birth, and sometimes the birthday is celebrated annually. East Asian age reckoning starts newborns at "1", incrementing each Lunar New Year.

Some families view the placenta as a special part of birth, since it has been the child's life support for so many months. The placenta may be eaten by the newborn's family, ceremonially or otherwise (for nutrition; the great majority of animals in fact do this naturally).[108] Most recently there is a category of birth professionals available who will encapsulate placenta for use as placenta medicine by postpartum mothers.

The exact location in which childbirth takes place is an important factor in determining nationality, in particular for birth aboard aircraft and ships.

### Facilities [edit]

Following are facilities that are particularly intended to house women during childbirth:

- A *labour ward*, also called a *delivery ward* or *labour and delivery*, is generally a department of a hospital that focuses on providing health care to women and their children during childbirth. It is generally closely linked to the hospital's neonatal intensive care unit and/or obstetric surgery unit if present. A *maternity ward* or *maternity unit* may include facilities both for childbirth and for postpartum rest and observation of mothers in normal as well as complicated cases.
- A birthing center generally presents a simulated home-like environment. Birthing centers may be located on hospital grounds or "free standing" (i.e., not hospital-affiliated).

In addition, it is possible to have a home birth.

### Associated professions [edit]

Different categories of birth attendants may provide support and care during pregnancy and childbirth, although there are important differences across categories based on professional training and skills, practice regulations, as well as nature of care delivered.

"Childbirth educators" are instructors who aim to educate pregnant women and their partners about the nature of pregnancy, labour signs and stages, techniques for giving birth, breastfeeding and newborn baby care. In the United States and elsewhere, classes for training as a childbirth educator can be found in hospital settings or through many

independent certifying organizations such as Birthing From Within, BirthWorks, The Bradley Method, Birth Arts International, CAPPA, HypBirth, HypnoBabies, HypnoBirthing,[78] ICTC, ICEA, Lamaze, etc. Each organization teaches its own curriculum and each emphasizes different techniques. Information about each can be obtained through their individual websites.

Doulas are assistants who support mothers during pregnancy, labour, birth, and postpartum. They are not medical attendants; rather, they provide emotional support and non-medical pain relief for women during labour. Like childbirth educators and other assistive personnel, certification to become a doula is not compulsory, thus, anyone can call themself a doula or a childbirth educator.

Confinement nannies are individuals who are employed to provide assistance and stay with the mothers at their home after childbirth. They are usually experienced mothers who took courses on how to take care of mothers and newborn babies.[109]

Midwives are autonomous practitioners who provide basic and emergency health care before, during and after pregnancy and childbirth, generally to women with low-risk pregnancies. Midwives are trained to assist during labour and birth, either through direct-entry or nurse-midwifery education programs. Jurisdictions where midwifery is a regulated profession will typically have a registering and disciplinary body for quality control, such as the American Midwifery Certification Board in the United States,[110] the College of Midwives of British Columbia (CMBC) in Canada[111][112] or the Nursing and Midwifery Council (NMC) in the United Kingdom.[113][114]

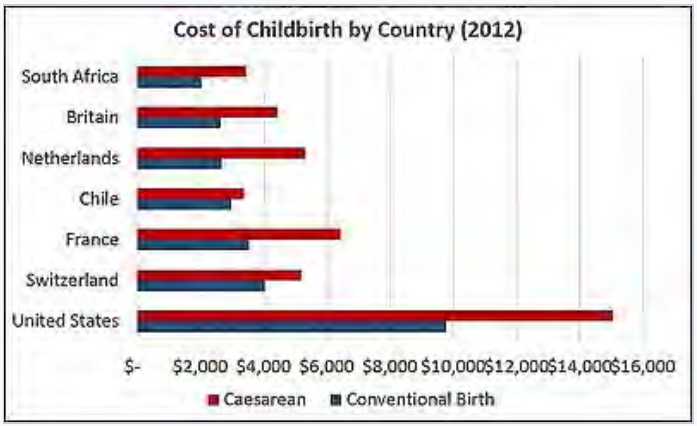
In jurisdictions where midwifery is not a regulated profession, traditional or lay midwives may assist women during childbirth, although they do not typically receive formal health care education and training.

Medical doctors who practice obstetrics include categorically specialized obstetricians, family practitioners and general practitioners whose training, skills and practices include obstetrics, and in some contexts general surgeons. These physicians and surgeons variously provide care across the whole spectrum of normal and abnormal births and pathological labour conditions. Categorically specialized obstetricians are qualified surgeons, so they can undertake surgical procedures relating to childbirth. Some family practitioners or general practitioners also perform obstetrical surgery. Obstetrical procedures include cesarean sections, episiotomies, and assisted delivery. Categorical specialists in obstetrics are commonly dually trained in obstetrics and gynecology (OB/GYN), and may provide other medical and surgical gynecological care, and may incorporate more general, well-woman, primary care elements in their practices. Maternal-fetal medicine specialists are obstetrician/gynecologists subspecialized in managing and treating high-risk pregnancy and delivery.

Anaesthetists or anesthesiologists are medical doctors who specialise in pain relief and the use of drugs to facilitate surgery and other painful procedures. They may contribute to the care of a woman in labour by performing epidurals or by providing anaesthesia (often spinal anaesthesia) for Cesarean section or forceps delivery.

Obstetric nurses assist midwives, doctors, women, and babies before, during, and after the birth process, in the hospital system. Obstetric nurses hold various certifications and typically undergo additional obstetric training in addition to standard nursing training.

## Costs [edit]



Cost of Childbirth in Several Countries in 2012.[115]

According to a 2013 analysis performed commissioned by the New York Times and performed by Truven Healthcare Analytics, the cost of childbirth varies dramatically by country. In the United States the average amount actually paid by insurance companies or other payers in 2012 averaged $9,775 for an uncomplicated conventional delivery and $15,041 for a caesarean birth.[115] The aggregate charges of healthcare facilities for 4 million annual births in the United States was estimated at over $50 billion. The summed cost of prenatal care, childbirth, and newborn care came to $30,000 for a vaginal delivery and $50,000 for a caesarian section.

In the United States, childbirth hospital stays have some of the lowest ICU utilizations. Vaginal delivery with and without complicating diagnoses and caesarean section with and without comorbidities or major comorbidities account for four of the fifteen types of hospital stays with low rates of ICU utilization (where less than 20% of visits were admitted to the ICU). During

stays with ICU services, approximately 20% of costs were attributable to the ICU.[116]

A 2013 study published in BMJ Open found widely varying costs by facility for childbirth expenses in California, varying from $3,296 to $37,227 for vaginal birth and from $8,312 to $70,908 for a caesarean birth.[117]

Beginning in 2014, the United Kingdom National Institute for Health and Care Excellence began recommending that many women give birth at home under the care of a midwife rather than an obstetrician, citing lower expenses and better healthcare outcomes.[118] The median cost associated with home birth was estimated to be about $1,500 vs. about $2,500 in hospital.[119]

# Dysmenorrhea

From Wikipedia, the free encyclopedia

**Dysmenorrhea**, also known as **dysmenorrhoea**, **painful periods**, or **menstrual cramps**, is pain during menstruation.[1][2] It usually begins around the time that menstruation begins. Symptoms typically last less than three days. The pain is usually in the pelvis or lower abdomen. Other symptoms may include back pain, diarrhea, or nausea.[1]

In young women painful periods often occur without an underlying problem. In older women it is more often due to an underlying issues such as uterine fibroids, adenomyosis, or endometriosis.[3] It is more common among those with heavy periods, irregular periods, whose periods started before twelve years of age, or who have a low body weight.[1] A pelvic exam in those who are sexually active and ultrasound may be useful to help in diagnosis.[1] Conditions that should be ruled out include ectopic pregnancy, pelvic inflammatory disease, interstitial cystitis, and chronic pelvic pain.[1]

Dysmenorrhea occurs less often in those who exercise regularly and those who have children early in life.[1] Treatment may include the use of a heating pad.[3] Medications that may help include NSAIDs such as ibuprofen, hormonal birth control, and the IUD with progestogen.[1][3] Taking vitamin B or magnesium may help.[2] Evidence for yoga, acupuncture, and massage is insufficient.[1] Surgery may be useful if certain underlying problems are present.[2]

Dysmenorrhea is estimated to occur in 20% to 90% of women of reproductive age.[1] It is the most common menstrual disorder.[2] Typically it starts within a year of the first menstrual period.[1] When there is no underlying cause often the pain improves with age or following having a child.[2]

## Variants

## Signs and symptoms [edit]

The main symptom of dysmenorrhea is pain concentrated in the lower abdomen or pelvis.[1] It is also commonly felt in the right or left side of the abdomen. It may radiate to the thighs and lower back.[1]

Symptoms often co-occurring with menstrual pain include nausea and vomiting, diarrhea or constipation, headache, dizziness, disorientation, hypersensitivity to sound, light, smell and touch, fainting, and fatigue. Symptoms of dysmenorrhea often begin immediately after ovulation and can last until the end of menstruation. This is because dysmenorrhea is often associated with changes in hormonal levels in the body that occur with ovulation. The use of certain types of birth control pills can prevent the symptoms of dysmenorrhea because they stop ovulation from occurring.

## Causes [edit]

Dysmenorrhea can be classified as either primary or secondary based on the absence or presence of an underlying cause. Secondary dysmenorrhea is dysmenorrhea which is associated with an existing condition.

The most common cause of secondary dysmenorrhea is endometriosis, which can be visually confirmed by laparoscopy in approximately 70% of adolescents with dysmenorrhea.[4]

Other causes of secondary dysmenorrhea include leiomyoma,[5] adenomyosis,[6] ovarian cysts, and pelvic congestion.[7]

Unequal leg length might hypothetically be one of the contributors, as it may contribute to a tilted pelvis, which may cause lower back pain,[8] which in turn may be mistaken for menstrual pain, as women with lower back pain experience increased pain during their periods.

Other skeletal abnormalities, such as scoliosis (sometimes caused by spina bifida) might be possible contributors as well.

## Mechanism [edit]

During a woman's menstrual cycle, the endometrium thickens in preparation for potential pregnancy. After ovulation, if the ovum is not fertilized and there is no pregnancy, the built-up uterine tissue is not needed and thus shed.

Molecular compounds called prostaglandins are released during menstruation, due to the destruction of the endometrial cells, and the resultant release of their contents.[9][*needs update*] Release of prostaglandins and other inflammatory mediators in the uterus cause the uterus to contract. These substances are thought to be a major factor in primary dysmenorrhea.[10] When the uterine muscles contract, they constrict the blood supply to the tissue of the endometrium, which, in turn, breaks down and dies. These uterine contractions continue as they squeeze the old, dead endometrial tissue through the cervix and out of the body through the vagina. These contractions, and the resulting temporary oxygen deprivation to nearby tissues, are responsible for the pain or "cramps" experienced during menstruation.

Compared with other women, women with primary dysmenorrhea have increased activity of the uterine muscle with increased contractility and increased frequency of contractions.[11]

In one research study using MRI, visible features of the uterus were compared in dysmenorrheic and eumenorrheic (normal) participants. The study concluded that in dysmenorrheic patients, visible features on cycle days 1-3 correlated with the degree of pain, and differed significantly from the control group.[12]

## Diagnosis [edit]

The diagnosis of dysmenorrhea is usually made simply on a medical history of menstrual pain that interferes with daily activities. However, there is no universally accepted gold standard technique for quantifying the

severity of menstrual pains.[13] Yet, there are quantification models, called *menstrual symptometrics*, that can be used to estimate the severity of menstrual pains as well as correlate them with pain in other parts of the body, menstrual bleeding and degree of interference with daily activities.[13]

### Further work-up [edit]

Once a diagnosis of dysmenorrhea is made, further workup is required to search for any secondary underlying cause of it, in order to be able to treat it specifically and to avoid the aggravation of a perhaps serious underlying cause.

Further work-up includes a specific medical history of symptoms and menstrual cycles and a pelvic exam.[2] Based on results from these, additional exams and tests may be motivated, such as:

- Laboratory tests[2]
- Gynecologic ultrasonography[2]
- Laparoscopy may be required.[2]

## Management [edit]

### NSAIDs [edit]

Non-steroidal anti-inflammatory drugs (NSAIDs) are effective in relieving the pain of primary dysmenorrhea.[14][*needs update*] They can have side effects of nausea, dyspepsia, peptic ulcer, and diarrhea.[15] People who are unable to take the more common NSAIDs may be prescribed a COX-2 inhibitor.[16]

### Hormonal birth control [edit]

Although use of hormonal birth control can improve or relieve symptoms of primary dysmenorrhea,[17][18] a 2001 systematic review found that no conclusions can be made about the efficacy of commonly used modern lower dose combined oral contraceptive pills for primary dysmenorrhea.[19][*needs update*] Norplant[20] and Depo-provera[21][22] are also effective, since these methods often induce amenorrhea. The intrauterine system (Mirena IUD) may be useful in reducing symptoms.[23]

### Other [edit]

A review indicated the effectiveness of transdermal nitroglycerin.[24]

### Alternative medicine [edit]

There is poor evidence for treatments other than medications.[1]

One review found thiamine and vitamin E to be likely effective.[25] It found the effects of fish oil and vitamin B12 to be unknown.[25]

Another review found that Vitamin B1 to be effective. Magnesium supplementation are a promising possible treatment. And insufficient evidence to recommend any other herbal or dietary supplement, including omega-3 fatty acids, vitamin E, vitamin B6 among others which have been studied.[26][*needs update*]

A 2008 review found promising evidence for Chinese herbal medicine for primary dysmenorrhea, but that the evidence was limited by its poor methodological quality.[27] Reviews found tentative evidence that ginger powder may be effective for primary dysmenorrhea.[28][29]

### Procedures [edit]

One review found acupressure, topical heat, transcutaneous electrical nerve stimulation, and behavioral interventions likely effective.[25] It found acupuncture and magnets to be unknown.[25] Another review found tentative evidence for acupuncture.[30][*needs update*]

A 2007 systematic review found some scientific evidence that behavioral interventions may be effective, but that the results should be viewed with caution due to poor quality of the data.[31]

Spinal manipulation does not appear to be helpful.[25] Although claims have been made for chiropractic care, under the theory that treating subluxations in the spine may decrease symptoms,[32] a 2006 systematic review found that overall no evidence suggests that spinal manipulation is effective for treatment of primary and secondary dysmenorrhea.[33]

## Epidemiology [edit]

Dysmenorrhea is estimated to affect approximately 25% of women.[34] Reports of dysmenorrhea are greatest among individuals in their late teens and 20s, with reports usually declining with age. The prevalence in adolescent females has been reported to be 67.2% by one study[35] and 90% by another.[34] It has been stated that there is no significant difference in prevalence or incidence between races.[34] Yet, a study of Hispanic adolescent females indicated a high prevalence and impact in this group.[36] Another study indicated that dysmenorrhea was present in 36.4% of participants, and was significantly associated with lower age and lower parity.[37] Childbearing is said to relieve dysmenorrhea, but this does not always occur. One study indicated that in nulliparous women with primary dysmenorrhea, the severity of menstrual pain decreased significantly after age 40.[38] A questionnaire concluded that menstrual problems, including dysmenorrhea, were more common in females who had been sexually abused.[39]

A survey in Norway showed that 14 percent of females between the ages of 20 to 35 experience symptoms so severe that they stay home from school or work.[40] Among adolescent girls, dysmenorrhea is the leading cause of recurrent short-term school absence.[41]

# Eclampsia

From Wikipedia, the free encyclopedia

**Eclampsia** is the onset of [seizures](#) (convulsions) in a woman with [pre-eclampsia](#).[1] Pre-eclampsia is a disorder of [pregnancy](#) in which there is [high blood pressure](#) and either large amounts of [protein in the urine](#) or other organ dysfunction.[2][3] Onset may be before, during, or after [delivery](#). Most often it is during the second half of pregnancy. The seizures are of the [tonic–clonic](#) type and typically last about a minute. Following the seizure there is typically either a [period of confusion](#) or [coma](#). Complications include [aspiration pneumonia](#), [cerebral hemorrhage](#), [kidney failure](#), and [cardiac arrest](#). Preeclampsia and eclampsia are part of a larger group of conditions known as [hypertensive disorders of pregnancy](#).[1]

Recommendations for prevention include [aspirin](#) in those at high risk, [calcium supplementation](#) in areas with low intake, and treatment of prior hypertension with medications.[4][5] Exercise during pregnancy may also be useful.[1] The use of intravenous or intramuscular [magnesium sulfate](#) improves outcomes in those with eclampsia and is generally safe.[6][7] This is true in both the [developed](#) and [developing world](#).[6] Breathing may need to be supported. Other treatments may include blood pressure medications such as [hydralazine](#) and emergency delivery of the baby either vaginally or by [cesarean section](#).[1]

Pre-eclampsia is estimated to affect about 5% of deliveries while eclampsia affects about 1.4% of deliveries.[8] In the developed world rates are about 1 in 2,000 deliveries due to improved medical care.[1] Hypertensive disorders of pregnancy are one of the most common causes of death in pregnancy.[9] They resulted in 29,000 deaths in 2013 – down from 37,000 deaths in 1990.[10] Around one percent of women with eclampsia die.[1] The word eclampsia is from the Greek term for lightning. The first known description of the condition was by [Hippocrates](#) in the 5th century BCE.[11]

## Signs and symptoms [edit]

Typically the pregnant woman develops [hypertension](#) and [proteinuria](#) before the onset of a convulsion, the hallmark of eclampsia.[12] Eclampsia is preeclampsia and seizures. Other cerebral signs may immediately precede the convulsion, such as nausea, vomiting, headaches, and [cortical blindness](#). If the complication of multi-organ failure ensues, signs and symptoms of those failing organs will appear, such as abdominal pain, jaundice, shortness of breath, and diminished urine output.

The fetus may develop [intrauterine growth retardation](#), and with maternal convulsions, [bradycardia](#),[13] and [fetal distress](#). Placental bleeding, and [placental abruption](#) may also occur.

Sometimes the pregnant woman becomes comatose without preceding convulsions. Upon awakening from the coma, some experience amaurosis fugax: a "dark" and "fleeting" unilateral temporary blindness.[14]

## Risk factors [edit]

Eclampsia, like pre-eclampsia, tends to occur more commonly in first pregnancies and young mothers where it is thought that novel exposure to paternal antigens is involved. Furthermore, women with pre-existing vascular diseases (hypertension, diabetes, and nephropathy) or thrombophilic diseases such as the antiphospholipid syndrome are at higher risk to develop pre-eclampsia and eclampsia. Having a large placenta (multiple gestation, hydatidiform mole) also predisposes women to eclampsia. In addition, there is a genetic component: a woman whose mother or sister had the condition is at higher risk than otherwise.[15] Women who have experienced eclampsia are at increased risk for pre-eclampsia/eclampsia in a later pregnancy. Pulmonary edema is a rather common complication of severe eclampsia affecting approximately 3% of the people with eclampsia: most is caused by too much intravenous fluid.

## Mechanism [edit]

The presence of a placenta is required, and eclampsia resolves if it is removed.[16] Reduced blood flow to the placenta (placental hypoperfusion) is a key feature of the process. It is accompanied by increased sensitivity of the maternal vasculature to agents which cause constriction of the small arteries, leading to reduced blood flow to multiple organs. Also, an activation of the coagulation cascade may lead to microthrombi formation, which can further impair blood flow. Thirdly, increased vascular permeability results in the shift of extracellular fluid from the blood to the interstitial space, with further reduction in blood flow, and edema. These events lead to hypertension; renal, pulmonary, and hepatic dysfunction; and cerebral edema with cerebral dysfunction and convulsions.[16] Before symptoms appear, increased platelet and endothelial activation[16] may be detected.

Placental hypoperfusion is linked to abnormal modelling of the fetal–maternal placental interface that may be immunologically mediated.[16] The invasion of the trophoblast appears to be incomplete.[17] The placenta produces the potent vasodilator adrenomedullin: it is reduced in pre-eclampsia and eclampsia.[18] Other vasodilators are also reduced, including prostacyclin, thromboxane A2, nitric oxide, and endothelins, also leading to vasoconstriction.[13] Many studies have suggested the importance of a woman's reduced immunological tolerance to her baby's father, whose genes are present in the young fetus and the placenta.[19]

Eclampsia is a form of hypertensive encephalopathy: cerebral vascular resistance is reduced, leading to increased blood flow to the brain, cerebral edema and resultant convulsions.[20] An eclamptic convulsion usually does not cause chronic brain damage unless intracranial haemorrhage occurs.[21]

## Differential diagnosis [edit]

Convulsions during pregnancy that are unrelated to pre-eclampsia need to be distinguished from eclampsia. Such disorders include seizure disorders as well as brain tumor, aneurysm of the brain, and medication- or drug-related seizures. Usually the presence of the signs of severe pre-eclampsia precede and accompany eclampsia, facilitating the diagnosis.

Investigations include: CBC, renal function test (RFT), liver function tests (LFT), coagulation screen, 24-hour urine creatinine and protein, and fetal/placental ultrasound.

## Prevention [edit]

Detection and management of pre-eclampsia is critical to reduce the risk of eclampsia. Appropriate management of women with pre-eclampsia generally involves the use of magnesium sulphate to prevent convulsions.

## Treatment [edit]

The four goals of the treatment of eclampsia are to stop and prevent further convulsions, to control the elevated blood pressure, to deliver the baby as promptly as possible, and to monitor closely for the onset of multi-organ failure.

### Convulsions [edit]

Convulsions are prevented and treated using magnesium sulfate.[22] The study demonstrating the effectiveness of magnesium sulfate for the management of eclampsia was first published in 1955.[23] Serum magnesium concentrations associated with maternal toxicity as well as neonatal depression, hypotonia, and low Apgar scores[24] are:

7.0–10.0 mEq/L: loss of patellar reflex
- 10.0–13.0 mEq/L: respiratory depression
- 15.0–25.0 mEq/L: altered atrioventricular conduction and (further) complete heart block
- >25.0 mEq/L: cardiac arrest

With intravenous administration the onset of anticonvulsant action is fast and lasts about 30 minutes. Following intramuscular administration the onset of action is about one hour and lasts for three to four hours. Effective anticonvulsant serum levels range from 2.5 to 7.5 mEq/liter. Magnesium is excreted solely by the kidneys at a rate proportional to the plasma concentration and glomerular filtration.[25]

Even with therapeutic serum magnesium concentrations, recurrent convulsions may occur, and additional magnesium may be needed, but with close monitoring for respiratory, cardiac, and neurological depression. If magnesium administration with resultant high serum concentrations fail to control convulsions, the addition of other intravenous anticonvulsants may be used, facilitate intubation and mechanical ventilation, and to avoid magnesium toxicity including maternal thoracic muscle paralysis.

Magnesium sulfate results in better outcomes than diazepam, phenytoin or a combination of chlorpromazine, promethazine and pethidine.[26][27][28]

### Blood pressure management [edit]

The agents of choice for blood pressure control during eclampsia are hydralazine and/or labetalol.[13] This is because of their effectiveness, lack of negative effects on the fetus, and mechanism of action.

### Delivery [edit]

If the baby has not yet been delivered, steps need to be taken to stabilize the woman and deliver her speedily. This needs to be done even if the baby is immature, as the eclamptic condition is unsafe for both baby and mother. As eclampsia is a manifestation of a multiorgan failure, other organs (liver, kidney, lungs, cardiovascular system, and coagulation system) need to be assessed in preparation for a delivery (often a caesarean section), unless the woman is already in advanced labor. Regional anesthesia for caesarean section is contraindicated when a coagulopathy has developed.

### Monitoring [edit]

Invasive haemodynamic monitoring may be elected in an eclamptic woman at risk for or with cardiac disease, renal disease, refractory hypertension, pulmonary edema, or poor urine output.[13]

## Etymology [edit]

The Greek noun "ἔκλαμψία", *eklampsía*, denotes a "light burst"; metaphorically, in this context, "sudden occurrence." The New Latin term first appeared in Johannes Varandaeus' 1620 treatise on gynaecology *Tractatus de affectibus Renum et Vesicae*.[29] The term toxemia of pregnancy is no longer recommended: placental toxins are not the cause of eclampsia occurrences, as previously believed.[30]

## Popular culture [edit]

In *Downton Abbey*, an historical drama television series, the character (in season 3, episode 5) Lady Sybil dies of eclampsia shortly after child birth.[31]

In *Call the Midwife*, a medical drama television series set in London in the 1950s and 1960s, the character (in season 1, episode 4) named Margaret Jones is struck with pre-eclampsia, ultimately proceeding from a comatose condition to death. The term "toxemia" was also used for the condition, in the dialogue.[32]

# Ectopic pregnancy

From Wikipedia, the free encyclopedia

**Ectopic pregnancy**, also known as **eccyesis** or **tubal pregnancy**, is a complication of pregnancy in which the embryo attaches outside the uterus.[1] Signs and symptoms classically include abdominal pain and vaginal bleeding. Less than 50 percent of women have both of these symptoms. The pain may be described as sharp, dull, or crampy. Pain may also spread to the shoulder if bleeding into the abdomen has occurred.[2] Severe bleeding may result in a fast heart rate, fainting, or shock.[1][2] With very rare exceptions the fetus is unable to survive.[3]

Risk factors for ectopic pregnancy include: pelvic inflammatory disease, often due to Chlamydia infection, tobacco smoking, prior tubal surgery, a history of infertility, and the use of assisted reproductive technology. Those who have previously had an ectopic pregnancy are at much higher risk of having another one. Most ectopic pregnancies (90%) occur in the Fallopian tube which are known as tubal pregnancies.[4] Implantation can also occur on the cervix, ovaries, or within the abdomen.[2] Detection of ectopic pregnancy is typically by blood tests for human chorionic gonadotropin (hCG) and ultrasound. This may require testing on more than one occasion. Ultrasound works best when performed from within the vagina. Other causes of similar symptoms include: miscarriage, ovarian torsion, and acute appendicitis.[2]

Prevention is by decreasing risk factors such as chlamydia infections through screening and treatment.[5] While some ectopic pregnancies will resolve without treatment, this approach has not been well studied as of 2014. The use of the medication methotrexate works as well as surgery in some cases. Specifically it works well when the beta-HCG is low and the size of the ectopic is small. Surgery is still typically recommended if the tube has ruptured, there is a fetal heartbeat, or the person's vital signs are unstable.[4] The surgery may be laparoscopic or through a larger incision, known as a laparotomy.[1] Outcomes are generally good with treatment.[4]

The rate of ectopic pregnancy is about 1 and 2% that of live births in developed countries, though it may be as high as 4% among those using assisted reproductive technology.[1] It is the most common cause of death during the first trimester at approximately 10% of the total.[4] In the developed world outcomes have improved while in the developing world they often remain poor.[5] The risk of death among those in the developed world is between 0.1 and 0.3 percent while in the developing world it is between one and three percent.[6] The first known description of an ectopic pregnancy is by Albucasis in the 11th century.[5] The word "ectopic" means "out of place".[7]

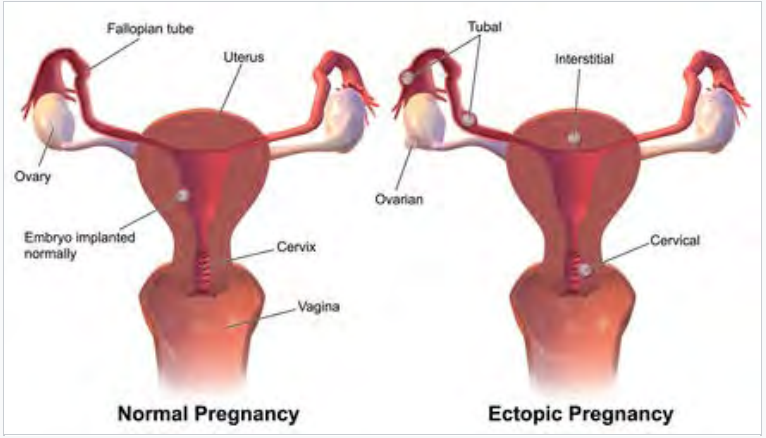
## Signs and symptoms [edit]

Up to 10% of women with ectopic pregnancy have no symptoms, and one-third have no medical signs.[1] In many cases the symptoms have low specificity, and can be similar to those of other genitourinary and gastrointestinal disorders, such as appendicitis, salpingitis, rupture of a corpus luteum cyst, miscarriage, ovarian torsion or urinary tract infection.[1] Clinical presentation of ectopic pregnancy occurs at a mean of 7.2 weeks after the last normal menstrual period, with a range of 4 to 8 weeks. Later presentations are more common in communities deprived of modern diagnostic ability.



Ectopic pregnancy.

Signs and symptoms of ectopic pregnancy include increased hCG, vaginal bleeding (in varying amounts), sudden lower abdominal pain,[1] pelvic pain, a tender cervix, an adnexal mass, or adnexal tenderness.[2] In the absence of ultrasound or hCG assessment, heavy vaginal bleeding may lead to a misdiagnosis of miscarriage.[1] Nausea, vomiting and diarrhea are more rare symptoms of ectopic pregnancy.[1]

Rupture of an ectopic pregnancy can lead to symptoms such as abdominal distension, tenderness, peritonism and hypovolemic shock.[1] A woman with ectopic pregnancy may be excessively mobile with upright posturing, in order to decrease intrapelvic blood flow, which can lead to swelling of the abdominal cavity and cause additional pain.[8]

## Causes [edit]

There are a number of risk factors for ectopic pregnancies. However, in as many as one third[9] to one half[10] no risk factors can be identified. Risk factors include: pelvic inflammatory disease, infertility, use of an intrauterine device (IUD), previous exposure to DES, tubal surgery, intrauterine surgery (e.g. D&C), smoking, previous ectopic pregnancy, endometriosis, and tubal ligation.[11][12] A previous induced abortion does not appear to increase the risk.[13]

### Tube damage [edit]

Tubal pregnancy is when the egg is implanted in the Fallopian tubes. Hair-like cilia located on the internal surface of the Fallopian tubes carry the fertilized egg to the uterus. Fallopian cilia are sometimes seen in reduced numbers subsequent to an ectopic pregnancy, leading to a hypothesis that cilia damage in the Fallopian tubes is likely to lead to an ectopic pregnancy.[14] Women who smoke have a higher chance of an ectopic pregnancy in the fallopian tubes. Smoking leads to risk factors of damaging and or killing cilia.[14] As cilia degenerate the amount of time it takes for the fertilized egg to reach the uterus will increase. The fertilized egg, if it doesn't reach the uterus in time, will hatch from the non-adhesive zona pellucida and implant itself inside the fallopian tube, thus causing the pregnancy.

Women with pelvic inflammatory disease (PID) have a high occurrence of ectopic pregnancy.[15] This results from the build-up of scar tissue in the Fallopian tubes, causing damage to cilia.[16] If however both tubes were completely blocked, so that sperm and egg were physically unable to meet, then fertilization of the egg would naturally be impossible, and neither normal pregnancy nor ectopic pregnancy could occur. Intrauterine adhesions (IUA) present in Asherman's syndrome can cause ectopic cervical pregnancy or, if adhesions partially block access to the tubes via the ostia, ectopic tubal pregnancy.[17][18][19] Asherman's syndrome usually occurs from intrauterine surgery, most commonly after D&C.[17] Endometrial/pelvic/genital

tuberculosis, another cause of Asherman's syndrome, can also lead to ectopic pregnancy as infection may lead to tubal adhesions in addition to intrauterine adhesions.[20]

Tubal ligation can predispose to ectopic pregnancy. Reversal of tubal sterilization (Tubal reversal) carries a risk for ectopic pregnancy. This is higher if more destructive methods of tubal ligation (tubal cautery, partial removal of the tubes) have been used than less destructive methods (tubal clipping). A history of a tubal pregnancy increases the risk of future occurrences to about 10%.[16] This risk is not reduced by removing the affected tube, even if the other tube appears normal. The best method for diagnosing this is to do an early ultrasound.

### Other [edit]

Although some investigations have shown that patients may be at higher risk for ectopic pregnancy with advancing age, it is believed that age is a variable which could act as a surrogate for other risk factors. Vaginal douching is thought by some to increase ectopic pregnancies.[16] Women exposed to diethylstilbestrol (DES) in utero (also known as "DES daughters") also have an elevated risk of ectopic pregnancy.[21] It has also been suggested that pathologic generation of nitric oxide through increased iNOS production may decrease tubal ciliary beats and smooth muscle contractions and thus affect embryo transport, which may consequently result in ectopic pregnancy.[22] The low socioeconomic status may be risk factors for ectopic pregnancy.[23]

## Diagnosis [edit]

An ectopic pregnancy should be considered as the cause of abdominal pain or vaginal bleeding in every woman who has a positive pregnancy test.[2] The primary goal of diagnostic procedures in possible ectopic pregnancy is to triage according to risk rather than establishing pregnancy location.[1]

### Transvaginal ultrasonography [edit]

An ultrasound showing a gestational sac with fetal heart in the fallopian tube has a very high specificity of ectopic pregnancy. Transvaginal ultrasonography has a sensitivity of at least 90% for ectopic pregnancy.[1] The diagnostic ultrasonographic finding in ectopic pregnancy is an adnexal mass that moves separately from the ovary. In around 60% of cases, it is an inhomogeneous or a noncystic adnexal mass sometimes known as the "blob sign". It is generally spherical, but a more tubular appearance may be seen in case of hematosalpinx. This sign has been estimated to have a sensitivity of 84% and specificity of 99% in diagnosing ectopic pregnancy.[1] In the study estimating these values, the blob sign had a positive predictive value of 96% and a negative predictive value of 95%.[1] The visualization of an empty extrauterine gestational sac is sometimes known as the "bagel sign", and is present in around 20% of cases.[1] In another 20% of cases, there is visualization of a gestational sac containing a yolk sac and/or an embryo.[1] Ectopic pregnancies where there is visualization of cardiac activity are sometimes termed "viable ectopic".[1]

This patient had an intrauterine device (IUD) with progestogen, whose cross-section is visible in the field, leaving an ultrasound shadow distally to it.

The combination of a positive pregnancy test and the presence of what appears to be a normal intrauterine pregnancy does not exclude an ectopic pregnancy, since there may be either a heterotopic pregnancy or a "pseudosac", which is a collection of within the endometrial cavity that may be seen in up to 20% of women.[1]

A small amount of anechogenic free fluid in the rectouterine pouch is commonly found in both intrauterine and ectopic pregnancies.[1] The presence of echogenic fluid is estimated at between 28 and 56% of women with an ectopic pregnancy, and strongly indicates the presence of hemoperitoneum.[1] However, it does not necessarily result from tubal rupture, but is commonly a result from leakage from the distal tubal opening.[1] As a rule of thumb, the finding of free fluid is significant if it reaches the fundus or is present in the vesico-uterine pouch.[1] A further marker of serious intra-abdominal bleeding is the

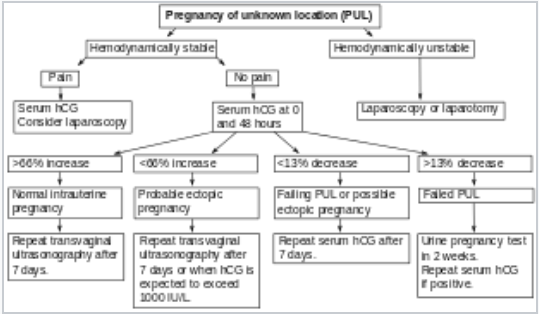
presence of fluid in the hepatorenal recess of the subhepatic space.[1]

Currently, Doppler ultrasonography is not considered to significantly contribute to the diagnosis of ectopic pregnancy.[1]

A common misdiagnosis is of a normal intrauterine pregnancy is where the pregnancy is implanted laterally in an arcuate uterus, potentially being misdiagnosed as an interstitial pregnancy.[1]

## Ultrasonography and β-hCG [edit]

Where no intrauterine pregnancy is seen on ultrasound, measuring β-human chorionic gonadotropin (β-hCG) levels may aid in the diagnosis. The rationale is that a low β-hCG level may indicate that the pregnancy is intrauterine but yet too small to be visible on ultrasonography. While some physicians consider that the threshold where an intrauterine pregnancy should be visible on transvaginal ultrasound is around 1500 IU/ml of β-hCG, a review in the JAMA Rational Clinical Examination Series showed that there is no single threshold for the β-human chorionic gonadotropin that confirms an ectopic pregnancy. Instead, the best test in a pregnant woman is a high resolution transvaginal ultrasound.[2] The presence of an adnexal mass in the absence of an intrauterine pregnancy on transvaginal sonography increases the likelihood of an ectopic pregnancy 100-fold (LR+ 111). When there are no adnexal abnormalities on transvaginal sonography, the likelihood of an ectopic pregnancy decreases (LR- 0.12). An empty uterus with levels higher than 1500 IU/ml may be evidence of an ectopic pregnancy, but may also be consistent with an intrauterine pregnancy which is simply too small to be seen on ultrasound. If the diagnosis is uncertain, it may be necessary to wait a few days and repeat the blood work. This can be done by measuring the β-hCG level approximately 48 hours later and repeating the ultrasound. The serum hCG ratios and logistic regression models appear to be better than absolute single serum hCG level.[24] If the β-hCG falls on repeat examination, this strongly suggests a spontaneous abortion or rupture. The fall in serum hCG over 48 hours may be measured as the hCG ratio, which is calculated as:[1]



Algorithm of the management of a pregnancy of unknown location, that is, a positive pregnancy test but no pregnancy is found on transvaginal ultrasonography.[1] If serum hCG at 0 hours is more than 1000 IU/L and there is no history suggestive of complete miscarriage, the ultrasonography should be repeated as soon as possible.[1]

An hCG ratio of 0.87, that is, a decrease in hCG of 13% over 48 hours, has a sensitivity of 93% and specificity of 97% for predicting a failing PUL.[1] The majority of cases of ectopic pregnancy will have serial serum hCG levels that increase more slowly than would be expected with an IUP (that is, a *suboptimal rise*), or decrease more slowly than would be expected with a failing PUL. However, up to 20% of cases of ectopic pregnancy have serum hCG doubling times similar to that of an IUP, and around 10% of EP cases have hCG patterns similar to a failing PUL.[1]

## Other diagnostic methods [edit]

A laparoscopy or laparotomy can also be performed to visually confirm an ectopic pregnancy. This is generally reserved for women presenting with signs of an acute abdomen and/or hypovolemic shock.[1] Often if a tubal abortion or tubal rupture has occurred, it is difficult to find the pregnancy tissue. A laparoscopy in very early ectopic pregnancy rarely shows a normal looking fallopian tube.

Culdocentesis, in which fluid is retrieved from the space separating the vagina and rectum, is a less commonly performed test that may be used to look for internal bleeding. In this test, a needle is inserted into the space at the very top of the vagina, behind the uterus and in front of the rectum. Any blood or fluid found may have been derived from a ruptured ectopic pregnancy.

Progesterone levels of less than 20 nmol/l have a high predictive value for failing pregnancies, whilst levels over 25 nmol/l are likely to predict viable pregnancies, and levels over 60 nmol/l are strongly so. This may help in identifying failing PULs that are at low risk and thereby needing less follow-up.[1] Inhibin A may also be useful for predicting spontaneous resolution of PUL, but is not as good as progesterone for this purpose.[1]

In addition, there are various mathematical models, such as logistic regression models and Bayesian networks, for the prediction of PUL outcome based on multiple parameters.[1] Mathematical models also aim to identify PULs that are *low risk*, that is, failing PULs and IUPs.[1]

Dilation and curettage is sometimes used to diagnose pregnancy location with the aim of differentiating between an EP and a non-viable IUP in situations where a viable IUP can be ruled out. Specific indications for this procedure include either of the following:[1]

- no visible IUP on transvaginal ultrasonography with a serum hCG of more than 2000 IU/ml
- an abnormal rise in hCG level. A rise of 35% over 48 hours is proposed as the minimal rise consistent with a viable intrauterine pregnancy.

- an abnormal fall in hCG level, such as defined as one of less than 20% in 2 days

## Classification [edit]

### Tubal pregnancy [edit]

The vast majority of ectopic pregnancies implant in the Fallopian tube. Pregnancies can grow in the fimabrial end (5% of all ectopic pregnancies), the ampullary section (80%), the isthmus (12%), and the cornual and interstitial part of the tube (2%).[16] Mortality of a tubal pregnancy at the isthmus or within the uterus (interstitial pregnancy) is higher as there is increased vascularity that may result more likely in sudden major internal bleeding. A review published in 2010 supports the hypothesis that tubal ectopic pregnancy is caused by a combination of retention of the embryo within the fallopian tube due to impaired embryo-tubal transport and alterations in the tubal environment allowing early implantation to occur.[25]

### Nontubal ectopic pregnancy [edit]

Two percent of ectopic pregnancies occur in the ovary, cervix, or are intraabdominal. Transvaginal ultrasound examination is usually able to detect a cervical pregnancy. An ovarian pregnancy is differentiated from a tubal pregnancy by the Spiegelberg criteria.[26]

While a fetus of ectopic pregnancy is typically not viable, very rarely, a live baby has been delivered from an abdominal pregnancy. In such a situation the placenta sits on the intraabdominal organs or the peritoneum and has found sufficient blood supply. This is generally bowel or mesentery, but other sites, such as the renal (kidney), liver or hepatic (liver) artery or even aorta have been described. Support to near viability has occasionally been described, but even in third world countries, the diagnosis is most commonly made at 16 to 20 weeks gestation. Such a fetus would have to be delivered by laparotomy. Maternal morbidity and mortality from extrauterine pregnancy are high as attempts to remove the placenta from the organs to which it is attached usually lead to uncontrollable bleeding from the attachment site. If the organ to which the placenta is attached is removable, such as a section of bowel, then the placenta should be removed together with that organ. This is such a rare occurrence that true data are unavailable and reliance must be made on anecdotal reports.[27][28][29] However, the vast majority of abdominal pregnancies require intervention well before fetal viability because of the risk of bleeding.

### Heterotopic pregnancy [edit]

In rare cases of ectopic pregnancy, there may be two fertilized eggs, one outside the uterus and the other inside. This is called a heterotopic pregnancy.[2] Often the intrauterine pregnancy is discovered later than the ectopic, mainly because of the painful emergency nature of ectopic pregnancies. Since ectopic pregnancies are normally discovered and removed very early in the pregnancy, an ultrasound may not find the additional pregnancy inside the uterus. When hCG levels continue to rise after the removal of the ectopic pregnancy, there is the chance that a pregnancy inside the uterus is still viable. This is normally discovered through an ultrasound.

Although rare, heterotopic pregnancies are becoming more common, likely due to increased use of IVF. The survival rate of the uterine fetus of an ectopic pregnancy is around 70%.[30]

### Persistent ectopic pregnancy [edit]

A persistent ectopic pregnancy refers to the continuation of trophoblastic growth after a surgical intervention to remove an ectopic pregnancy. After a conservative procedure that attempts to preserve the affected fallopian tube such as a salpingotomy, in about 15-20% the major portion of the ectopic growth may have been removed, but some trophoblastic tissue, perhaps deeply embedded, has escaped removal and continues to grow, generating a new rise in hCG levels.[31] After weeks this may lead to new clinical symptoms including bleeding. For this reason hCG levels may have to be monitored after removal of an ectopic pregnancy to assure their decline, also methotrexate can be given at the time of surgery prophylactically.

### Pregnancy of unknown location [edit]

Pregnancy of unknown location (PUL) is the term used for a pregnancy where there is a positive pregnancy test but no pregnancy has been visualized using transvaginal ultrasonography.[1] Specialized early pregnancy departments have estimated that between 8 and 10% of women attending for an ultrasound assessment in early pregnancy will be classified as having a PUL.[1] The true nature of the pregnancy can be an ongoing viable intrauterine pregnancy, a failed pregnancy, an ectopic pregnancy or rarely a persisting PUL.[1]

Because of frequent ambiguity on ultrasonography examinations, the following classification is proposed:[1]

| Condition | Criteria |
|---|---|
| Definite ectopic pregnancy | Extrauterine gestational sac with yolk sac and/or embryo (with or without cardiac activity). |

| | |
|---|---|
| Pregnancy of unknown location - probable ectopic pregnancy | Inhomogeneous adnexal mass or extrauterine sac-like structure. |
| "True" pregnancy of unknown location | No signs of intrauterine nor extrauterine pregnancy on transvaginal ultrasonography. |
| Pregnancy of unknown location - probable intrauterine pregnancy | Intrauterine gestational sac-like structure. |
| Definite intrauterine pregnancy | Intrauterine gestational sac with yolk sac and/or embryo (with or without cardiac activity). |

In women with a pregnancy of unknown location, between 6% and 20% have an ectopic pregnancy.[1] In cases of pregnancy of unknown location and a history of heavy bleeding, is has been estimated that approximately 6% have an underlying ectopic pregnancy.[1] Between 30 and 47% of women with pregnancy of unknown location are ultimately diagnosed with an ongoing intrauterine pregnancy, whereof the majority (50 –70%) will be found to have failing pregnancies where the location is never confirmed.[1]

Persisting PUL is where the hCG level does not spontaneously decline and no intrauterine or ectopic pregnancy is identified on follow-up transvaginal ultrasonography.[1] A persisting PUL is likely either a small ectopic pregnancy that has not been visualized, or a retained trophoblast in the endometrial cavity.[1] Treatment should only be considered when a potentially viable intrauterine pregnancy has been definitively excluded.[1] A *treated persistent PUL* is defined as one managed medically (generally with methotrexate) without confirmation of the location of the pregnancy such as by ultrasound, laparoscopy or uterine evacuation.[1] A *resolved persistent PUL* is defined as serum hCG reaching a non-pregnant value (generally less than 5 IU/l) after expectant management, or after uterine evacuation without evidence of chorionic villi on histopathological examination.[1] In contrast, a relatively low and unresolving level of serum hCG indicates the possibility of an hCG-secreting tumour.[1]

### Differential diagnosis [edit]

Other conditions that cause similar symptoms include: miscarriage, ovarian torsion, and acute appendicitis, ruptured ovarian cyst, kidney stone, and pelvic inflammatory disease, among others.[2]

## Treatment [edit]

### Expectant management [edit]

Most women with a PUL are followed up with serum hCG measurements and repeat TVS examinations until a final diagnosis is confirmed.[1] Low-risk cases of PUL that appear to be failing pregnancies may be followed up with a urinary pregnancy test after 2 weeks and get subsequent telephone advice.[1] Low-risk cases of PUL that are likely intrauterine pregnancies may have another TVS in 2 weeks to access viability.[1] High-risk cases of PUL require further assessment, either with a TVS within 48 h or additional hCG measurement.[1]

### Medical [edit]

Early treatment of an ectopic pregnancy with methotrexate is a viable alternative to surgical treatment[32] which was developed in the 1980s.[33] If administered early in the pregnancy, methotrexate terminates the growth of the developing embryo; this may cause an abortion, or the developing embryo may then be either resorbed by the woman's body or pass with a menstrual period. Contraindications include liver, kidney, or blood disease, as well as an ectopic embryonic mass > 3.5 cm.

Also, it may lead to the inadvertent termination of an undetected intrauterine pregnancy, or severe abnormality in any surviving pregnancy.[1] Therefore, it is recommended that methotrexate should only be administered when hCG has been serially monitored with a rise less than 35% over 48 hours, which practically excludes a viable intrauterine pregnancy.[1]

### Surgical [edit]

If bleeding has already occurred, surgical intervention may be necessary. However, whether to pursue surgical intervention is an often difficult decision in a stable patient with minimal evidence of blood clot on ultrasound.[*citation needed*]

Surgeons use laparoscopy or laparotomy to gain access to the pelvis and can either incise the affected Fallopian and remove only the pregnancy (salpingostomy) or remove the affected tube with the pregnancy (salpingectomy). The first successful surgery for an ectopic pregnancy was performed by Robert Lawson Tait in 1883.[34] It is estimated that

an acceptable rate of PULs that eventually undergo surgery is between 0.5 and 11%.[1]

Autotransfusion of a woman's own blood as drained during surgery may be useful in those who have a lot of bleeding into their abdomen.[35]

Published reports that a re-implanted embryo survived to birth were debunked as false.[36]

## Complications [edit]

The most common complication is rupture with internal bleeding which may lead to hypovolemic shock. Death from rupture is still the leading cause of death in the first trimester of the pregnancy.[*citation needed*]

## Prognosis [edit]

When ectopic pregnancies are treated, the prognosis for the mother is very good in Western countries; maternal death is rare, but most fetuses die or are aborted. For instance, in the UK, between 2003 and 2005 there were 32,100 ectopic pregnancies resulting in 10 maternal deaths (meaning that 1 in 3,210 women with an ectopic pregnancy died).[37]

In the developing world, however, especially in Africa, the death rate is very high, and ectopic pregnancies are a major cause of death among women of childbearing age.

### Future fertility [edit]

Fertility following ectopic pregnancy depends upon several factors, the most important of which is a prior history of infertility.[38] The treatment choice does not play a major role; A randomized study in 2013 concluded that the rates of intrauterine pregnancy 2 years after treatment of ectopic pregnancy are approximately 64% with radical surgery, 67% with medication, and 70% with conservative surgery.[39] In comparison, the cumulative pregnancy rate of women under 40 years of age in the general population over 2 years is over 90%.[40]

## Epidemiology [edit]

The rate of ectopic pregnancy is about 1 and 2% of that of live births in developed countries, though it is as high as 4% in pregnancies involving assisted reproductive technology.[1] Between 93 and 97% of ectopic pregnancies are located in a Fallopian tube.[2] Of these, in turn, 13% are located in the isthmus, 75% are located in the ampulla, and 12% in the fimbriae.[1] Ectopic pregnancy is responsible for 6% of maternal deaths during the first trimester of pregnancy making it the leading cause of maternal death during this stage of pregnancy.[2]

Between 5% and 42% of women seen for ultrasound assessment with a positive pregnancy test have a *pregnancy of unknown location* (PUL), that is a positive pregnancy test but no pregnancy visualized at transvaginal ultrasonography.[1] Between 6 and 20% of PUL are subsequently diagnosed with actual ectopic pregnancy.[1]

## Society and culture [edit]

Salpingectomy as a treatment for ectopic pregnancy is one of the common cases when the principle of double effect can be used to justify accelerating the death of the embryo by doctors and patients opposed to outright abortions.[42]

In the Catholic church, there are moral debates on certain treatments. A significant number of Catholic moralists consider use of methotrexate and the salpingostomy procedure to be not "morally permissible" because they destroy the embryo; however situations are considered differently in which the mother's health in endangered, and the whole fallopian tube with the developing embryo inside is removed.[43][44]

## Live birth [edit]

There have been cases where ectopic pregnancy lasted many months and ended in a live baby delivered by laparotomy.

In July 1999, Lori Dalton gave birth by Cesarean section in Ogden, Utah, United States, to a healthy baby girl who had developed outside of the uterus. Previous ultrasounds had not discovered the problem. "[Sage Dalton]'s delivery was slated as a routine Cesarean birth at Ogden Regional Medical Center in Utah. When Dr. Naisbitt performed Lori's Cesarean, he was astonished to find Sage within the amniotic membrane outside the womb [...]."[45] "But what makes this case so rare is that not only did mother and baby survive — they're both in perfect health. John Dalton [(the father)] took home video inside the delivery room. Sage came out doing extremely well because even though she had been implanted outside the womb, a rich blood supply from a uterine fibroid along the outer uterus wall had nourished her with a rich source of blood."[46]

On 19 April 2008 an English woman, Jayne Jones (age 37) who had an ectopic pregnancy attached to the omentum, the fatty covering of her large bowel, gave birth to her son Billy by a laparotomy at 28 weeks gestation. The surgery, the first of its kind to be performed in the UK, was successful, and both mother and baby survived.[47]

On May 29, 2008 an Australian woman, Meera Thangarajah (age 34), who had an ectopic pregnancy in the ovary, gave birth to a healthy full term 6 pound 3 ounce (2.8 kg) baby girl, Durga, via Cesarean section. She had no problems or complications during the 38 week pregnancy.[48][49]

In September 1999 an English woman, Jane Ingram (age 32) gave birth to triplets: Olivia, Mary and Ronan, with an extrauterine fetus (Ronan) below the womb and twins in the womb. All three survived. The twins in the womb were taken out first.[50]

## Other animals [edit]

Ectopic gestation exists in mammals other than humans. In sheep, it can go to term, with mammary preparation to parturition, and expulsion efforts. The fetus can be removed by cesarian section. Pictures of cesarian section of a euthanized ewe, 5 days after parturition signs.

# Endometriosis

From Wikipedia, the free encyclopedia

**Endometriosis** is a disease in which tissue that normally grows inside the uterus (endometrium) grows outside it.[1][2] Most often this is on the ovaries, fallopian tubes, and tissue around the uterus and ovaries; however, in rare cases it may also occur in other parts of the body.[3] The main symptoms are pelvic pain and infertility. Nearly half of those affected have chronic pelvic pain, while in 70% pain occurs during menstruation. Pain during sex is also common. Infertility occurs in up to half of women affected.[4] Less common symptoms include urinary or bowel symptoms. About 25% of women have no symptoms.[4] Endometriosis can have both social and psychological effects.[5]

The cause is not entirely clear.[4] Risk factors include having a family history of the condition. The areas of endometriosis bleed each month, resulting in inflammation and scarring.[3][4] The growths due to endometriosis are not cancer.[3] Diagnosis is usually based on symptoms in combination with medical imaging. Biopsy is the most sure method of diagnosis.[3] Other causes of similar symptoms include pelvic inflammatory disease, irritable bowel syndrome, interstitial cystitis, and fibromyalgia.[4]

Tentative evidence suggests that the use of combined oral contraceptives reduces the risk of endometriosis.[6] Exercise and avoiding large amounts of alcohol may also be preventative.[3] There is no cure for endometriosis, but a number of treatments may improve symptoms.[4] This may include pain medication, hormonal treatments, or surgery. The recommended pain medication is usually an NSAID such as naproxen. Taking the active component of the birth control pill continuously or using an intrauterine device with progestogen may also be useful. Gonadotropin-releasing hormone agonist may improve the ability of those who are infertile to get pregnant. Surgical removal of endometriosis may be used to treat those whose symptoms are not manageable with other treatments.[3]

Endometriosis is estimated to occur in roughly 6–10% of women.[4] It is most common in those in their thirties and forties; however, can begin in girls as early as 8 years old.[3][7] It results in few deaths with this being estimated at 200 globally in 2013.[8] Endometriosis was first determined to be a separate condition in the 1920s. Before that time endometriosis and adenomyosis were considered together. It is unclear who first described the disease.[9]

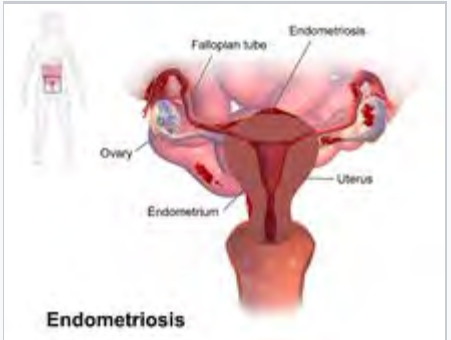
# Signs and symptoms [edit]

Although 20–25% of women with endometriosis have no symptoms, pain and infertility are common signs.[4]



Drawing showing endometriosis.

## Pelvic pain [edit]

A major symptom of endometriosis is recurring pelvic pain. The pain can range from mild to severe cramping or stabbing pain that occurs on both sides of the pelvis, in the lower back and rectal area, and even down the legs. The amount of pain a woman feels correlates poorly with the extent or stage (1 through 4) of endometriosis, with some women having little or no pain despite having extensive endometriosis or endometriosis with scarring, while other women may have severe pain even though they have only a few small areas of endometriosis.[10] Symptoms of endometriosis-related pain may include:[11]

- dysmenorrhea – painful, sometimes disabling cramps during the menstrual period; pain may get worse over time (progressive pain), also lower back pains linked to the pelvis
- chronic pelvic pain – typically accompanied by lower back pain or abdominal pain
- dyspareunia – painful sex
- dysuria – urinary urgency, frequency, and sometimes painful voiding

Throbbing, gnawing, and dragging pain to the legs are reported more commonly by women with

endometriosis.[*unreliable medical source?*][12] Compared with women with superficial endometriosis, those with deep disease appear to be more likely to report shooting rectal pain and a sense of their insides being pulled down.[12] Individual pain areas and pain intensity appears to be unrelated to the surgical diagnosis, and the area of pain unrelated to area of endometriosis.[12]

Endometriosis lesions react to hormonal stimulation and may "bleed" at the time of menstruation. The blood accumulates locally, causes swelling, and triggers inflammatory responses with the activation of cytokines. This process may cause pain. Pain can also occur from adhesions (internal scar tissue) binding internal organs to each other, causing organ dislocation. Fallopian tubes, ovaries, the uterus, the bowels, and the bladder can be bound together in ways that are painful on a daily basis, not just during menstrual periods.[13]

Also, endometriotic lesions can develop their own nerve supply, thereby creating a direct and two-way interaction between lesions and the central nervous system, potentially producing a variety of individual differences in pain that can, in some women, become independent of the disease itself.[10] Nerve fibres and blood vessels are thought to grow into endometriosis lesions by a process known as Neuroangiogenesis.[14]

### Infertility [edit]

*Main article: Endometriosis and infertility*

Many women with infertility may have endometriosis. Among women with endometriosis, up to half may experience infertility.[4]

### Other [edit]

Other symptoms include diarrhea or constipation,[*unreliable medical source?*][12] chronic fatigue,[*medical citation needed*] nausea and vomiting, headaches, low-grade fevers, heavy and/or irregular periods, and hypoglycemia.[*unreliable medical source?*][15]

In addition to pain during menstruation, the pain of endometriosis can occur at other times of the month. There can be a pain with ovulation, pain associated with adhesions, pain caused by inflammation in the pelvic cavity, pain during bowel movements and urination, during general bodily movement like exercise, pain from standing or walking, and pain with intercourse. The most severe pain is typically associated with menstruation. Pain can also start a week before a menstrual period, during and even a week after a menstrual period, or it can be constant. The pain can be debilitating and the emotional stress can take a toll.[16]

There is an association between endometriosis and certain types of cancers, notably some types of ovarian cancer,[17][18] non-Hodgkin's lymphoma and brain cancer.[19] Endometriosis is unrelated to endometrial cancer.[20]

## Risk factors [edit]

### Genetics [edit]

Genetic predisposition plays a role in endometriosis.[21] Daughters or sisters of women with endometriosis are at higher risk of developing endometriosis themselves; low progesterone levels may be genetic, and may contribute to a hormone imbalance.[22] There is an about six-fold increased incidence in women with an affected first-degree relative.[23]

It has been proposed that endometriosis results from a series of multiple hits within target genes, in a mechanism similar to the development of cancer.[21] In this case, the initial mutation may be either somatic or heritable.[21]

Individual genomic changes (found by genotyping including genome-wide association studies) that have been associated with endometriosis include:

- Changes on chromosome 1 near WNT4.[24]
- Changes on chromosome 2 near GREB1.[24]
- Changes on chromosome 6 near ID4.[24]
- Changes on chromosome 7 in the 7p15.2 region.[24][25]
- Changes on chromosome 9 near CDKN2BAS.[24]
- Changes on chromosome 10 at region 10q26.[26]
- Changes on chromosome 12 near VEZT.[24]

In addition, there is a weaker association with changes in the fibronectin gene as well as in the 2p14 region of chromosome 2.[24]

In addition, there are many findings of altered gene expression and epigenetics, but both of these can also be a secondary result of, for example, environmental factors and altered metabolism. Examples of altered gene expression include that of miRNAs.[21]

### Environmental toxins [edit]

Several studies have investigated the potential link between exposure to dioxins and endometriosis, but the evidence is equivocal and potential mechanisms are poorly understood.[27] A 2004 review of studies of dioxin and endometriosis concluded that "the human data supporting the dioxin-endometriosis association are scanty and conflicting",[28] and a 2009 follow-up review also found that there was "insufficient evidence" in support of a link between dioxin exposure and women developing endometriosis.[29] A 2008 review concluded that more work was needed, stating that "although preliminary work suggests a potential involvement of exposure to dioxins in the pathogenesis of endometriosis, much work remains to clearly define cause and effect and to understand the potential mechanism of toxicity".[30]

## Pathophysiology [edit]

While the exact cause of endometriosis remains unknown, many theories have been presented to better understand and explain its development. These concepts do not necessarily exclude each other. The pathophysiology of endometriosis is likely to be multifactorial and to involve an interplay between several factors.[21]

### Formation [edit]

The main theories for the formation of the ectopic endometrium are retrograde menstruation, müllerianosis, coelomic metaplasia and transplantation, each further described below.

### Retrograde menstruation theory [edit]

The theory of retrograde menstruation (also called the *implantation theory* or *transplantation theory*)[31] is the most widely accepted theory for the formation of ectopic endometrium in endometriosis.[21] It suggests that during a woman's menstrual flow, some of the endometrial debris exits the uterus through the fallopian tubes and attaches itself to the peritoneal surface (the lining of the abdominal cavity) where it can proceed to invade the tissue as endometriosis.[21]

Retrograde menstruation alone is not able to explain all instances of endometriosis, and additional factors such as genetic or immune differences need to be invoked to account for the fact that many women with retrograde menstruation do not have endometriosis. Researchers are investigating the possibility that the

immune system may not be able to cope with the cyclic onslaught of retrograde menstrual fluid. In this context there is interest in studying the relationship of endometriosis to autoimmune disease, allergic reactions, and the impact of toxic materials.[32][33] It is still unclear what, if any, causal relationship exists between toxic materials, autoimmune disease, and endometriosis. There are immune system changes in women with endometriosis, such as an increase macrophage-derived secretion products, but it is unknown if these are contributing to the disorder or are reactions from it.[34]

In addition, at least one study found that endometriotic lesions differ in their biochemistry from artificially transplanted ectopic tissue.[35] This is likely because the cells that give rise to endometriosis are a side population of cells.[21] Similarly, there are changes in for example the mesothelium of the peritoneum in women with endometriosis, such as loss of tight junctions, but it is unknown if these are causes or effects of the disorder.[34]

In rare cases where imperforate hymen does not resolve itself prior to the first menstrual cycle and goes undetected, blood and endometrium are trapped within the uterus of the woman until such time as the problem is resolved by surgical incision. Many health care practitioners never encounter this defect, and due to the flu-like symptoms it is often misdiagnosed or overlooked until multiple menstrual cycles have passed. By the time a correct diagnosis has been made, endometrium and other fluids have filled the uterus and fallopian tubes with results similar to retrograde menstruation resulting in endometriosis. The initial stage of endometriosis may vary based on the time elapsed between onset and surgical procedure.[*citation needed*]

The theory of retrograde menstruation as a cause of endometriosis was first proposed by John A. Sampson.

## Other theories [edit]

- Stem cells: Endometriosis may arise from stem cells from bone marrow and potentially other sources. In particular this theory explains endometriosis found in areas remote from the pelvis such as the brain or lungs.[36]
- Environment; Environmental toxins (e.g.; dioxin, nickel) may cause endometriosis.[37]
- Müllerianosis: A theory supported by foetal autopsy is that cells with the potential to become endometrial, which are laid down in tracts during embryonic development called the female reproductive (Mullerian) tract as it migrates downward at 8–10 weeks of embryonic life, could become dislocated from the migrating uterus and act like seeds or stem cells.[38]
- Coelomic metaplasia: Coelomic cells which are the common ancestor of endometrial and peritoneal cells may undergo metaplasia (transformation) from one type of cell to the other, perhaps triggered by inflammation.[39]
- Vasculogenesis: Up to 37% of the microvascular endothelium of ectopic endometrial tissue originates from endothelial progenitor cells, which result in *de novo* formation of microvessels by the process of vasculogenesis rather than the conventional process of angiogenesis.[40][*clarification needed*]
- Neural growth: An increased expression of new nerve fibres is found in endometriosis, but does not fully explain the formation of ectopic endometrial tissue, and is not definitely correlated with the amount of perceived pain.[41][*clarification needed*]
- Autoimmune: Graves disease is an autoimmune disease characterized by hyperthyroidism, goiter, ophthalmopathy, and dermopathy. Women with endometriosis had higher rates of Graves disease. One of these potential links between Graves disease and endometriosis is autoimmunity.[42][43]

## Localization [edit]

Most endometriosis is found on these structures in the pelvic cavity:[44]

- Ovaries (the most common site)
- Fallopian tubes
- The back of the uterus and the posterior cul-de-sac
- The front of the uterus and the anterior cul-de-sac
- Uterine ligaments such as the broad or round ligament of the uterus
- Pelvic and back wall

possible locations of endometriosis

Intestines, most commonly the rectosigmoid
- Urinary bladder and ureters

Rectovaginal or bowel endometriosis affects approximately 5-12% of women with endometriosis, and can cause severe pain with bowel movements.[45]

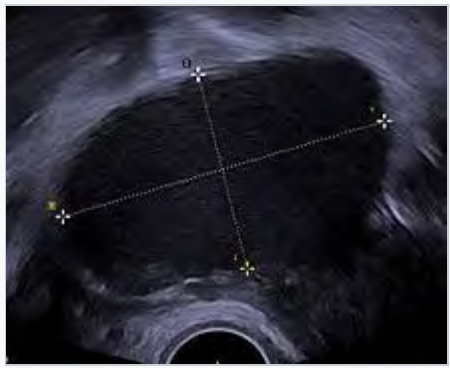
Endometriosis may spread to the cervix and vagina or to sites of a surgical abdominal incision, known as "scar endometriosis."[46] Risk factors for scar endometriosis include previous abdominal surgeries, such as a hysterotomy or cesarean section, or ectopic pregnancies, salpingostomy puerperal sterilization, laparoscopy, amniocentesis, appendectomy, episiotomy, vaginal hysterectomies, and hernia repair.[47][48][49]

Endometriosis may also present with skin lesions in cutaneous endometriosis.

Less commonly lesions can be found on the diaphragm. Diaphragmatic endometriosis is rare, almost always on the right hemidiaphragm, and may inflict the cyclic pain of the right shoulder just before and during a menstrual period. Rarely, endometriosis can be extraperitoneal and is found in the lungs and CNS.[50]

## Diagnosis [edit]

A health history and a physical examination can lead the health care practitioner to suspect endometriosis. Although doctors can often feel the endometrial growths during a pelvic exam, and these symptoms may be signs of endometriosis, diagnosis cannot be confirmed by exam only. Use of pelvic ultrasound may identify large endometriotic cysts (called endometriomas). However, smaller endometriosis implants cannot be visualized with ultrasound technique.[*citation needed*]



Transvaginal ultrasonography showing a 67 x 40 mm endometrioma as distinguished from other types of ovarian cysts by a somewhat grainy and not completely anechoic content.

### Laparoscopy [edit]

Laparoscopy, a surgical procedure where a camera is used to look inside the abdominal cavity, is the only way to officially diagnose endometriosis as it permits lesion visualization unless the lesion is visible externally, e.g. an endometriotic nodule in the vagina. If the growths are not visible, a biopsy may be taken to determine the diagnosis.[51] Surgery for diagnoses also allows for surgical treatment of endometriosis at the same time.

To the eye, lesions can appear dark blue, powder-burn black, red, white, yellow, brown or non-pigmented. Lesions vary in size. Some within the pelvis walls may not be visible, as normal-appearing peritoneum of infertile women reveals endometriosis on biopsy in 6–13% of cases.[52] Early endometriosis typically occurs on the surfaces of organs in the pelvic and intra-abdominal areas. Health care providers may call areas of endometriosis by different names, such as implants, lesions, or nodules. Larger lesions may be seen within the ovaries as endometriomas or "chocolate cysts", "chocolate" because they contain a thick brownish fluid, mostly old blood.[*citation needed*]

Frequently during diagnostic laparoscopy, no lesions are found in women with chronic pelvic pain, a symptom common to other disorders including adenomyosis, pelvic adhesions, pelvic inflammatory disease, congenital anomalies of the reproductive tract, and ovarian or tubal masses.[53]

## Staging [edit]

Surgically, endometriosis can be staged I–IV by the revised classification of the American Society of Reproductive Medicine from 1997.[54] The process is a complex point system that assesses lesions and adhesions in the pelvic organs, but it is important to note staging assesses physical disease only, not the level of pain or infertility. A person with Stage I endometriosis may have a little disease and severe pain, while a person with Stage IV endometriosis may have severe disease and no pain or vice versa. In principle the various stages show these findings:[*citation needed*]

**Stage I (Minimal)**
Findings restricted to only superficial lesions and possibly a few filmy adhesions
**Stage II (Mild)**
In addition, some deep lesions are present in the cul-de-sac
**Stage III (Moderate)**
As above, plus the presence of endometriomas on the ovary and more adhesions.
**Stage IV (Severe)**
As above, plus large endometriomas, extensive adhesions.

## Markers [edit]

An area of research is the search for endometriosis markers.[55]

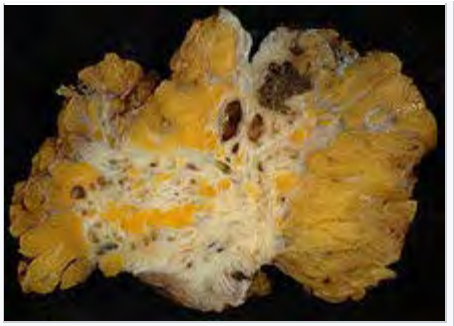
In 2010 essentially all proposed biomarkers for endometriosis were of unclear medical use, although some appear to be promising.[55] The one biomarker that has been in use over the last 20 years is CA-125.[55] A 2016 review found that in those with symptoms of endometriosis and once ovarian cancer has been ruled out, a positive CA-125 may confirm the diagnosis.[56] Its performance in ruling out endometriosis; however, is low.[56] CA-125 levels appear to fall during endometriosis treatment, but has not shown a correlation with disease response.[55]

Another review in 2011 identified several putative biomarkers upon biopsy, including findings of small sensory nerve fibers or defectively expressed β3 integrin subunit.[57] It has been postulated a future diagnostic tool for endometriosis will consist of a panel of several specific and sensitive biomarkers, including both substance concentrations and genetic predisposition.[55]

## Histopathology [edit]

Typical endometriotic lesions show histopathologic features similar to endometrium, namely endometrial stroma, endometrial epithelium, and glands that respond to hormonal stimuli. Older lesions may display no glands but hemosiderin deposits (see photomicrograph on right) as residual.[*citation needed*]

Immunohistochemistry has been found to be useful in diagnosing

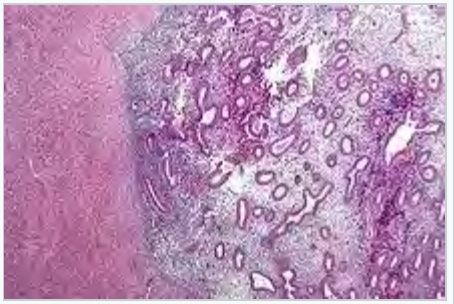


Endometriosis, abdominal wall

endometriosis as stromal cells have a peculiar surface antigen, CD10, thus allowing the pathologist go straight to a staining area and hence confirm the presence of stromal cells and sometimes glandular tissue is thus identified that was missed on routine H&E staining.[58][*better source needed*]

### Pain quantification [edit]

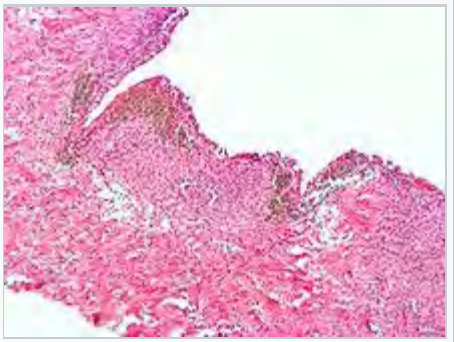
The most common pain scale for quantification of endometriosis-related pain is the visual analogue scale (VAS); VAS and numerical rating scale (NRS) were the best adapted pain scales for pain measurement in endometriosis. For research purposes, and for more detailed pain measurement in clinical practice, VAS or NRS for each type of typical pain related to endometriosis (dysmenorrhea, deep dyspareunia and non-menstrual chronic pelvic pain), combined with the clinical global impression (CGI) and a quality of life scale, are used.[59]



Micrograph showing endometriosis (right) and ovarian stroma (left). H&E stain.

## Prevention [edit]

Limited evidence indicates that the use of combined oral contraceptives is associated with a reduced risk of endometriosis.[6]



Micrograph of the wall of an endometrioma. All features of endometriosis are present (endometrial glands, endometrial stroma and hemosiderin-laden macrophages). H&E stain.

## Management [edit]

While there is no cure for endometriosis, there are two types of interventions; treatment of pain and treatment of endometriosis-associated infertility.[60] In many women menopause (natural or surgical) will abate the process.[61] In women in the reproductive years, endometriosis is merely managed: the goal is to provide pain relief, to restrict progression of the process, and to restore or preserve fertility where needed. In younger women, surgical treatment attempts to remove endometrial tissue and preserve the ovaries without damaging normal tissue.[62]

In general, the diagnosis of endometriosis is confirmed during surgery, at which time ablative steps can be taken. Further steps depend on circumstances: a woman without infertility can be managed with hormonal medication that suppresses the natural cycle and pain medication, while an infertile woman may be treated expectantly after surgery, with fertility medication, or with IVF. As to the surgical procedure, ablation (or fulguration) of endometriosis (burning and vaporizing the lesions with an electric device) has shown a high rate of short-term recurrence after the procedure. The best surgical procedure with much less rate of short-term recurrence is to excise (cut and remove) the lesions completely.[*medical citation needed*]

### Surgery [edit]

Conservative treatment consists of the excision of the endometrium, adhesions, resection of endometriomas, and restoration of normal pelvic anatomy as much as is possible.[63] Endometrioma on the

ovary of any significant size (Approx. 2 cm +) -sometimes misdiagnosed as ovarian cysts- must be removed surgically because hormonal treatment alone will not remove the full endometrioma cyst, which can progress to acute pain from the rupturing of the cyst and internal bleeding.[*medical citation needed*] Laparoscopy, besides being used for diagnosis, can also be used to perform surgery. It's considered a "minimally invasive" surgery because the surgeon makes very small openings (incisions) at (or around) the belly button and lower portion of the belly. A thin telescope-like instrument (the laparoscope) is placed through one incision, which allows the doctor to look for endometriosis using a small camera attached to the laparoscope. Small instruments are inserted through the incisions to remove the endometriosis tissue and adhesions. Because the incisions are very small, there will only be small scars on the skin after the procedure, and all endometriosis can be removed, and women recover from surgery quicker and have a lower risk of adhesions.[64]

55% to 100% of women develop adhesions following pelvic surgery,[65] which can result in infertility, chronic abdominal and pelvic pain, and difficult reoperative surgery. Trehan's temporary ovarian suspension, a technique in which the ovaries are suspended for a week after surgery may be used to reduce the incidence of adhesions after endometriosis surgery.[66][67]

Conservative treatment involves excision of endometriosis while preserving the ovaries and uterus, very important for women wishing to conceive, but may increase the risk of recurrence.[68]

Endometriosis recurrence following conservative surgery is estimated as 21.5% at 2 years and 40-50% at 5 years.[69]

A hysterectomy (removal of the uterus) can be used to treat endometriosis in women who do not wish to conceive. However, this should only be done when combined with removal of the endometriosis by excision, as if endometriosis is not also removed at the time of hysterectomy, pain may persist.[70]

For women with extreme pain, a presacral neurectomy may be very rarely performed where the nerves to the uterus are cut. However, this technique is almost never used due to the high incidence of associated complications including presacral hematoma and irreversible problems with urination and constipation.[70]

## Hormones [edit]

- Progesterone or Progestins: Progesterone counteracts estrogen and inhibits the growth of the endometrium.[71] Such therapy can reduce or eliminate menstruation in a controlled and reversible fashion. Progestins are chemical variants of natural progesterone. An example of a Progestin is Dienogest (Visanne).
- Avoiding products with xenoestrogens, which have a similar effect to naturally produced estrogen and can increase growth of the endometrium.[*medical citation needed*]
- Hormone contraception therapy: Oral contraceptives reduce the menstrual pain associated with endometriosis.[*unreliable medical source?*][72] They may function by reducing or eliminating menstrual flow and providing estrogen support. Typically, it is a long-term approach.
- Danazol (Danocrine) and gestrinone are suppressive steroids with some androgenic activity.[62] Both agents inhibit the growth of endometriosis but their use remains limited as they may cause hirsutism and voice changes.[*medical citation needed*]
- Gonadotropin-releasing hormone (GnRH) agonists: These drugs are thought to work by decreasing hormone levels.[73] A 2010 Cochrane review found that GnRH agonists were more effective for pain relief in endometriosis than no treatment or placebo, but were no more effective than danazol or intrauterine progestagen, and had more side effects than danazol.[73]
- Aromatase inhibitors are medications that block the formation of estrogen and have become of interest for researchers who are treating endometriosis.[74]

## Other medication [edit]

- NSAIDs: Anti-inflammatory. They are commonly used in conjunction with other therapy. For more severe cases narcotic prescription drugs may be used. NSAID injections can be helpful for severe pain or if stomach pain prevents oral NSAID use.

- Opioids: Morphine sulphate tablets and other opioid painkillers work by mimicking the action of naturally occurring pain-reducing chemicals called "endorphins". There are different long acting and short acting medications that can be used alone or in combination to provide appropriate pain control.
- Following laparoscopic surgery women who were given Chinese herbs were reported to have comparable benefits to women with conventional drug treatments, though the journal article that reviewed this study also noted that "the two trials included in this review are of poor methodological quality so these findings must be interpreted cautiously. Better quality randomised controlled trials are needed to investigate a possible role for CHM [Chinese Herbal Medicine] in the treatment of endometriosis."[75]
- Pentoxifylline, an immunomodulating agent, has been theorized to improve pain as well as improve pregnancy rates in women with endometriosis. A 2012 Cochrane review, however, found that there was not enough evidence to support the effectiveness or safety of either of these uses.[76] Current American Congress of Obstetricians and Gynecologists (ACOG) guidelines do not include immune-modulators, such as pentoxifylline, in standard treatment protocols.[77]
- Angiogenesis inhibitors lack clinical evidence of efficacy in endometriosis therapy.[78] Under experimental *in vitro* and *in vivo* conditions, compounds that have been shown to exert inhibitory effects on endometriotic lesions include growth factor inhibitors, endogenous angiogenesis inhibitors, fumagillin analogues, statins, cyclo-oxygenase-2 inhibitors, phytochemical compounds, immunomodulators, dopamine agonists, peroxisome proliferator-activated receptor agonists, progestins, danazol and gonadotropin-releasing hormone agonists.[78] However, many of these agents are associated with undesirable side effects and more research is necessary. An ideal therapy would diminish inflammation and underlying symptoms without being contraceptive.[79][80]

The overall effectiveness of manual physical therapy to treat endometriosis has not yet been identified.[81] There is no evidence to support nutritional therapy as effective.

## Comparison of interventions [edit]

Medicinal and surgical interventions produce roughly equivalent pain-relief benefits. Recurrence of pain was found to be 44 and 53 percent with medicinal and surgical interventions, respectively.[22] Each approach has advantages and disadvantages.[39] Manual therapy showed a decrease in pain for 84 percent of study participants, and a 93 percent improvement in sexual function.[*unreliable medical source?*][82]

Evidence on how effective medication is for relieving pain associated with endometriosis is limited.[60]

The advantages of surgery are demonstrated efficacy for pain control,[83] it is more effective for infertility than medicinal intervention,[62] it provides a definitive diagnosis,[62] and surgery can often be performed as a minimally invasive (laparoscopic) procedure to reduce morbidity and minimize the risk of post-operative adhesions.[84] Efforts to develop effective strategies to reduce or prevent adhesions have been undertaken, but their formation remain a frequent side effect of abdominal surgery.[65]

The advantages of physical therapy techniques are decreased cost, absence of major side-effects, it does not interfere with fertility, and near-universal increase of sexual function.[82] Disadvantages are that there are no large or long-term studies of its use for treating pain or infertility related to endometriosis.[82]

## Treatment of infertility [edit]

*Main article: Endometriosis and infertility*

Surgery is more effective than medicinal intervention for addressing infertility associated with endometriosis.[62] Surgery attempts to remove endometrial tissue and preserve the ovaries without damaging normal tissue.[62] In-vitro fertilization (IVF) procedures are effective in improving fertility in many women with endometriosis.[*medical citation needed*]

# Prognosis [edit]

Proper counseling of women with endometriosis requires attention to several aspects of the disorder. Of primary importance is the initial operative staging of the disease to obtain adequate information on which to base future decisions about therapy. The woman's symptoms and desire for childbearing dictate appropriate therapy. Not all therapy works for all women. Some women have recurrences after surgery or pseudo-menopause. In most cases, treatment will give women significant relief from pelvic pain and assist them in achieving pregnancy.[85]

The underlying process that causes endometriosis may not cease after a surgical or medical intervention. Studies have shown that endometriosis recurs at a rate of 20 to 40 percent within five years following conservative surgery,[*unreliable medical source?*][86] unless hysterectomy is performed or menopause reached. Monitoring of women consists of periodic clinical examinations and sonography.

Vaginal childbirth decreases recurrence of endometriosis. In contrast, endometriosis recurrence rates have been shown to be higher in women who have not given birth vaginally, such as in cesarean section.[*unreliable medical source?*][87]

### Complications [edit]

Complications of endometriosis include internal scarring, adhesions, pelvic cysts, chocolate cyst of ovaries, ruptured cysts, and bowel and ureteral obstruction resulting from pelvic adhesions.[88] Endometriosis-associated infertility can be related to scar formation and anatomical distortions due to the endometriosis.[*medical citation needed*]

Ovarian endometriosis may complicate pregnancy by decidualization,[*clarification needed*] abscess and/or rupture.[89]

Thoracic endometriosis is associated with recurrent pneumothoraces at times of a menstrual period, termed catamenial pneumothorax.[90]

## Epidemiology [edit]

Endometriosis can affect any female, from premenarche to postmenopause, regardless of race or ethnicity or whether or not they have had children. It is primarily a disease of the reproductive years.[91] The number of women affected is between 6–10%.[4] It is more common in women with infertility and chronic pelvic pain (35–50%).[4]

Incidences of endometriosis have occurred in postmenopausal women,[92] and in less common cases, girls may have endometriosis symptoms before they even reach menarche.[93][94]

## History [edit]

Endometriosis was first discovered microscopically by Karl von Rokitansky in 1860,[95] although it was documented in medical texts more than 4,000 years ago.[96] The Hippocratic Corpus outlines symptoms similar to endometriosis, including uterine ulcers, adhesions, and infertility.[96] Historically, women with these symptoms were treated with leeches, straitjackets, bloodletting, chemical douches, genital mutilation, pregnancy (as a form of treatment), hanging upside down, surgical intervention, and even killing due to suspicion of demonic possession.[96] Hippocratic doctors recognized and treated chronic pelvic pain as a true organic disorder 2,500 years ago, but during the Middle Ages, there was a shift into believing that women with pelvic pain were mad, immoral, imagining the pain, or simply misbehaving.[96] The symptoms of inexplicable chronic pelvic pain were often attributed to imagined madness, female weakness, promiscuity, or hysteria.[96] The historical diagnosis of hysteria, which was thought to be a psychological disease, may have indeed been endometriosis.[96] The idea that chronic pelvic pain was related to mental illness influenced modern attitudes regarding women with endometriosis, leading to delays in correct [96]

diagnosis and indifference to the patients' true pain during the 20th century.

Hippocratic doctors believed that delaying childbearing could trigger diseases of the uterus, which caused endometriosis-like symptoms. Women with dysmenorrhea were encouraged to marry and have children at a young age.[96] The fact that Hippocratics were recommending changes in marriage practices due to an endometriosis-like illness implies that this disease was likely common, with rates higher than the 5-15% prevalence that is often cited today.[96] If indeed this disorder was so common historically, this may point away from modern theories that suggest links between endometriosis and dioxins, PCBs, and chemicals.[96]

## Society and culture [edit]

As recently as 1995, reports found that over 50% of women with chronic pelvic pain had no organic cause, with women still often being considered mentally unstable.[97] Self-help groups say practitioners delay making the diagnosis, often because they don't consider it a possibility. In the US, as of 2007, about 27% of women with endometriosis had had the symptoms for at least six years before it is diagnosed.[*needs update*][98]

The economic effects associated with endometriosis are substantial and are similar to that of other chronic diseases such as Crohn's disease, diabetes, or rheumatoid arthritis.[99] This economic burden is attributed mostly to the inability to consistently work and predicted by decreased quality of life.[99]

# Hyperemesis gravidarum

From Wikipedia, the free encyclopedia

**Hyperemesis gravidarum** (**HG**) is a complication of pregnancy that is characterized by severe nausea and vomiting such that weight loss and dehydration occur.[1] Signs and symptoms may include vomiting several times a day and feeling faint. It is more severe than morning sickness. Often symptoms get better after the 20th week of pregnancy but may last the entire pregnancy.[2]

The exact cause of hyperemesis gravidarum is not known.[3] Risk factors include the first pregnancy, multiple pregnancy, obesity, prior or family history of hyperemesis gravidarum, trophoblastic disorder, and a history of an eating disorder.[3][4] The diagnosis is usually made based on the signs and symptoms. It has been technically defined as more than three episodes of vomiting per day such that weight loss of 5% or three kilograms has occurred and ketones are present in the urine.[3] Other potential causes of the symptoms should be excluded including urinary tract infection and high thyroid levels.[5]

Treatment includes drinking fluids and a bland diet.[2] Recommendations may include electrolyte-replacement drinks, thiamine, and a higher protein diet.[3][6] Some women require intravenous fluids.[2] With respect to medications pyridoxine or metoclopramide are preferred.[5] Prochlorperazine, dimenhydrinate, or ondansetron may be used if these are not effective.[3][5] Hospitalization may be required. Psychotherapy may improve outcomes. Evidence for acupressure is poor.[3]

While vomiting in pregnancy has been described as early as 2,000 BC, the first clear medical description of hyperemesis gravidarum was in 1852 by Antoine Dubois.[7] Hyperemesis gravidarum is estimated to affect 0.3–2.0% of pregnant women.[8] While previously a common cause of death in pregnancy, with proper treatment this is now very rare.[9][10] Those affected have a low risk of miscarriage but a higher risk of premature birth.[4] Some women opt to have an abortion because of the symptoms.[6]

## Signs and symptoms [edit]

When vomiting is severe it may result in the following:[11]

- Loss of 5% or more of pre-pregnancy body weight [12]

Dehydration, causing ketosis, and constipation
- Nutritional disorders such as vitamin B1 (thiamine) deficiency, vitamin B6 deficiency or vitamin B12 deficiency
- Metabolic imbalances such as metabolic ketoacidosis[11] or thyrotoxicosis[13]
- Physical and emotional stress of pregnancy on the body
- Difficulty with activities of daily living

Symptoms can be aggravated by hunger, fatigue, prenatal vitamins (especially those containing iron), and diet.[14] Many people with HG are extremely sensitive to odors in their environment; certain smells may exacerbate symptoms. This is known as hyperolfaction. Ptyalism, or hypersalivation, is another symptom experienced by some women suffering from HG.

Hyperemesis gravidarum tends to occur in the first trimester of pregnancy[12] and lasts significantly longer than morning sickness. While most women will experience near-complete relief of morning sickness symptoms near the beginning of their second trimester, some sufferers of HG will experience severe symptoms until they give birth to their baby, and sometimes even after giving birth.[15]

A small percentage rarely vomit, but the nausea still causes most (if not all) of the same issues that hyperemesis with vomiting does.[*citation needed*]

## Causes [edit]

There are numerous theories regarding the cause of HG, but the cause remains controversial. It is thought that HG is due to a combination of factors which may vary between women and include genetics.[11] Women with family members who had Hyperemesis are more likely to develop the disease.[16]

One factor is an adverse reaction to the hormonal changes of pregnancy, in particular, elevated levels of beta human chorionic gonadotropin (hCG).[17][18] This theory would also explain why hyperemesis gravidarum is most frequently encountered in the first trimester (often around 8–12 weeks of gestation), as hCG levels are highest at that time and decline afterward. Another postulated cause of HG is an increase in maternal levels of estrogens (decreasing intestinal motility and gastric emptying leading to nausea/vomiting).[11]

## Pathophysiology [edit]

Although the pathophysiology of HG is poorly understood, the most commonly accepted theory suggests that levels of hCG are associated with it.[5] Leptin may also play a role.[19]

Possible pathophysiological processes involved are summarized in the following table:[20]

| Source | Etiology | Pathophysiology |
|---|---|---|
| ▪ Placenta<br>▪ Corpus luteum | hCG | ▪ Distention of gastrointestinal tract<br>▪ Crossover with TSH, causing gestational thyrotoxicosis[5] |
| Placenta | ▪ Estrogen<br>▪ Progesterone | ▪ Decreased gut mobility<br>▪ Elevated liver enzymes<br>▪ Decreased lower esophageal sphincter pressure<br>▪ Increased levels of sex steroids in hepatic portal system[21] |
| Gastrointestinal tract | *Helicobacter pylori* | Increased steroid levels in circulation[22] |

## Diagnosis [edit]

Hyperemesis gravidarum is considered a diagnosis of exclusion.[11] HG can be associated with serious problems in the mother or baby, such as Wernicke's encephalopathy, coagulopathy, peripheral neuropathy.[5]

Women experiencing hyperemesis gravidarum often are dehydrated and lose weight despite efforts to eat.[23][24] The onset of the nausea and vomiting in hyperemesis gravidarum is typically before the twenty-second week of pregnancy.[11]

## Differential diagnosis [edit]

Diagnoses to be ruled out include the following:[20]

| Type | Differential diagnoses |
|---|---|
| Infections<br>(usually accompanied by fever or associated neurological symptoms) | ▪ Urinary tract infection<br>▪ Hepatitis<br>▪ Meningitis<br>▪ Gastroenteritis |
| Gastrointestinal disorders<br>(usually accompanied by abdominal pain) | ▪ Appendicitis<br>▪ Cholecystitis<br>▪ Pancreatitis<br>▪ Fatty liver<br>▪ Peptic ulcer<br>▪ Small bowel obstruction |
| Metabolic | ▪ Thyrotoxicosis (common in Asian subcontinent)[5]<br>▪ Addison's disease<br>▪ Diabetic ketoacidosis<br>▪ Hyperparathyroidism |
| Drugs | ▪ Antibiotics<br>▪ Iron supplements |
| Gestational trophoblastic diseases (rule out with urine β-hCG) | ▪ Molar pregnancy<br>▪ choriocarcinoma |

## Investigations [edit]

Common investigations include blood urea nitrogen (BUN) and electrolytes, liver function tests, urinalysis,[24] and thyroid function tests. Hematological investigations include hematocrit levels, which are usually raised in HG.[24] An ultrasound scan may be needed to know gestational status and to exclude molar or partial molar pregnancy.[25]

# Management [edit]

Dry bland food and oral rehydration are first-line treatments.[26] Due to the potential for severe dehydration and other complications, HG is treated as an emergency. If conservative dietary measures fail, more extensive treatment such as the use of antiemetic medications and intravenous rehydration may be required. If oral nutrition is insufficient, intravenous nutritional support may be needed.[12] For women who require hospital admission, thromboembolic stockings or low-molecular-weight heparin may be used as measures to prevent the formation of a blood clot.[20]

## Intravenous fluids [edit]

Intravenous (IV) hydration often includes supplementation of electrolytes as persistent vomiting frequently leads to a deficiency. Likewise, supplementation for lost thiamine (Vitamin $B_1$) must be considered to reduce the risk of Wernicke's encephalopathy.[27] A and B vitamins are depleted within two weeks, so extended malnutrition indicates a need for evaluation and supplementation. In addition, electrolyte levels should be monitored and supplemented; of particular concern are sodium and potassium.

After IV rehydration is completed, patients in general progress to frequent small liquid or bland meals. After rehydration, treatment focuses on managing symptoms to allow normal intake of food. However, cycles of hydration and dehydration can occur, making continuing care necessary. Home care is available in the form of a PICC line for hydration and nutrition (called total parenteral nutrition).[28] Home treatment is often less expensive than long-term or repeated hospitalizations.

## Medications [edit]

A number of antiemetics are effective and safe in pregnancy including: pyridoxine/doxylamine, antihistamines (such as diphenhydramine), and phenothiazines (such as promethazine).[29] With respect to effectiveness, it is unknown if one is superior to another,[29] and there is even limited evidence of significant effect at all of pharmacological therapy in hyperemesis gravidarum.[30]

While pyridoxine/doxylamine, a combination of vitamin $B_6$ and doxylamine, is effective in nausea and vomiting of pregnancy,[31] some have questioned its effectiveness in HG.[32] Ondansetron may be beneficial, however, there are some concerns regarding an association with cleft palate,[33] and there is little high-quality data.[29] Metoclopramide is also used and relatively well tolerated.[34] Evidence for the use of corticosteroids is weak; there is some evidence that corticosteroid use in pregnant women may slightly increase the risk of oral facial clefts in the infant and may suppress fetal adrenal activity.[11][35] However, hydrocortisone and prednisolone are inactivated in the placenta and may be used in the treatment of hyperemesis gravidarum after 12 weeks.[11]

### Nutritional support [edit]

Women not responding to IV rehydration and medication may require nutritional support. Patients might receive parenteral nutrition (intravenous feeding via a PICC line) or enteral nutrition (via a nasogastric tube or a nasojejunal tube). There is only limited evidence from trials to support the use of vitamin B6 to improve outcome.[30] Hyperalimentation may be necessary in certain cases to help maintain volume requirements and allow weight gain.[25] A physician might also prescribe Vitamin B1 (to prevent Wernicke's encephalopathy) and folic acid supplementation.[20]

### Alternative medicine [edit]

Acupuncture (both with P6 and traditional method) has been found to be ineffective.[30][*needs update*][36][*needs update*] The use of ginger products may be helpful, but evidence of effectiveness is limited and inconsistent, though two recent studies support ginger over placebo.[30]

## Complications [edit]

### Pregnant woman [edit]

If HG is inadequately treated, anemia,[11] hyponatremia,[11] Wernicke's encephalopathy,[11] kidney failure, central pontine myelinolysis, coagulopathy, atrophy, Mallory-Weiss tears,[11] hypoglycemia, jaundice, malnutrition, pneumomediastinum, rhabdomyolysis, deconditioning, deep vein thrombosis, pulmonary embolism, splenic avulsion, or vasospasms of cerebral arteries are possible consequences. Depression and PTSD [37] are common secondary complications of HG and emotional support can be beneficial.[11]

### Infant [edit]

The effects of HG on the fetus are mainly due to electrolyte imbalances caused by HG in the mother.[20] Infants of women with severe hyperemesis who gain less than 7 kg (15.4 lb) during pregnancy tend to be of lower birth weight, small for gestational age, and born before 37 weeks gestation.[12] In contrast, infants of women with hyperemesis who have a pregnancy weight gain of more than 7 kg appear similar to infants from uncomplicated pregnancies.[38] There is no significant difference in the neonatal death rate in infants born to mothers with HG compared to infants born to mothers who do not have HG.[11] Children born to mothers with undertreated Hyperemesis have a fourfold increase in neurobehavioral diagnoses.[39]

## Epidemiology [edit]

Vomiting is a common condition affecting about 50% of pregnant women, with another 25% having nausea.[40] However, the incidence of HG is only 0.3–1.5%.[5] After preterm labor, hyperemesis gravidarum is the second most common reason for hospital admission during the first half of pregnancy.[11] Factors such as infection with *Helicobacter pylori*, a rise in thyroid hormone production, low age, low body mass index prior to pregnancy, multiple pregnancies, molar pregnancies, and a past history of hyperemesis gravidarum have been associated with the development of HG.[11]

## History [edit]

Thalidomide was prescribed for treatment of HG in Europe until it was recognized that thalidomide is teratogenic and is a cause of phocomelia in neonates.[41]

### Etymology [edit]

Hyperemesis gravidarum is from the Greek *hyper-*, meaning excessive, and *emesis*, meaning vomiting, and the Latin *gravidarum*, the feminine genitive plural form of an adjective, here used as a noun, meaning "pregnant [woman]". Therefore,

hyperemesis gravidarum means "excessive vomiting of pregnant women".

## Notable cases [edit]

Author Charlotte Brontë is often thought to have suffered from hyperemesis gravidarum. She died in 1855 while four months pregnant, having been afflicted by intractable nausea and vomiting throughout her pregnancy, and was unable to tolerate food or even water.[42]

Catherine, Duchess of Cambridge was hospitalised due to hyperemesis gravidarum during her first pregnancy, and was treated for a similar condition during her second pregnancy.[43]

The Saturdays singer Frankie Bridge had hyperemesis gravidarum during her second pregnancy.[44]

# Menopause

From Wikipedia, the free encyclopedia

*This article is about women. For the condition called male menopause, see Andropause. For the medical journal, see Menopause (journal).*

**Menopause**, also known as the **climacteric**, is the time in most women's lives when menstrual periods stop permanently, and they are no longer able to bear children.[2][3] Menopause typically occurs between 49 and 52 years of age.[4] Medical professionals often define menopause as having occurred when a woman has not had any vaginal bleeding for a year.[5] It may also be defined by a decrease in hormone production by the ovaries.[6] In those who have had surgery to remove their uterus but they still have ovaries, menopause may be viewed to have occurred at the time of the surgery or when their hormone levels fell.[6] Following the removal of the uterus, symptoms typically occur earlier, at an average of 45 years of age.[7]

Before menopause, a woman's periods typically become irregular, which means that periods may be longer or shorter in duration or be lighter or heavier in the amount of flow. During this time, women often experience hot flashes; these typically last from 30 seconds to ten minutes and may be associated with shivering, sweating, and reddening of the skin.[8] Hot flashes often stop occurring after a year or two.[3] Other symptoms may include vaginal dryness, trouble sleeping, and mood changes.[8] The severity of symptoms varies between women.[3] While menopause is often thought to be linked to an increase in heart disease, this primarily occurs due to increasing age and does not have a direct relationship with menopause. In some women, problems that were present like endometriosis or painful periods will improve after menopause.[3]

Menopause is usually a natural change.[9] It can occur earlier in those who smoke tobacco.[5][10] Other causes include surgery that removes both ovaries or some types of chemotherapy.[5] At the physiological level, menopause happens because of a decrease in the ovaries' production of the hormones estrogen and progesterone.[2] While typically not needed, a diagnosis of menopause can be confirmed by measuring hormone levels in the blood or urine.[11] Menopause is the opposite of menarche, the time when a girl's periods start.[12]

Specific treatment is not usually needed. Some symptoms, however, may be improved with treatment. With respect to hot flashes, avoiding smoking, caffeine, and alcohol is often recommended. Sleeping in a cool room and using a fan may help.[13] The following medications may help: menopausal hormone therapy

(MHT), clonidine, gabapentin, or selective serotonin reuptake inhibitors.[13][14] Exercise may help with sleeping problems. While MHT was once routinely prescribed, it is now only recommended in those with significant symptoms, as there are concerns about side effects.[13] High-quality evidence for the effectiveness of alternative medicine has not been found.[3] There is tentative evidence for soy isoflavones.[15]

## Signs and symptoms [edit]

During early menopause transition, the menstrual cycles remain regular but the interval between cycles begins to lengthen. Hormone levels begin to fluctuate. Ovulation may not occur with each cycle.[16]

The date of the final menstrual period is usually taken as the point when menopause has occurred.[16] During the menopausal transition and after menopause, women can experience a wide range of symptoms.

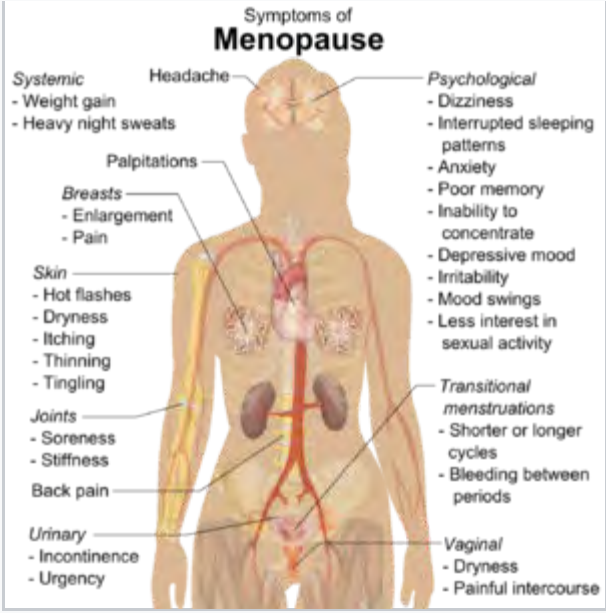
### Vagina and uterus [edit]

During the transition to menopause, menstrual patterns can show shorter cycling (by 2–7 days);[16] longer cycles remain



Symptoms of menopause

possible.[16] There may be irregular bleeding (lighter, heavier, spotting).[16] Dysfunctional uterine bleeding is often experienced by women approaching menopause due to the hormonal changes that accompany the menopause transition. Spotting or bleeding may simply be related to vaginal atrophy, a benign sore (polyp or lesion), or may be a functional endometrial response. The European Menopause and Andropause Society has released guidelines for assessment of the endometrium, which is usually the main source of spotting or bleeding.[17]

In post-menopausal women, however, any genital bleeding is an alarming symptom that requires an appropriate study to rule out the possibility of malignant diseases.

Symptoms that may appear during menopause and continue through postmenopause include:

- painful intercourse[16]
- vaginal dryness[16]
- atrophic vaginitis — thinning of the membranes of the vulva, the vagina, the cervix, and the outer urinary tract, along with considerable shrinking and loss in elasticity of all of the outer and inner genital areas.

Vaginal canal, normal vs. menopause

## Other physical [edit]

Other physical symptoms of menopause include lack of energy, joint soreness, stiffness,[16] back pain,[16] breast enlargement,[16] breast pain,[16] heart palpitations,[16] headache,[16] dizziness,[16] dry, itchy skin,[16] thinning, tingling skin, weight gain,[16] urinary incontinence,[16][18] urinary urgency,[16] interrupted sleeping patterns,[16][19][20][21] heavy night sweats,[16] hot flashes.[16]

## Psychological [edit]

Psychological symptoms include anxiety,[22] poor memory,[16] inability to concentrate,[16] depressive mood,[16][22] irritability,[16] mood swings,[16] less interest in sexual activity.[16]

## Long term effects [edit]

Menopause confers:

- A possible but contentious increased risk of atherosclerosis.[23] The risk of acute myocardial infarction and other cardiovascular diseases rises sharply after menopause, but the risk can be reduced by managing risk factors, such as tobacco smoking, hypertension, increased blood lipids and body

weight.[24][25]
- Increased risk of osteopenia and osteoporosis[*citation needed*]

Women who experience menopause before 45 years of age have an increased risk of heart disease and death.[26]

## Causes [edit]

### Age [edit]

In the Western world, the typical age of menopause (last period from natural causes) is between 40 and 61[27] and the average age for last period is 51 years.[28] The average age of natural menopause in Australia is 51.7 years.[29] In India and the Philippines, the median age of natural menopause is considerably earlier, at 44 years.[30]

In rare cases, a woman's ovaries stop working at a very early age, ranging anywhere from the age of puberty to age 40. This is known as premature ovarian failure and affects 1 to 2% of women by age 40.[31]

Undiagnosed and untreated coeliac disease is a risk factor for early menopause. Coeliac disease can present with several non-gastrointestinal symptoms, in the absence of gastrointestinal symptoms, and most cases escape timely recognition and go undiagnosed, leading to a risk of long-term complications. A strict gluten-free diet reduces the risk. Women with early diagnosis and treatment of coeliac disease present a normal duration of fertile life span.[32][33]

Women who have undergone hysterectomy with ovary conservation go through menopause on average 3.7 years earlier than the expected age. Other factors that can promote an earlier onset of menopause (usually 1 to 3 years early) are smoking cigarettes or being extremely thin.[34]

### Premature ovarian failure [edit]

Premature ovarian failure (POF) is diagnosed or confirmed by high blood levels of follicle stimulating hormone (FSH) and luteinizing hormone (LH) on at least three occasions at least four weeks apart.[35]

Known causes of premature ovarian failure include autoimmune disorders, thyroid disease, diabetes mellitus, chemotherapy, being a carrier of the fragile X syndrome gene, and radiotherapy. However, in the majority of spontaneous cases of premature ovarian failure, the cause is unknown, i.e., it is generally idiopathic.[35]

Women who have a functional disorder affecting the reproductive system (e.g., endometriosis, polycystic ovary syndrome, cancer of the reproductive organs) can go into menopause at a younger age than the normal timeframe. The functional disorders often significantly speed up the menopausal process.

An early menopause can be related to cigarette smoking, higher body mass index, racial and ethnic factors, illnesses, and the surgical removal of the ovaries, with or without the removal of the uterus.[36]

Rates of premature menopause have been found to be significantly higher in fraternal and identical twins; approximately 5% of twins reach menopause before the age of 40. The reasons for this are not completely understood. Transplants of ovarian tissue between identical twins have been successful in restoring fertility.

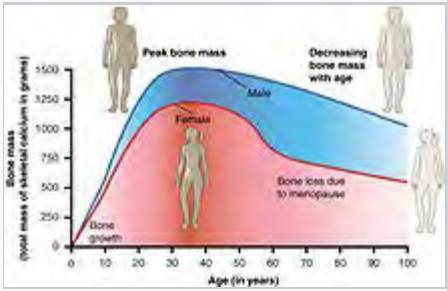
### Surgical menopause [edit]

Menopause can be surgically induced by bilateral oophorectomy (removal of ovaries), which is often, but not always, done in conjunction with removal of the Fallopian tubes (salpingo-oophorectomy) and uterus (hysterectomy).[37] Cessation of menses as a result of removal of the ovaries is called "surgical menopause". The sudden and complete drop in hormone levels usually produces extreme withdrawal symptoms such as hot flashes, etc.

Removal of the uterus *without* removal of the ovaries does *not* directly cause menopause, although pelvic

surgery of this type can often precipitate a somewhat earlier menopause, perhaps because of a compromised blood supply to the ovaries.[*citation needed*]

## Mechanism [edit]



Bone loss due to menopause occurs due to changes in a woman's hormone levels.

The menopausal transition, and postmenopause itself, is a natural change, not usually a disease state or a disorder. The main cause of this transition is the natural depletion and aging of the finite amount of oocytes (ovarian reserve). This process is sometimes accelerated by other conditions and is known to occur earlier after a wide range of gynecologic procedures such as hysterectomy (with and without ovariectomy), endometrial ablation and uterine artery embolisation. The depletion of the ovarian reserve causes an increase in circulating follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels because there are a decreased number of oocytes and follicles responding to these hormones and producing estrogen.

The transition has a variable degree of effects.[38]

The stages of the menopause transition have been classified according to a woman's reported bleeding pattern, supported by changes in the pituitary follicle-stimulating hormone (FSH) levels.[39]

In younger women, during a normal menstrual cycle the ovaries produce estradiol, testosterone and progesterone in a cyclical pattern under the control of FSH and luteinising hormone (LH) which are both produced by the pituitary gland. During perimenopause (approaching menopause), estradiol levels and patterns of production remain relatively unchanged or may increase compared to young women, but the cycles become frequently shorter or irregular.[40] The often observed increase in estrogen is presumed to be in response to elevated FSH levels that, in turn, is hypothesized to be caused by decreased feedback by inhibin.[41] Similarly, decreased inhibin feedback after hysterectomy is hypothesized to contribute to increased ovarian stimulation and earlier menopause.[42][43]

The menopausal transition is characterized by marked, and often dramatic, variations in FSH and estradiol levels. Because of this, measurements of these hormones are *not* considered to be reliable guides to a woman's exact menopausal status.[44]

Menopause occurs because of the sharp decrease of estradiol and progesterone production by the ovaries. After menopause, estrogen continues to be produced mostly by aromatase in fat tissues and is produced in small amounts in many other tissues such as ovaries, bone, blood vessels, and the brain where it acts locally.[45] The substantial fall in circulating estradiol levels at menopause impacts many tissues, from brain to skin.

In contrast to the sudden fall in estradiol during menopause, the levels of total and free testosterone, as well as dehydroepiandrosterone sulfate (DHEAS) and androstenedione appear to decline more or less steadily with age. An effect of natural menopause on circulating androgen levels has not been observed.[46] Thus specific tissue effects of natural menopause cannot be attributed to loss of androgenic hormone production.[47]

Hot flushes and other vasomotor symptoms accompany the menopausal transition. While many sources continue to claim that hot flashes during the menopausal transition are caused by low estrogen levels, this assertion was shown incorrect in 1935 and, in most cases, hot flushes are observed despite elevated estrogen levels. The exact cause of these symptoms is not yet understood, possible factors considered are higher and erratic variation of estradiol level during the cycle, elevated FSH levels which may indicate hypothalamic dysregulation perhaps caused by missing feedback by inhibin. It has been also observed that the vasomotor symptoms differ during early perimenopause and late menopausal transition and it is possible that they are caused by a different mechanism.[40]

Long-term effects of menopause may include osteoporosis, vaginal atrophy as well as changed metabolic

profile resulting in cardiac risks.

### Ovarian aging [edit]

Decreased inhibin feedback after hysterectomy is hypothesized to contribute to increased ovarian stimulation and earlier menopause. Hastened ovarian aging has been observed after endometrial ablation. While it is difficult to prove that these surgeries are causative, it has been hypothesized that the endometrium may be producing endocrine factors contributing to the endocrine feedback and regulation of the ovarian stimulation. Elimination of this factors contributes to faster depletion of the ovarian reserve. Reduced blood supply to the ovaries that may occur as a consequence of hysterectomy and uterine artery embolisation has been hypothesized to contribute to this effect.[42][43]

Impaired DNA repair mechanisms may contribute to earlier depletion of the ovarian reserve during aging.[48] As women age, double-strand breaks accumulate in the DNA of their primordial follicles. Primordial follicles are immature primary oocytes surrounded by a single layer of granulosa cells. An enzyme system is present in oocytes that ordinarily accurately repairs DNA double-strand breaks. This repair system is called "homologous recombinational repair", and it is especially effective during meiosis. Meiosis is the general process by which germ cells are formed in all sexual eukaryotes; it appears to be an adaptation for efficiently removing damages in germ line DNA.[49] (See Meiosis.)

Human primary oocytes are present at an intermediate stage of meiosis, termed prophase I (see Oogenesis). Expression of four key DNA repair genes that are necessary for homologous recombinational repair during meiosis (BRCA1, MRE11, Rad51, and ATM) decline with age in oocytes.[48] This age-related decline in ability to repair DNA double-strand damages can account for the accumulation of these damages, that then likely contributes to the depletion of the ovarian reserve.

## Diagnosis [edit]

One way of assessing the impact on women of some of these menopause effects are the Greene Climacteric Scale questionnaire,[50] the Cervantes Scale[51] and the Menopause Rating Scale.[19]

### Premenopause [edit]

Premenopause is a term used to mean the years leading up to the last period, when the levels of reproductive hormones are becoming more variable and lower, and the effects of hormone withdrawal are present.[37] Premenopause starts some time before the monthly cycles become noticeably irregular in timing.[52]

### Perimenopause [edit]

The term "perimenopause", which literally means "around the menopause", refers to the menopause transition years, a time before *and* after the date of the final episode of flow. According to the North American Menopause Society, this transition can last for four to eight years.[53] The Centre for Menstrual Cycle and Ovulation Research describes it as a six- to ten-year phase ending 12 months after the last menstrual period.[54]

During perimenopause, estrogen levels average about 20–30% higher than during premenopause, often with wide fluctuations.[54] These fluctuations cause many of the physical changes during perimenopause as well as menopause.[55] Some of these changes are hot flashes, night sweats, difficulty sleeping, vaginal dryness or atrophy, incontinence, osteoporosis, and heart disease.[54] During this period, fertility diminishes but is not considered to reach zero until the official date of menopause. The official date is determined retroactively, once 12 months have passed after the last appearance of menstrual blood.

The menopause transition typically begins between 40 and 50 years of age (average 47.5).[56][57] The duration of perimenopause may be for up to eight years.[57] Women will often, but not always, start these [58]

transitions (perimenopause and menopause) about the same time as their mother did.

In some women, menopause may bring about a sense of loss related to the end of fertility. In addition, this change often occurs when other stressors may be present in a woman's life:

- Caring for, and/or the death of, elderly parents
- Empty nest syndrome when children leave home
- The birth of grandchildren, which places people of "middle age" into a new category of "older people" (especially in cultures where being older is a state that is looked down on)

Some research appears to show that melatonin supplementation in perimenopausal women can improve thyroid function and gonadotropin levels, as well as restoring fertility and menstruation and preventing depression associated with menopause.[59]

### Postmenopause [edit]

The term "postmenopausal" describes women who have not experienced any menstrual flow for a minimum of 12 months, assuming that they have a uterus and are not pregnant or lactating.[37] In women without a uterus, menopause or postmenopause can be identified by a blood test showing a very high FSH level. Thus postmenopause the time in a woman's life that take place after her last period or, more accurately, after the point when her ovaries become inactive.

The reason for this delay in declaring postmenopause is because periods are usually erratic at this time of life. Therefore, a reasonably long stretch of time is necessary to be sure that the cycling has ceased. At this point a woman is considered infertile; however, the possibility of becoming pregnant has usually been very low (but not quite zero) for a number of years before this point is reached.

A woman's reproductive hormone levels continue to drop and fluctuate for some time into post-menopause, so hormone withdrawal effects such as hot flashes may take several years to disappear.

Any period-like flow during postmenopause, even spotting, must be reported to a doctor. The cause may be minor, but the possibility of endometrial cancer must be checked for.

## Management [edit]

Perimenopause is a natural stage of life. It is not a disease or a disorder. Therefore, it does not automatically require any kind of medical treatment. However, in those cases where the physical, mental, and emotional effects of perimenopause are strong enough that they significantly disrupt the life of the woman experiencing them, palliative medical therapy may sometimes be appropriate.

### Hormone replacement therapy [edit]

*Main article: Hormone replacement therapy (menopause)*

In the context of the menopause, hormone replacement therapy (HRT) is the use of estrogen in women without a uterus and estrogen plus progestin in women who have an intact uterus.[60]

HRT may be reasonable for the treatment of menopausal symptoms, such as hot flashes and osteoporosis.[61] Its use appears to increase the risk of strokes and blood clots.[62] When used for menopausal symptoms it should be used for the shortest time possible and at the lowest dose possible.[62] The response to HRT in each postmenopausal woman may not be the same. Genetic polymorphism in estrogen receptors appears to be associated with inter-individual variability in metabolic response to HRT in postmenopausal women.[63]

It also appears effective for preventing bone loss and osteoporotic fracture.[64] It is often seen as a second line agent for this purpose.[65] There is some concern that this treatment increases the risk of breast cancer.[66]

Adding testosterone to hormone therapy has a positive effect on sexual function in postmenopausal women, although it may be accompanied by hair growth, acne and a reduction in high-density lipoprotein (HDL)

cholesterol.[67] These side effects diverge depending on the doses and methods of using testosterone.[67]

### Selective estrogen receptor modulators [edit]

SERMs are a category of drugs, either synthetically produced or derived from a botanical source, that act selectively as agonists or antagonists on the estrogen receptors throughout the body. The most commonly prescribed SERMs are raloxifene and tamoxifen. Raloxifene exhibits oestrogen agonist activity on bone and lipids, and antagonist activity on breast and the endometrium.[68] Tamoxifen is in widespread use for treatment of hormone sensitive breast cancer. Raloxifene prevents vertebral fractures in postmenopausal, osteoporotic women and reduces the risk of invasive breast cancer.[69]

### Other medication [edit]

Some of the SSRIs and SNRIs appear to provide some relief.[14] Low dose paroxetine has been FDA-approved for hot moderate-to-severe vasomotor symptoms associated with menopause.[70] They may, however, be associated with sleeping problems.[14]

Gabapentin or clonidine may help but does not work as well as hormone therapy.[14] Clonidine may be associated with constipation and sleeping problems.[14]

### Alternative medicine [edit]

There is no evidence of consistent benefit of alternative therapies for menopausal symptoms despite their popularity.[71] The effect of soy isoflavones on menopausal symptoms is promising for reduction of hot flashes and vaginal dryness.[15][72] Evidence does not support a benefit from phytoestrogens such as coumestrol,[73] femarelle,[74] or black cohosh.[15][75] There is no evidence to support the efficacy of acupuncture as a management for menopausal symptoms.[76] As of 2011 there is no support for herbal or dietary supplements in the prevention or treatment of the mental changes that occur around menopause.[77] A 2016 Cochrane review found not enough evidence to show a difference between Chinese herbal medicine and placebo for the vasomotor symptoms.[78]

### Other therapies [edit]

- Lack of lubrication is a common problem during and after perimenopause. Vaginal moisturizers can help women with overall dryness, and lubricants can help with lubrication difficulties that may be present during intercourse. It is worth pointing out that moisturizers and lubricants are different products for different issues: some women complain that their genitalia are uncomfortably dry all the time, and they may do better with moisturizers. Those who need only lubricants do well using them only during intercourse.
- Low-dose prescription vaginal estrogen products such as estrogen creams are generally a safe way to use estrogen topically, to help vaginal thinning and dryness problems (see vaginal atrophy) while only minimally increasing the levels of estrogen in the bloodstream.
- In terms of managing hot flashes, lifestyle measures such as drinking cold liquids, staying in cool rooms, using fans, removing excess clothing, and avoiding hot flash triggers such as hot drinks, spicy foods, etc., may partially supplement (or even obviate) the use of medications for some women.
- Individual counseling or support groups can sometimes be helpful to handle sad, depressed, anxious or confused feelings women may be having as they pass through what can be for some a very challenging transition time.
- Osteoporosis can be minimized by smoking cessation, adequate vitamin D intake and regular weight-bearing exercise. The bisphosphate drug alendronate may decrease the risk of a fracture, in women that have both bone loss and a previous fracture and less so for those with just osteoporosis.[79]

## Society and culture [edit]

The cultural context within which a woman lives can have a significant impact on the way she experiences the menopausal transition. Menopause has been described as a subjective experience, with social and cultural factors playing a prominent role in the way menopause is experienced and perceived.

Within the United States, social location affects the way women perceive menopause and its related biological effects. Research indicates that whether a woman views menopause as a medical issue or an expected life change is correlated with her socio-economic status.[80] The paradigm within which a woman considers menopause influences the way she views it: Women who understand menopause as a medical condition rate it significantly more negatively than those who view it as a life transition or a symbol of aging.[81]

Ethnicity and geography play roles in the experience of menopause. American women of different ethnicities report significantly different types of menopausal effects. One major study found Caucasian women most likely to report what are sometimes described as psychosomatic symptoms, while African-American women were more likely to report vasomotor symptoms.[82]

It seems that Japanese women experience menopause effects, or *konenki*, in a different way from American women.[83] Japanese women report lower rates of hot flashes and night sweats; this can be attributed to a variety of factors, both biological and social. Historically, konenki was associated with wealthy middle-class housewives in Japan, i.e., it was a "luxury disease" that women from traditional, inter-generational rural households did not report. Menopause in Japan was viewed as a symptom of the inevitable process of aging, rather than a "revolutionary transition", or a "deficiency disease" in need of management.[83]

In Japanese culture, reporting of vasomotor symptoms has been on the increase, with research conducted by Melissa Melby in 2005 finding that of 140 Japanese participants, hot flashes were prevalent in 22.1%.[84] This was almost double that of 20 years prior.[85] Whilst the exact cause for this is unknown, possible contributing factors include significant dietary changes, increased medicalisation of middle-aged women and increased media attention on the subject.[85] However, reporting of vasomotor symptoms is still significantly lower than North America.[86]

Additionally, while most women in the United States apparently have a negative view of menopause as a time of deterioration or decline, some studies seem to indicate that women from some Asian cultures have an understanding of menopause that focuses on a sense of liberation and celebrates the freedom from the risk of pregnancy.[87] Postmenopausal Indian women can enter Hindu temples and participate in rituals, marking it as a celebration for reaching an age of wisdom and experience.

Diverging from these conclusions, one study appeared to show that many American women "experience this time as one of liberation and self-actualization".[88]

Generally speaking, women raised in the Western world or developed countries in Asia live long enough so that a third of their life is spent in post-menopause. For some women, the menopausal transition represents a major life change, similar to menarche in the magnitude of its social and psychological significance. Although the significance of the changes that surround menarche is fairly well recognized, in countries such as the United States, the social and psychological ramifications of the menopause transition are frequently ignored or underestimated.[*citation needed*]

## Medicalization [edit]

The medicalization of menopause within biomedical practice began in the early 19th century and has affected the way menopause is viewed within society. By the 1930s in North America and Europe, biomedicine practitioners began to think of menopause as a disease-like state. This idea coincided with the concept of the "standardization of the body". The bodies of young premenopausal women began to be considered the "normal", against which all female bodies were compared.[89]

## Etymology [edit]

Menopause literally means the "end of monthly cycles" (the end of monthly periods or menstruation), from

the Greek word *pausis* ("pause") and *mēn* ("month"). This is a medical calque; the Greek word for menses is actually different. In Ancient Greek, the menses were described in the plural, *ta emmēnia*, ("the monthlies"), and its modern descendant has been clipped to *ta emmēna*. The Modern Greek medical term is *emmenopausis* in Katharevousa or *emmenopausi* in Demotic Greek.

The word "menopause" was coined specifically for human females, where the end of fertility is traditionally indicated by the permanent stopping of monthly menstruations. However, menopause exists in some other animals, many of which do not have monthly menstruation;[90] in this case, the term means a natural end to fertility that occurs before the end of the natural lifespan.

## Evolutionary rationale [edit]

Various theories have been suggested that attempt to suggest evolutionary benefits to the human species stemming from the cessation of women's reproductive capability before the end of their natural lifespan. Explanations can be categorized as adaptive and non-adaptive:

### Non-adaptive hypotheses [edit]

The high cost of female investment in offspring may lead to physiological deteriorations that amplify susceptibility to becoming infertile. This hypothesis suggests the reproductive lifespan in humans has been optimized, but it has proven more difficult in females and thus their reproductive span is shorter. If this hypothesis were true, however, age at menopause should be negatively correlated with reproductive effort[91] and the available data does not support this.[92]

A recent increase in female longevity due to improvements in the standard of living and social care has also been suggested.[93] It is difficult for selection, however, to favour aid to offspring from parents and grandparents.[94] Irrespective of living standards, adaptive responses are limited by physiological mechanisms. In other words, senescence is programmed and regulated by specific genes.[95]

### Adaptive hypotheses [edit]

#### "Survival of the fittest" hypothesis [edit]

This hypothesis suggests that younger mothers and offspring under their care will fare better in a difficult and predatory environment because a younger mother will be stronger and more agile in providing protection and sustenance for herself and a nursing baby. The various biological factors associated with menopause had the effect of male members of the species investing their effort with the most viable of potential female mates.[96][*page needed*] One problem with this hypothesis is that we would expect to see menopause exhibited in the animal kingdom.[90]

#### Mother hypothesis [edit]

The mother hypothesis suggests that menopause was selected for humans because of the extended development period of human offspring and high costs of reproduction so that mothers gain an advantage in reproductive fitness by redirecting their effort from new offspring with a low survival chance to existing children with a higher survival chance.[97]

#### Grandmother hypothesis [edit]

The Grandmother hypothesis suggests that menopause was selected for humans because it promotes the survival of grandchildren. According to this hypothesis, post-reproductive women feed and care for children, adult nursing daughters, and grandchildren whose mothers have weaned them. Human babies require large and steady supplies of glucose to feed the growing brain. In infants in the first year of life, the brain consumes 60% of all calories, so both babies and their mothers require a dependable food supply. Some evidence suggests that hunters contribute less than half the total food budget of most hunter-gatherer

societies, and often much less than half, so that foraging grandmothers can contribute substantially to the survival of grandchildren at times when mothers and fathers are unable to gather enough food for all of their children. In general, selection operates most powerfully during times of famine or other privation. So although grandmothers might not be necessary during good times, many grandchildren cannot survive without them during times of famine. Arguably, however, there is no firm consensus on the supposed evolutionary advantages (or simply neutrality) of menopause to the survival of the species in the evolutionary past.

Indeed, analysis of historical data found that the length of a female's post-reproductive lifespan was reflected in the reproductive success of her offspring and the survival of her grandchildren.[98] Interestingly, another study found comparative effects but only in the maternal grandmother—paternal grandmothers had a detrimental effect on infant mortality (probably due to paternity uncertainty).[99] Differing assistance strategies for maternal and paternal grandmothers have also been demonstrated. Maternal grandmothers concentrate on offspring survival, whereas paternal grandmothers increase birth rates.[100]

Some believe a problem concerning the grandmother hypothesis is that it requires a history of female philopatry while in the present day the majority of hunter-gatherer societies are patriarchal.[101] However, there is disagreement split along ideological lines about whether patrilineality would have existed before modern times.[102] Some believe variations on the mother, or grandmother effect fail to explain longevity with continued spermatogenesis in males (oldest verified paternity is 94 years, 35 years beyond the oldest documented birth attributed to females).[103] Notably, the survival time past menopause is roughly the same as the maturation time for a human child. That a mother's presence could aid in the survival of a developing child, while an unidentified father's absence might not have affected survival, could explain the paternal fertility near the end of the father's lifespan.[104] A man with no certainty of which children are his may merely attempt to father additional children, with support of existing children present but small. Note the existence of partible paternity supporting this.[105] Some argue that the mother and grandmother hypotheses fail to explain the detrimental effects of losing ovarian follicular activity, such as osteoporosis, osteoarthritis, Alzheimer's disease and coronary artery disease.[106]

The theories discussed above assume that evolution directly selected for menopause. Another theory states that menopause is the byproduct of the evolutionary selection for follicular atresia, a factor that causes menopause. Menopause results from having too few ovarian follicles to produce enough estrogen to maintain the ovarian-pituitary-hypothalamic loop, which results in the cessation of menses and the beginning of menopause. Human females are born with approximately a million oocytes, and approximately 400 oocytes are lost to ovulation throughout life.[107][108]

## Other animals [edit]

Menopause in the animal kingdom appears to be uncommon, but the presence of this phenomenon in different species has not been thoroughly researched. Life histories show a varying degree of senescence; rapid senescing organisms (e.g., Pacific salmon and annual plants) do not have a post-reproductive life-stage. Gradual senescence is exhibited by all placental mammalian life histories.

Menopause has been observed in several species of nonhuman primates,[90] including rhesus monkeys,[109] and chimpanzees.[110] Menopause also has been reported in a variety of other vertebrate species including elephants,[111] short-finned pilot whales,[112] killer whales,[113] and other cetaceans,[114][115] the guppy,[116] the platyfish, the budgerigar, the laboratory rat and mouse, and the opossum. However, with the exception of the short-finned pilot whale, such examples tend to be from captive individuals, and thus they are not necessarily representative of what happens in natural populations in the wild.

Dogs do not experience menopause; the canine estrus cycle simply becomes irregular and infrequent. Although older female dogs are not considered good candidates for breeding, offspring have been produced by older animals.[117] Similar observations have been made in cats.[118]

*This article is about humans. For other mammals, see Menstruation (mammals).*

**Menstruation**, also known as a **period** or **monthly**,[1] is the regular discharge of blood and mucosal tissue from the inner lining of the uterus through the vagina.[2] The first period usually begins between twelve and fifteen years of age, a point in time known as menarche.[1] However, periods may occasionally start as young as eight years old and still be considered normal.[2] The average age of the first period is generally later in the developing world, and earlier in the developed world. The typical length of time between the first day of one period and the first day of the next is 21 to 45 days in young women, and 21 to 31 days in adults (an average of 28 days).[2][3] Bleeding usually lasts around 2 to 7 days.[2] Menstruation stops occurring after menopause, which usually occurs between 45 and 55 years of age.[4] Periods also stop during pregnancy and typically do not resume during the initial months of breastfeeding.[2]

Up to 80% of women report having some symptoms prior to menstruation.[5] Common signs and symptoms include acne, tender breasts, bloating, feeling tired, irritability, and mood changes.[6] These may interfere with normal life, therefore qualifying as premenstrual syndrome, in 20 to 30% of women. In 3 to 8%, symptoms are severe.[5]

A lack of periods, known as amenorrhea, is when periods do not occur by age 15 or have not occurred in 90 days. Other problems with the menstrual cycle include painful periods and abnormal bleeding such as bleeding between periods or heavy bleeding.[2] Menstruation in other animals occurs in primates, such as apes and monkeys, as well as bats and the elephant shrew.[7][8]

The menstrual cycle occurs due to the rise and fall of hormones. This cycle results in the thickening of the lining of the uterus, and the growth of an egg, (which is required for pregnancy). The egg is released from an ovary around day fourteen in the cycle; the thickened lining of the uterus provides nutrients to an embryo after implantation. If pregnancy does not occur, the lining is released in what is known as menstruation.[2]

## Variants

## Onset and frequency

The first menstrual period occurs after the onset of pubertal growth, and is called menarche. The average age of menarche is 12 to 15.[1][9] However, it may start as early as eight.[2] The average age of the first period is generally later in the developing world, and earlier in the developed world.[3] The average age of menarche has changed little in the United States since the 1950s.[3]

Diagram illustrating how the uterus lining builds up and breaks down during the menstrual cycle.

Menstruation is the most visible phase of the menstrual cycle and its beginning is used as the marker between cycles. The first day of menstrual bleeding is the date used for the last menstrual period (LMP). The typical length of time between the first day of one period and the first day of the next is 21 to 45 days in young women, and 21 to 31 days in adults (an average of 28 days).[2][3]

Perimenopause is when fertility in a female declines, and menstruation occurs less regularly in the years leading up to the final menstrual period, when a female stops menstruating completely and is no longer fertile. The medical definition of menopause is one year without a period and typically occurs between 45 and 55 in Western countries.[4][10]:p. 381

During pregnancy and for some time after childbirth, menstruation does not occur; this state is known as amenorrhoea. If menstruation has not resumed, fertility is low during lactation. The average length of postpartum amenorrhoea is longer when certain breastfeeding practices are followed; this may be done intentionally as birth control.

## Health effects

*Further information: Premenstrual syndrome*

In most women, various physical changes are brought about by fluctuations in hormone levels during the

menstrual cycle. This includes muscle contractions of the uterus (menstrual cramping) that can precede or accompany menstruation. Some may notice water retention, changes in sex drive, fatigue, breast tenderness, or nausea. Breast swelling and discomfort may be caused by water retention during menstruation.[11] Usually, such sensations are mild, and some females notice very few physical changes associated with menstruation. A healthy diet, reduced consumption of salt, caffeine and alcohol, and regular exercise may be effective for women in controlling some symptoms.[12] Severe symptoms that disrupt daily activities and functioning may be diagnosed as premenstrual dysphoric disorder. Symptoms before menstruation are known as premenstrual molimina.

## Cramps

*Further information: Dysmenorrhea*

Many women experience painful cramps, also known as dysmenorrhea, during menstruation.[*citation needed*] Pain results from ischemia and muscle contractions. Spiral arteries in the secretory endometrium constrict, resulting in ischemia to the secretory endometrium. This allows the uterine lining to slough off. The myometrium contracts spasmodically in order to push the menstrual fluid through the cervix and out of the vagina. The contractions are mediated by a release of prostaglandins.

Painful menstrual cramps that result from an excess of prostaglandin release are referred to as primary dysmenorrhea. Primary dysmenorrhea usually begins within a year or two of menarche, typically with the onset of ovulatory cycles.[13] Treatments that target the mechanism of pain include non-steroidal anti-inflammatory drugs (NSAIDs) and hormonal contraceptives. NSAIDs inhibit prostaglandin production. With long-term treatment, hormonal birth control reduces the amount of uterine fluid/tissue expelled from the uterus. Thus resulting in shorter, less painful menstruation.[14] These drugs are typically more effective than treatments that do not target the source of the pain (e.g. acetaminophen).[15][*needs update*] Risk factors for primary dysmenorrhea include: early age at menarche, long or heavy menstrual periods, smoking, and a family history of dysmenorrhea.[13] Regular physical activity may limit the severity of uterine cramps.[13]

For many women, primary dysmenorrhea gradually subsides in late second generation. Pregnancy has also been demonstrated to lessen the severity of dysmenorrhea, when menstruation resumes. However, dysmenorrhea can continue until menopause. 5–15% of women with dysmenorrhea experience symptoms severe enough to interfere with daily activities.[13]

Secondary dysmenorrhea is the diagnosis given when menstruation pain is a secondary cause to another disorder. Conditions causing secondary dysmenorrhea include endometriosis, uterine fibroids, and uterine adenomyosis. Rarely, congenital malformations, intrauterine devices, certain cancers, and pelvic infections cause secondary dysmenorrhea.[13] Symptoms include pain spreading to hips, lower back and thighs, nausea, and frequent diarrhea or constipation.[16] If the pain occurs between menstrual periods, lasts longer than the first few days of the period, or is not adequately relieved by the use of non-steroidal anti-inflammatory drugs (NSAIDs) or hormonal contraceptives, women should be evaluated for secondary causes of dysmenorrhea.[10]:p. 379

When severe pelvic pain and bleeding suddenly occur or worsen during a cycle, the woman or girl should be evaluated for ectopic pregnancy and spontaneous abortion. This evaluation begins with a pregnancy test and should be done as soon as unusual pain begins, because ectopic pregnancies can be life threatening.[17]

In some cases, stronger physical and emotional or psychological sensations may interfere with normal activities, and include menstrual pain (dysmenorrhea), migraine headaches, and depression. Dysmenorrhea, or severe uterine pain, is particularly common for young females (one study found that 67.2% of girls aged 13–19 have it).[18]

The medications in the non-steroidal anti-inflammatory drugs (NSAIDs) class are commonly used to relieve menstrual cramps. Some herbs are also claimed to help.

## Mood and behavior

Some women experience emotional disturbances starting one or two weeks before their period, and stopping soon after the period has started.[6] Symptoms may include mental tension, irritability, mood swings, and crying spells. Problems with concentration and memory may occur.[6] There may also be depression or anxiety.[6]

This is part of premenstrual syndrome (PMS) and is estimated to occur in 20 to 30% of women. In 3 to 8% it is severe.[5]

More severe symptoms of anxiety or depression may be signs of premenstrual dysphoric disorder (PMDD). Rarely, in individuals who are susceptible, menstruation may be a trigger for menstrual psychosis.

## Bleeding

The average volume of menstrual fluid during a monthly menstrual period is 35 milliliters (2.4 tablespoons of menstrual fluid) with 10–80 milliliters (1–6 tablespoons of menstrual fluid) considered typical. Menstrual fluid is the correct name for the flow, although many people prefer to refer to it as menstrual blood. Menstrual fluid contains some blood, as well as cervical mucus, vaginal secretions, and endometrial tissue. Menstrual fluid is reddish-brown, a slightly darker color than venous blood.[10]:p. 381

Unless a woman has a bloodborne illness, menstrual fluid is harmless. No toxins are released in menstrual flow, as this is a lining that must be pure and clean enough to have nurtured a baby. Menstrual fluid is no more dangerous than regular blood.

About half of menstrual fluid is blood. This blood contains sodium, calcium, phosphate, iron, and chloride, the extent of which depends on the woman. As well as blood, the fluid consists of cervical mucus, vaginal secretions, and endometrial tissue. Vaginal fluids in menses mainly contribute water, common electrolytes, organ moieties, and at least 14 proteins, including glycoproteins.[19]

Many mature females notice blood clots during menstruation. These appear as clumps of blood that may look like tissue. If there are questions (for example, was there a miscarriage?), examination under a microscope can confirm if it was endometrial tissue or pregnancy tissue (products of conception) that was shed.[20] Sometimes menstrual clots or shed endometrial tissue is incorrectly thought to indicate an early-term miscarriage of an embryo. An enzyme called plasmin – contained in the endometrium – tends to inhibit the blood from clotting.

The amount of iron lost in menstrual fluid is relatively small for most women.[21] In one study, premenopausal women who exhibited symptoms of iron deficiency were given endoscopies. 86% of them actually had gastrointestinal disease and were at risk of being misdiagnosed simply because they were menstruating.[22] Heavy menstrual bleeding, occurring monthly, can result in anemia.

## Menstrual disorders

There is a wide spectrum of differences in how women experience menstruation. There are several ways that someone's menstrual cycle can differ from the norm, any of which should be discussed with a doctor to identify the underlying cause:

| Symptom | See article |
|---|---|
| Infrequent periods | Oligomenorrhea |
| Short or extremely light periods | Hypomenorrhea |
| Too-frequent periods (defined as more frequently than every 21 days) | Polymenorrhea |
| Extremely heavy or long periods (one guideline is soaking a sanitary napkin or tampon every hour or so, or menstruating for longer than 7 days) | Hypermenorrhea |
| Extremely painful periods | Dysmenorrhea |
| Breakthrough bleeding (also called spotting) between periods; normal in many females | Metrorrhagia |
| Absent periods | Amenorrhea |

There is a movement among gynecologists to discard the terms noted above, which although they are widely used, do not have precise definitions. Many now argue to describe menstruation in simple terminology, including:

- Cycle regularity (irregular, regular, or absent)
- Frequency of menstruation (frequent, normal, or infrequent)
- Duration of menstrual flow (prolonged, normal, or shortened)
- Volume of menstrual flow (heavy, normal, or light)[23]

Dysfunctional uterine bleeding is a hormonally caused bleeding abnormality. Dysfunctional uterine bleeding typically occurs in premenopausal women who do not ovulate normally (i.e. are anovulatory). All these bleeding abnormalities need medical attention; they may indicate hormone imbalances, uterine fibroids, or other problems. As pregnant women may bleed, a pregnancy test forms part of the evaluation of abnormal bleeding.

Women who had undergone female genital mutilation (particularly type III- infibulation) a practice common in parts of Africa, may experience menstrual problems, such as slow and painful menstruation, that is caused by the near-complete sealing off of the vagina.[24]

Premature or delayed menarche should be investigated if menarche begins before 9 years, if menarche has not begun by age 15, if there is no breast development by age 13, or if there is no period by 3 years after the onset of breast development.[3]

## Birth control

*Main article: Hormonal contraception*

Half-used blister pack of a combined oral contraceptive. The white pills are placebos, mainly for the purpose of reminding the woman to continue taking the pills.

Since the late 1960s, many women have chosen to control the frequency of menstruation with hormonal birth control pills. They are most often combined hormone pills containing estrogen and are taken in 28-day cycles, 21 hormonal pills with either a 7-day break from pills, or 7 placebo pills during which the woman menstruates. Hormonal birth control acts by using low doses of hormones to prevent ovulation, and thus prevent pregnancy in sexually active women. But by using placebo pills for a 7-day span during the month, a regular bleeding period is still experienced.

Injections such as depo-provera became available in the 1960s. Progestogen implants such as Norplant in the 1980s and extended cycle combined oral contraceptive pills in the early 2000s.

Using synthetic hormones, it is possible for a woman to completely eliminate menstrual periods.[25] When using progestogen implants, menstruation may be reduced to 3 or 4 menstrual periods per year. By taking progestogen-only contraceptive pills (sometimes called the 'mini-pill') continuously without a 7-day span of using placebo pills, menstrual periods do not occur. Some women do this simply for convenience in the short-term,[26] while others prefer to eliminate periods altogether when possible.

Some women use hormonal contraception in this way to eliminate their periods for months or years at a time, a practice called menstrual suppression. When the first birth control pill was being developed, the researchers were aware that they could use the contraceptive to space menstrual periods up to 90 days apart, but they settled on a 28-day cycle that would mimic a natural menstrual cycle and produce monthly periods. The intention behind this decision was the hope of the inventor, John Rock, to win approval for his invention from the Roman Catholic Church. That attempt failed, but the 28-day cycle remained the standard when the pill became available to the public.[27] There is debate among medical researchers about the

potential long-term impacts of these practices upon female health. Some researchers point to the fact that historically, females have had far fewer menstrual periods throughout their lifetimes, a result of shorter life expectancies, as well as a greater length of time spent pregnant or breast-feeding, which reduced the number of periods experienced by females.[28] These researchers believe that the higher number of menstrual periods by females in modern societies may have a negative impact upon their health. On the other hand, some researchers believe there is a greater potential for negative impacts from exposing females perhaps unnecessarily to regular low doses of synthetic hormones over their reproductive years.[29]

### Breastfeeding

*Main article: Lactational amenorrhea method*

Breastfeeding causes negative feedback to occur on pulse secretion of gonadotropin-releasing hormone (GnRH) and luteinizing hormone (LH). Depending on the strength of the negative feedback, breastfeeding women may experience complete suppression of follicular development, follicular development but no ovulation, or normal menstrual cycles may resume.[30] Suppression of ovulation is more likely when suckling occurs more frequently.[31] The production of prolactin in response to suckling is important to maintaining lactational amenorrhea.[32] On average, women who are fully breastfeeding whose infants suckle frequently experience a return of menstruation at fourteen and a half months postpartum. There is a wide range of response among individual breastfeeding women, however, with some experiencing return of menstruation at two months and others remaining amenorrheic for up to 42 months postpartum.[33]

## Menstrual management

*Further information: Menstrual hygiene day*

Menstruation is managed by menstruating women to avoid damage to clothing or to accord with norms of public life. Menstrual management practices range from medical suppression of menstruation, through wearing special garments or other items, washing or avoidance of washing, disposal and laundry of stained materials, to separation of menstruators to particular places or activities.

Menstrual products (also called "feminine hygiene" products) are made to absorb or catch menstrual blood. A number of different products are available - some are disposable, some are reusable. Where women can afford it, items used to absorb or catch menses are usually commercially manufactured products. In developing countries, many women may not afford these products and use materials found in the environment or other improvised materials.

### Disposable items

- Sanitary napkins (Sanitary towels) or pads – Somewhat rectangular pieces of material worn in the underwear to absorb menstrual flow, often with "wings", pieces that fold around the undergarment and/or an adhesive backing to hold the pad in place. Disposable pads may contain wood pulp or gel products, usually with a plastic lining and bleached. Some sanitary napkins, particularly older styles, are held in place by a belt-like apparatus, instead of adhesive or wings.
- Tampons – Disposable cylinders of treated rayon/cotton blends or all-cotton fleece, usually bleached, that are inserted into the vagina to absorb menstrual flow.
- Padettes – Disposable wads of treated rayon/cotton blend fleece that are placed within the inner labia to absorb menstrual flow.
- Disposable menstrual cups – A firm, flexible cup-shaped device worn

inside the vagina to catch menstrual flow. Disposable cups are made of soft plastic.

## Reusable items

- Reusable cloth pads – Pads that are made of cotton (often organic), terrycloth, or flannel, and may be handsewn (from material or reused old clothes and towels) or storebought.
- Menstrual cups – A firm, flexible bell-shaped device worn inside the vagina for about half a day or overnight to catch menstrual flow. They are emptied into the toilet or sink when full, washed and re-inserted (washing hands with soap before doing so is crucial). Menstrual cups are usually made of silicone and can last 5 years or longer. At the end of the period, they are sterilised, usually by boiling in water.
- Sea sponges – Natural sponges, worn internally like a tampon to absorb menstrual flow.
- Padded panties – Reusable cloth (usually cotton) underwear with extra absorbent layers sewn in to absorb flow.
- Blanket, towel – (also known as a draw sheet) – large reusable piece of cloth, most often used at night, placed between legs to absorb menstrual flow.

## Non-commercial materials

Absorption materials that may be used by women who cannot afford anything else include: sand, ash, small hole in earth,[34] cloth - new or re-used, whole leaf, leaf fibre (such as water hyacinth, banana, papyrus, cotton fibre), paper (toilet paper, re-used newspaper, pulped and dried paper),[35] animal pelt e.g. goat skin,[34] double layer of underwear, skirt or sari.[36]

## Traditions and taboos

*Main article: Culture and menstruation*
*Further information: Menstrual taboo*

Amra Padatik India, celebration of Menstrual Hygiene Day in India

Many religions have menstruation-related traditions, for example the laws of Niddah in Judaism. These may ban certain actions during menstruation (such as sexual intercourse in some movements of Judaism and Islam), or rituals performed at the end of each menses (such as the *mikvah* in Judaism and the *ghusl* in Islam). Some traditional societies sequester women in residences called "menstrual huts" that are reserved for that exclusive purpose.

In Hinduism, it is also frowned upon to go to a temple and do *pooja* (i.e., pray) or do *pooja* at religious events if you are menstruating. Saraswati, the Hindu goddess of knowledge, is associated with menstruation; the literal translation of her name is "flow – woman". Metaformic Theory, as proposed by cultural theorist Judy Grahn and others, places menstruation as a central organizing idea in the creation of

culture[*citation needed*] and the formation of humans' earliest rituals.

Although most Christian denominations do not follow any specific or prescribed rites for menstruation, the Western civilization, which has been predominantly Christian, has a history of menstrual taboos, with menstruating women having been believed to be dangerous.[37][38]

Anthropologists, Lock and Nguyen (2010), have noted that the heavy medicalization of the reproductive life-stages of women in the West, mimic power structures that are deemed, in other cultural practices, to function as a form of "social control".[39] Medicalization of the stages of women's lives, such as birth and menstruation, has enlivened a feminist perspective that investigates the social implications of biomedicine's practice. "[C]ultural analysis of reproduction…attempts to show how women…exhibit resistance and create dominant alternative meanings about the body and reproduction to those dominant among the medical profession."[39]

In some parts of South Asia, women are isolated during menstruation. In 2005, in Nepal, the Supreme Court abolished the practice of chhaupadi, keeping women in cow-sheds during menstruation.[40]

### Sexual activity

Sexual intercourse during menstruation does not cause damage in and of itself, but the woman's body is more vulnerable during this time. Vaginal pH is higher and less acidic than normal,[41] the cervix is lower in its position, the cervical opening is more dilated, and the uterine endometrial lining is absent, thus allowing organisms direct access to the blood stream through the numerous blood vessels that nourish the uterus. All these conditions increase the chance of infection during menstruation.[*citation needed*]

### Other aspects

Male menstruation is a term used colloquially for a type of bleeding in the urine or faeces of males, reported in some tropical countries. It is actually caused by parasite infestation of the urinary tract or intestines by Schistosoma haematobium, and cases of it are actually schistosomiasis, formerly known as bilharziasis.

## Evolution

All female placental mammals have a uterine lining that builds up when the animal is fertile, but it is dismantled when the animal is infertile. Most female mammals have an estrous cycle, yet only primates (including humans), several species of bats, and elephant shrews have a menstrual cycle.[42] Some anthropologists have questioned the energy cost of rebuilding the endometrium every fertility cycle. However, anthropologist Beverly Strassmann has proposed that the energy savings of not having to *continuously* maintain the uterine lining more than offsets energy cost of having to rebuild the lining in the next fertility cycle, even in species such as humans where much of the lining is lost through bleeding (overt menstruation) rather than reabsorbed (covert menstruation).[43][44]

Many have questioned the evolution of overt menstruation in humans and related species, speculating on what advantage there could be to losing blood associated with dismantling the endometrium, rather than absorbing it, as most mammals do. Humans do, in fact, reabsorb about two-thirds of the endometrium each cycle. Strassmann asserts that overt menstruation occurs not because it is beneficial in itself. Rather, the fetal development of these species requires a more developed endometrium, one which is too thick to reabsorb completely. Strassman correlates species that have overt menstruation to those that have a large uterus relative to the adult female body size.[43]

Beginning in 1971, some research suggested that menstrual cycles of cohabiting human females became synchronized. A few anthropologists hypothesized that in hunter-gatherer societies, males would go on hunting journeys whilst the females of the tribe were menstruating, speculating that the females would not have been as receptive to sexual relations while menstruating.[45][46] However, there is currently significant dispute as to whether menstrual synchrony exists.[47]

# Morning sickness

From Wikipedia, the free encyclopedia

**Morning sickness**, also called **nausea and vomiting of pregnancy** (**NVP**), is a symptom of pregnancy that involves nausea or vomiting.[1] Despite the name, nausea or vomiting can occur at any time during the day. Typically these symptoms occur between the 4th and 16th week of pregnancy. About 10% of women still have symptoms after the 20th week of pregnancy.[2] A severe form of the condition is known as hyperemesis gravidarum and results in weight loss.[1][3]

The cause of morning sickness is unknown but may be related to changing levels of the hormone human chorionic gonadotrophin.[2] Some have proposed that it may be useful from an evolutionary point of view.[1] Diagnosis should only occur after other possible causes have been ruled out.[4] Abdominal pain, fever, or headaches are typically not present in morning sickness.[1]

Taking prenatal vitamins before pregnancy may decrease the risk.[4] Specific treatment other than a bland diet may not be required for mild cases.[2][3][4] If treatment is used the combination of doxylamine and pyridoxine is recommended initially.[4][5] Tentative evidence supports the use of ginger.[4][6] For severe cases that have not improved with other measures methylprednisolone may be tried. Tube feeding may be required in women who are losing weight.[4]

Morning sickness affects about 70-80% of all pregnant women to some extent.[5][7] About 60% of women have vomiting.[2] Hyperemesis gravidarum occurs in about 1.6% of pregnancies.[1] Morning sickness can negatively affect quality of life, result in decreased ability to work while pregnant, and result in health care expenses.[4] Generally mild to moderate cases have no effect on the baby. Most severe cases also have normal outcomes. Some women choose to have an abortion due to the severity of symptoms. Complications such as Wernicke encephalopathy or esophageal rupture may occur but are very rare.[1]

## Signs and symptoms [edit]

About 66% of women have both nausea and vomiting while 33% have just nausea.[1]

## Cause [edit]

The cause of morning sickness is unknown.[1] While some have claimed it to be due to psychological reasons, this is not supported by evidence.[1]

Nausea and vomiting may also occur with molar pregnancy.[8]

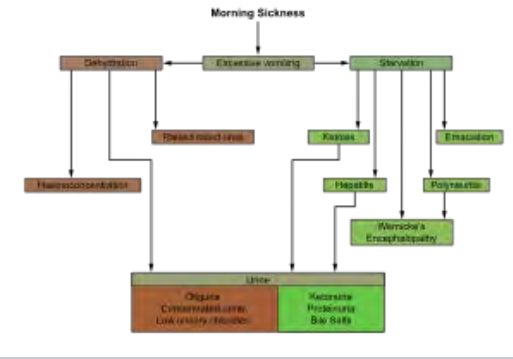
# Pathophysiology [edit]

## Hormone changes [edit]

- An increase in the circulating level of the hormone estrogen.[9] However, there is no consistent evidence of differences in estrogen levels and levels of bilirubin between women that experience sickness and those that do not.[10] Related to increased estrogen levels, a similar form of nausea is also seen in some women who use hormonal contraception or hormone replacement therapy.
- An increase in progesterone relaxes the muscles in the uterus, which prevents early childbirth, but may also relax the stomach and intestines, leading to excess stomach acids and gastroesophageal reflux disease (GERD).
- An increase in human chorionic gonadotropin. It is probably not the human chorionic gonadotropin itself that causes the nausea. More likely, it is the human chorionic gonadotropin stimulating the maternal ovaries to secrete estrogen, which in turn causes the nausea.[11]



Pathophysiology of vomiting in pregnancy

## Defense mechanism [edit]

Morning sickness may be an evolved trait that protects the baby against toxins ingested by the mother. Evidence in support of this theory, including:[12][13]

- Morning sickness is very common among pregnant women, which argues in favor of its being a functional adaptation and against the idea that it is a pathology.
- Fetal vulnerability to toxins peaks at around 3 months, which is also the time of peak susceptibility to morning sickness.
- There is a good correlation between toxin concentrations in foods, and the tastes and odors that cause revulsion.

Women who have *no* morning sickness are more likely to miscarry.[14] This may be because such women are more likely to ingest substances that are harmful to the fetus.[15]

In addition to protecting the fetus, morning sickness may also protect the mother. A pregnant woman's immune system is suppressed during pregnancy, presumably to reduce the chances of rejecting tissues of her own offspring.[16] Because of this, animal products containing parasites and harmful bacteria can be especially dangerous to pregnant women. There is evidence that morning sickness is often triggered by animal products including meat and fish.[17]

If morning sickness is a defense mechanism against the ingestion of toxins, the prescribing of anti-nausea medication to pregnant women may have the undesired side effect of causing birth defects or miscarriages by encouraging harmful dietary choices.[12]

# Treatments [edit]

There is unclear evidence about the effectiveness of home treatments for morning sickness.[18][*needs update*]

## Medications [edit]

A number of antiemetics are effective and safe in pregnancy including: pyridoxine/doxylamine, antihistamines (such as diphenhydramine), metoclopramide, and phenothiazines (such as promethazine).[19][20] With respect to effectiveness it is unknown if one is superior to another.[19] In the United States and Canada, the doxylamine-pyridoxine combination (as Diclegis in US and Diclectin in Canada) is the only approved pregnancy category "A" prescription treatment for nausea and vomiting of pregnancy.[20]

Ondansetron may be beneficial, but there are some concerns regarding an association with cleft palate,[21] and there is little high quality data.[19] Metoclopramide is also used and relatively well tolerated.[22] Evidence for the use of corticosteroids is weak.[23]

## Alternative medicine [edit]

There is tentative evidence that ginger may be useful; however, it is not clear.[24][*needs update*][25] Safety concerns have been raised regarding its anticoagulant properties.[26][27]

# History [edit]

## Thalidomide [edit]

Thalidomide was originally developed and prescribed as a cure for morning sickness in West Germany, but its use was discontinued when it was found to cause birth defects. The United States Food and Drug Administration never approved thalidomide for use as a cure for morning sickness.

# Obstructed labour

(Redirected from Obstructed labour)

**Obstructed labour**, also known as **labour dystocia**, is when, even though the uterus is contracting normally, the baby does not exit the pelvis during childbirth due to being physically blocked.[1] Complications for the baby include not getting enough oxygen which may result in death. It increases the risk of the mother getting an infection, having uterine rupture, or having post-partum bleeding.[2] Long term complications for the mother include obstetrical fistula. Obstructed labour is said to result in prolonged labour, when the active phase of labour is longer than twelve hours.[1]

The main causes of obstructed labour include: a large or abnormally positioned baby, a small pelvis, and problems with the birth canal. Abnormal positioning includes shoulder dystocia where the anterior shoulder does not pass easily below the pubic bone.[1] Risk factors for a small pelvis include malnutrition and a lack of exposure to sunlight causing vitamin D deficiency.[3] It is also more common in adolescence as the pelvis may not have finished growing.[2] Problems with the birth canal include a narrow vagina and perineum which may be due to female genital mutilation or tumors.[1] A partograph is often used to track labour progression and diagnose problems.[2] This combined with physical examination may identify obstructed labour.[4]

The treatment of obstructed labour may require cesarean section or vacuum extraction with possible surgical opening of the symphysis pubis. Other measures include: keeping the women hydrated and antibiotics if the membranes have been ruptured for more than 18 hours.[5] In Africa and Asia obstructed labor effects between two and five percent of deliveries.[6] In 2013 about 5.1 cases of obstructed labour occurred.[7] This resulted in 19,000 deaths down from 29,000 deaths in 1990 (about 8% of all deaths related to pregnancy).[1][8] Most deaths due to this condition occur in the developing world.[2]

## Diagnosis [edit]

Obstructed labour may be diagnosed based on physical examination.[4]

## Treatment [edit]

The treatment of obstructed labour may require cesarean section or vacuum extraction with possible surgical opening of the symphysis pubis.[5] Other measures include: keeping the women hydrated and antibiotics if the membranes have been ruptured for more than 18 hours.[5]

## Epidemiology [edit]

In 2013 it resulted in 19,000 deaths down from 29,000 deaths in 1990.[8]

## Etymology [edit]

The word dystocia means difficult labour.[2] Its antonym is eutocia (Ancient Greek: τόκος *tókos* "childbirth") or easy labour.

Other terms for obstructed labour include: difficult labour, abnormal labour, difficult childbirth, abnormal childbirth, and dysfunctional labour.

## Other animals [edit]

The term can also be used in the context of various animals. Dystocia pertaining to birds and reptiles is also called egg binding.

# Ovarian cyst

From Wikipedia, the free encyclopedia

An **ovarian cyst** is a fluid-filled sac within the ovary. Often they cause no symptoms. Occasionally they may produce bloating, lower abdominal pain, or lower back pain. If the cyst either breaks open or causes twisting of the ovary severe pain may occur. This may result in vomiting or feeling faint. The majority of cysts are, however, harmless.[1]

Most ovarian cysts are related to ovulation being either follicular cysts or corpus luteum cysts. Other types include cysts due to endometriosis, dermoid cysts, and cystadenomas. Many small cysts occur in both ovaries in polycystic ovarian syndrome. Pelvic inflammatory disease may also result in cysts. Rarely cysts may be a form of ovarian cancer. Diagnosis is undertaken by pelvic examination with an ultrasound or other testing used to gather further details.[1]

Often cysts are simply observed over time. If they cause pain, medications such as paracetamol (acetaminophen) or ibuprofen may be used. Hormonal birth control may be used to prevent further cysts in those who are frequently affected.[1] However, evidence does not support birth control as a treatment of current cysts.[2] If they do not go away after several months, get larger, look unusual, or cause pain they may be removed by surgery.[1]

Most women of reproductive age develop small cysts each month. Large cysts that cause problems occur in about 8% of women before menopause.[1] Ovarian cysts are present in about 16% of women after menopause and if present are more likely to be cancer.[1][3]

## Signs and symptoms [edit]

Some or all of the following symptoms may be present, though it is possible not to experience any symptoms:[4]

- Abdominal pain. Dull aching pain within the abdomen or pelvis, especially during intercourse.
- Uterine bleeding. Pain during or shortly after beginning or end of menstrual period; irregular periods, or abnormal uterine bleeding or spotting.
- Fullness, heaviness, pressure, swelling, or bloating in the abdomen.
- When a cyst ruptures from the ovary, there may be sudden and sharp pain in the lower abdomen on one side.
- Change in frequency or ease of urination (such as inability to fully empty the bladder), or difficulty with bowel movements due to pressure on adjacent pelvic anatomy.
- Constitutional symptoms such as fatigue, headaches
- Nausea or vomiting
- Weight gain

Other symptoms may depend on the cause of the cysts:[4]

- Symptoms that may occur if the cause of the cysts is polycystic ovarian syndrome (PCOS) may include increased facial hair or body hair, acne, obesity and infertility.
- If the cause is endometriosis, then periods may be heavy, and intercourse painful.

The effect of cysts not related to PCOS on fertility is unclear.[5]

### Cyst rupture [edit]

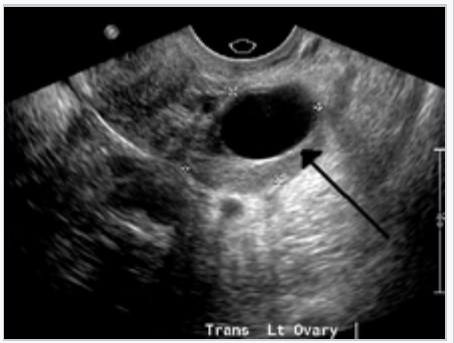
A ruptured ovarian cyst is usually self-limiting, and only requires keeping an eye on the situation and pain medications. The main symptom is abdominal pain, but they can also be asymptomatic. The pain may last from a few days to several weeks.[6] Rupture of large ovarian cysts can cause bleeding inside the abdominal cavity and in some cases shock.

### Ovarian torsion [edit]

Ovarian cysts increase the risk for ovarian torsion, cysts larger than 4 cm are associated with approximately 17% risk. The torsion can cause obstruction of blood flow and lead to infarction.[7]

## Diagnosis [edit]

Ovarian cysts are usually diagnosed by either ultrasound, CT scan or MRI, and correlated with clinical presentation and endocrinologic tests as appropriate.



A 2cm left ovarian cyst as seen on ultrasound

### Ultrasound [edit]

Follow-up imaging in women of reproductive age for incidentally discovered simple cysts on ultrasound is not needed until 5 cm, as these are usually normal ovarian follicles. For simple cysts greater than 5 cm but less than 7 cm in premenopausal females, cysts should be followed yearly. For simple cysts greater than 7 cm, further imaging with MRI or surgical assessment is mandated as, because of their large size, these cysts cannot be reliably assessed by ultrasound alone. The primary

concern for larger cysts is the potential for non-visualization of soft tissue nodularity or thickened septation at their posterior wall due to limited penetrance of the ultrasound beam. For the corpus luteum, a dominant ovulating follicle that typically appears as a cyst with circumferentially thickened walls and crenulated inner margins, follow up is not needed if the cyst is less than 3 cm in diameter. In postmenopausal patients, any simple cyst greater than 1 cm but less than 7 cm needs yearly follow-up, while those greater than 7 cm need MRI or surgical evaluation, similar to reproductive age females.[8]

For incidentally discovered dermoids, diagnosed on ultrasound by their pathognomonic echogenic fat, either surgical removal or yearly follow up is indicated, regardless of patient age. For peritoneal inclusion cysts, which have a crumpled tissue-paper appearance and tend to follow the contour of adjacent organs, follow up is based on clinical history. Hydrosalpinx, or fallopian tube dilation, can be mistaken for an ovarian cyst due to its anechoic appearance. Follow-up for this is also based on clinical presentation.[8]

For multiloculate cysts with thin septation less than 3 mm, surgical evaluation is recommended. The presence of multiloculation suggests a neoplasm, although the thin septation implies that the neoplasm is benign. For any thickened septation, nodularity, or vascular flow on color doppler assessment, surgical removal should be considered due to concern for malignancy.[8]

## Scoring systems [edit]

There are several systems to assess risk of an ovarian cyst of being an ovarian cancer, including the RMI (risk of malignancy index), LR2 and SR (simple rules). Sensitivities and specificities of these systems are given in tables below:[9]

| Scoring systems | Premenopausal | | Postmenopausal | |
|---|---|---|---|---|
| | Sensitivity | Specificity | Sensitivity | Specificity |
| RMI I | 44% | 95% | 79% | 90% |
| LR2 | 85% | 91% | 94% | 70% |
| SR | 93% | 83% | 93% | 76% |

Ovarian cysts may be classified according to whether they are a variant of the normal menstrual cycle, referred to as a functional or follicular cyst.[4]

Ovarian cysts are considered large when they are over 5 cm and giant when they are over 15 cm. In children ovarian cysts reaching above the level of the umbilicus are considered giant.

## Functional [edit]

Functional cysts form as a normal part of the menstrual cycle. There are several types of cysts:

- Follicular cyst, the most common type of ovarian cyst. In menstruating women, a follicle containing the ovum (unfertilized egg) will rupture during ovulation. If this does not occur, a follicular cyst of more than 2.5 cm diameter may result.[4]
- Corpus luteum cysts appear after ovulation. The corpus luteum is the remnant of the follicle after the ovum has moved to the fallopian tubes. This normally degrades within 5–9 days. A corpus luteum that is more than 3 cm is defined as cystic.[4]
- Theca lutein cysts occur within the thecal layer of cells surrounding developing oocytes. Under the influence of excessive hCG, thecal cells may proliferate and become cystic. This is usually on both ovaries.[4]

## Non-functional [edit]

Non-functional cysts may include the following:

- An ovary with many cysts, which may be found in normal women, or within the setting of polycystic ovary syndrome.
- Cysts caused by endometriosis, known as chocolate cysts.
- Hemorrhagic ovarian cyst
- Dermoid cyst
- Ovarian serous cystadenoma
- Ovarian mucinous cystadenoma
- Paraovarian cyst
- Cystic adenofibroma
- Borderline tumoral cysts

## Associated medical conditions [edit]

In juvenile hypothyroidism multicystic ovaries are present in about 75% of cases, while large ovarian cysts and elevated ovarian tumor marks are one of the symptoms of the Van Wyk and Grumbach syndrome.[10]

The CA-125 marker in children and adolescents can be frequently elevated even in absence of malignancy and conservative management should be considered.

Polycystic ovarian syndrome involves the development of multiple small cysts in both ovaries due to an elevated ratio of leutenizing hormone to follicle stimulating hormone, typically more than 25 cysts in each ovary, or an ovarian volume of greater than 10 mL.[11]

Larger bilateral cysts can develop as a result of fertility treatment due to elevated levels of HCG, as can be seen with the use of clomifene for follicular induction, in extreme cases resulting in a condition known as ovarian hyperstimulation syndrome.[12] Certain malignancies can mimic the effects of clomifene on the ovaries, also due to increased HCG, in particular gestational trophoblastic disease. Ovarian hyperstimulation occurs more often with invasive moles and choriocarcinoma than complete molar pregnancies.[13]

## Risk of cancer [edit]

A widely recognised method of estimating the risk of malignant ovarian cancer based on initial workup is the *risk of malignancy index* (RMI).[14] It is recommended that women with an RMI score over 200 should be referred to a centre with experience in ovarian cancer surgery.[15]

The RMI is calculated as follows:[15]

RMI = ultrasound score x menopausal score x CA-125 level in U/ml.

There are two methods to determine the ultrasound score and menopausal score, with the resultant RMI being called RMI 1 and RMI 2, respectively, depending on what method is used:[15]

| Feature | RMI 1 | RMI 2 |
|---|---|---|
| Ultrasound abnormalities:<br>▪ multilocular cyst<br>▪ solid areas<br>▪ bilateral lesions<br>▪ ascites | 0 = no abnormality<br>1 = one abnormality<br>3 = two or more abnormalities | 0 = none<br>1 = one abnormality<br>4 = two or more abnormalities |

| | | |
|---|---|---|
| ▪ intra-abdominal metastases | | |
| Menopausal score | 1 = premenopausal<br>3 = postmenopausal | 1 = premenopausal<br>4 = postmenopausal |
| CA-125 | Quantity in U/ml | Quantity in U/ml |

An RMI 2 of over 200 has been estimated to have a sensitivity of 74 to 80%, a specificity of 89 to 92% and a positive predictive value of around 80% of ovarian cancer.[15] RMI 2 is regarded as more sensitive than RMI 1.[15]

# Treatment [edit]

Cysts associated with hypothyroidism or other endocrine problems are managed by treating the underlying condition.

About 95% of ovarian cysts are benign, not cancerous.[16]

Functional cysts and hemorrhagic ovarian cysts usually resolve spontaneously.[17] However the bigger an ovarian cyst is, the less likely it is to disappear on its own.[18] Treatment may be required if cysts persist over several months, grow or cause increasing pain.[19]

Cysts that persist beyond two or three menstrual cycles, or occur in post-menopausal women, may indicate more serious disease and should be investigated through ultrasonography and laparoscopy, especially in cases where family members have had ovarian cancer. Such cysts may require surgical biopsy. Additionally, a blood test may be taken before surgery to check for elevated CA-125, a tumour marker, which is often found in increased levels in ovarian cancer, although it can also be elevated by other conditions resulting in a large number of false positives.[20]

## Pain [edit]

Pain associated with ovarian cysts may be treated in several ways:

- Pain relievers such as acetaminophen, nonsteroidal anti-inflammatory drugs,[1] or opioids.
- While hormonal birth control prevents the development of new cysts in those who frequently get them,[1] it is not useful for the treatment of current cysts.[2]

## Surgery [edit]

Although most cases of ovarian cysts involve monitoring, some cases require surgery.[21] This may involve removing the cyst, or one or both ovaries.[22] Technique is typically laparoscopic, unless the cyst is particularly large, or if pre-operative imaging suggests malignancy or complex anatomy.[23] In certain situations, the cyst is entirely removed, while with cysts with low recurrence risk, younger patients, or which are in anatomically eloquent areas of the pelvis, they can be drained.[24][25] Features that may indicate the need for surgery include:[26]

- Persistent complex ovarian cysts
- Persistent cysts that are causing symptoms
- Complex ovarian cysts larger than 5 cm
- Simple ovarian cysts larger 10 centimeters or larger than 5 cm in postmenopausal patients
- Women who are menopausal or perimenopausal

# Frequency [edit]

Most women of reproductive age develop small cysts each month. Large cysts that cause problems occur in about 8% of women before menopause.[1] Ovarian cysts are present in about 16% of women after [1][3]

menopause and if present are more likely to be cancer.

Benign ovarian cysts are common in asymptomatic premenarchal girls and found in approximately 68% of ovaries of girls 2–12 years old and in 84% of ovaries of girls 0–2 years old. Most of them are smaller than 9 mm while about 10-20% are larger macrocysts. While the smaller cysts mostly disappear within 6 months the larger ones appear to be more persistent.[27][28]

**Polycystic ovary syndrome** (**PCOS**) is a set of symptoms due to elevated androgens (male hormones) in women.[3][4] Signs and symptoms of PCOS include irregular or no menstrual periods, heavy periods, excess body and facial hair, acne, pelvic pain, difficulty getting pregnant, and patches of thick, darker, velvety skin.[5] Associated conditions include type 2 diabetes, obesity, obstructive sleep apnea, heart disease, mood disorders, and endometrial cancer.[3]

PCOS is due to a combination of genetic and environmental factors.[6][7][8] Risk factors include obesity, not enough physical exercise, and a family history of someone with the condition.[9] Diagnosis is based on two of the following three findings: no ovulation, high androgen levels, and ovarian cysts.[5] Cysts may be detectable by ultrasound. Other conditions that produce similar symptoms include adrenal hyperplasia, hypothyroidism, and hyperprolactinemia.[10]

PCOS has no cure.[11] Treatment may involve lifestyle changes such as weight loss and exercise.[12][13] Birth control pills may help with improving the regularity of periods, excess hair growth, and acne. Metformin and anti-androgens may also help. Other typical acne treatments and hair removal techniques may be used.[14] Efforts to improve fertility include weight loss, clomiphene, or metformin. In vitro fertilization is used by some in whom other measures are not effective.[15]

PCOS is the most common endocrine disorder among women between the ages of 18 and 44.[16] It affects approximately 2% to 20% of this age group depending on how it is defined.[9][17] It is one of the leading causes of poor fertility.[3] The earliest known description of what is now recognized as PCOS dates from 1721 in Italy.[18]

## Signs and symptoms [edit]

*Further information: Infertility in polycystic ovary syndrome*

Common signs and symptoms of PCOS include the following:

- Menstrual disorders: PCOS mostly produces oligomenorrhea (fewer than nine menstrual periods in a year) or amenorrhea (no menstrual periods for three or more consecutive months), but other types of menstrual disorders may also occur.[16][19]
- Infertility:[19] This generally results directly from chronic anovulation (lack of ovulation).[16]
- High levels of masculinizing hormones: Known as hyperandrogenism, the most common signs are acne and hirsutism (male pattern of hair growth, such as on the chin or chest), but it may produce hypermenorrhea (heavy and prolonged menstrual periods), androgenic alopecia (increased hair thinning or diffuse hair loss), or other symptoms.[16][20] Approximately three-quarters of women with PCOS (by the diagnostic criteria of NIH/NICHD 1990) have evidence of hyperandrogenemia.[21]
- Metabolic syndrome:[19] This appears as a tendency towards central obesity and other symptoms associated with insulin resistance.[16] Serum insulin, insulin resistance, and homocysteine levels are higher in women with PCOS.[22]

Asians affected by PCOS are less likely to develop hirsutism than those of other ethnic backgrounds.[23]

## Cause [edit]

PCOS is a heterogeneous disorder of uncertain cause.[19][24][25] There is some evidence that it is a genetic disease. Such evidence includes the familial clustering of cases, greater concordance in monozygotic compared with dizygotic twins and heritability of endocrine and metabolic features of PCOS.[8][24][25]

The genetic component appears to be inherited in an autosomal dominant fashion with high genetic penetrance but variable expressivity in females; this means that each child has a 50% chance of inheriting the predisposing genetic variant(s) from a parent, and, if a daughter receives the variant(s), the daughter will have the disease to some extent.[25][26][27][28] The genetic variant(s) can be inherited from either the father or the mother, and can be passed along to both sons (who may be asymptomatic carriers or may have symptoms such as early baldness and/or excessive hair) and daughters, who will show signs of PCOS.[26][28] The phenotype appears to manifest itself at least partially via heightened androgen levels secreted by ovarian follicle theca cells from women with the allele.[27] The exact gene affected has not yet been identified.[8][25][29] In rare instances, single-gene mutations can give rise to the phenotype of the syndrome.[30] Current understanding of the pathogenesis of the syndrome suggests, however, that it is a

complex multigenic disorder.[31]

The severity of PCOS symptoms appears to be largely determined by factors such as obesity.[8][16]

PCOS has some aspects of a metabolic disorder, since its symptoms are partly reversible. Even though considered as a gynecological problem, PCOS consists of 28 clinical symptoms.

Even though the name suggests that the ovaries are central to disease pathology, cysts are a symptom instead of the cause of the disease. Some symptoms of PCOS will persist even if both ovaries are removed; the disease can appear even if cysts are absent. Since its first description by Stein and Leventhal in 1935, the criteria of diagnosis, symptoms, and causative factors are subject to debate. Gynecologists often see it as a gynecological problem, with the ovaries being the primary organ affected. However, recent insights show a multisystem disorder, with the primary problem lying in hormonal regulation in the hypothalamus, with the involvement of many organs. The name PCOD is used when there is ultrasonographic evidence. The term PCOS is used since there is a wide spectrum of symptoms possible, and cysts in the ovaries are seen only in 15% of people.[32]

PCOS may be related to or worsened by exposures during the prenatal period, epigenetic factors, environmental impacts (especially industrial endocrine disruptors[33] such as bisphenol A and certain drugs) and the increasing rates of obesity.[33][34][35][36][37][38][39]

## Diagnosis [edit]

Not everyone with PCOS has polycystic ovaries (PCO), nor does everyone with ovarian cysts have PCOS; although a pelvic ultrasound is a major diagnostic tool, it is not the only one.[40] The diagnosis is straightforward using the Rotterdam criteria, even when the syndrome is associated with a wide range of symptoms.

### Definition [edit]

Two definitions are commonly used:

#### NIH [edit]

In 1990 a consensus workshop sponsored by the NIH/NICHD suggested that a person has PCOS if they have all of the following:[41]

1. oligoovulation
2. signs of androgen excess (clinical or biochemical)
3. exclusion of other disorders that can result in menstrual irregularity and hyperandrogenism

#### Rotterdam [edit]

In 2003 a consensus workshop sponsored by ESHRE/ASRM in Rotterdam indicated PCOS to be present if

any 2 out of 3 criteria are met, in the absence of other entities that might cause these findings[16][42][43]

1. oligoovulation and/or anovulation
2. excess androgen activity
3. polycystic ovaries (by gynecologic ultrasound)

The Rotterdam definition is wider, including many more women, the most notable ones being women without androgen excess. Critics say that findings obtained from the study of women with androgen excess cannot necessarily be extrapolated to women without androgen excess.[44][45]

**Androgen Excess PCOS Society**

In 2006, the Androgen Excess PCOS Society suggested a tightening of the diagnostic criteria to all of the following:[16]

1. excess androgen activity
2. oligoovulation/anovulation and/or polycystic ovaries
3. exclusion of other entities that would cause excess androgen activity

## Standard diagnostic assessments [edit]

- History-taking, specifically for menstrual pattern, obesity, hirsutism and acne. A clinical prediction rule found that these four questions can diagnose PCOS with a sensitivity of 77.1% (95% confidence interval [CI] 62.7%–88.0%) and a specificity of 93.8% (95% CI 82.8%–98.7%).[46]
- Gynecologic ultrasonography, specifically looking for small ovarian follicles. These are believed to be the result of disturbed ovarian function with failed ovulation, reflected by the infrequent or absent menstruation that is typical of the condition. In a normal menstrual cycle, one egg is released from a dominant follicle – in essence, a cyst that bursts to release the egg. After ovulation, the follicle remnant is transformed into a progesterone-producing corpus luteum, which shrinks and disappears after approximately 12–14 days. In PCOS, there is a so-called "follicular arrest"; i.e., several follicles develop to a size of 5–7 mm, but not further. No single follicle reaches the preovulatory size (16 mm or more). According to the Rotterdam criteria, which are widely used for diagnosis,[12] 12 or more small follicles should be seen in an ovary on ultrasound examination.[41] More recent research suggests that there should be at least 25 follicles in an ovary to designate it as having polycystic ovarian morphology (PCOM) in women aged 18–35 years.[47] The follicles may be oriented in the periphery, giving the appearance of a 'string of pearls'.[48] If a high resolution transvaginal ultrasonography machine is not available, an ovarian volume of at least 10 ml is regarded as an acceptable definition of having polycystic ovarian morphology instead of follicle count.[47]
- Laparoscopic examination may reveal a thickened, smooth, pearl-white outer surface of the ovary. (This would usually be an incidental finding if laparoscopy were performed for some other reason, as it would not be routine to examine the ovaries in this way to confirm a diagnosis of PCOS.)[*citation needed*]
- Serum (blood) levels of androgens (hormones associated with male development), including androstenedione and testosterone may be elevated.[16] Dehydroepiandrosterone sulfate levels above 700-800 µg/dL are highly suggestive of adrenal dysfunction because DHEA-S is made exclusively by the adrenal glands.[49][50] The free testosterone level is thought to be the best measure,[50][51] with ~60% of PCOS patients demonstrating supranormal levels.[21] The Free androgen index (FAI) of the ratio of testosterone to sex hormone-binding globulin (SHBG) is high[16][50] and is meant to be a predictor of free testosterone, but is a poor parameter for this and is no better than testosterone alone as a marker for PCOS,[52] possibly because FAI is correlated with the degree of obesity.[53]

Some other blood tests are suggestive but not diagnostic. The ratio of LH (Luteinizing hormone) to FSH (Follicle-stimulating hormone), when measured in international units, is elevated in women with PCOS. Common cut-offs to designate abnormally high LH/FSH ratios are 2:1[54] or 3:1[50] as tested on Day 3 of the menstrual cycle. The pattern is not very sensitive; a ratio of 2:1 or higher was present in less than 50% of women with PCOS in one study.[54] There are often low levels of sex hormone-binding globulin,[50] in particular among obese or overweight women.[*citation needed*]

Anti-Müllerian hormone (AMH) is increased in PCOS, and may become part of its diagnostic criteria.[55][56][57]

### Associated conditions [edit]

- Fasting biochemical screen and lipid profile[50]
- 2-Hour oral glucose tolerance test (GTT) in women with risk factors (obesity, family history, history of gestational diabetes)[16] may indicate impaired glucose tolerance (insulin resistance) in 15–33% of women with PCOS.[50] Frank diabetes can be seen in 65–68% of women with this condition.[*citation needed*] Insulin resistance can be observed in both normal weight and overweight people, although it is more common in the latter (and in those matching the stricter NIH criteria for diagnosis); 50–80% of people with PCOS may have insulin resistance at some level.[16]
- Fasting insulin level or GTT with insulin levels (also called IGTT). Elevated insulin levels have been helpful to predict response to medication and may indicate women needing higher dosages of metformin or the use of a second medication to significantly lower insulin levels. Elevated blood sugar and insulin values do not predict who responds to an insulin-lowering medication, low-glycemic diet, and exercise. Many women with normal levels may benefit from combination therapy. A hypoglycemic response in which the two-hour insulin level is higher and the blood sugar lower than fasting is consistent with insulin resistance. A mathematical derivation known as the HOMAI, calculated from the fasting values in glucose and insulin concentrations, allows a direct and moderately accurate measure of insulin sensitivity (glucose-level x insulin-level/22.5).[*citation needed*]
- Glucose tolerance testing (GTT) instead of fasting glucose can increase diagnosis of impaired glucose tolerance and frank diabetes among people with PCOS according to a prospective controlled trial.[58] While fasting glucose levels may remain within normal limits, oral glucose tests revealed that up to 38% of asymptomatic women with PCOS (versus 8.5% in the general population) actually had impaired glucose tolerance, 7.5% of those with frank diabetes according to ADA guidelines.[58]

### Differential diagnosis [edit]

Other causes of irregular or absent menstruation and hirsutism, such as hypothyroidism, congenital adrenal hyperplasia (21-hydroxylase deficiency), Cushing's syndrome, hyperprolactinemia, androgen secreting neoplasms, and other pituitary or adrenal disorders, should be investigated.[16][43][50]

## Pathogenesis [edit]

Polycystic ovaries develop when the ovaries are stimulated to produce excessive amounts of androgenic hormones, in particular testosterone, by either one or a combination of the following (almost certainly combined with genetic susceptibility[27]):

- the release of excessive luteinizing hormone (LH) by the anterior pituitary gland[*citation needed*]
- through high levels of insulin in the blood (hyperinsulinaemia) in women whose ovaries are sensitive to this stimulus[19]

The syndrome acquired its most widely used name due to the common sign on ultrasound examination of multiple (poly) ovarian cysts. These "cysts" are actually immature follicles not cysts. The follicles have developed from primordial follicles, but the development has stopped ("arrested") at an early antral stage due to the disturbed ovarian function. The follicles may be oriented along the ovarian periphery, appearing as a 'string of pearls' on ultrasound examination.[*citation needed*]

Women with PCOS experience an increased frequency of hypothalamic GnRH pulses, which in turn results in an increase in the LH/FSH ratio.[59]

A majority of women with PCOS have insulin resistance and/or are obese. Their elevated insulin levels contribute to or cause the abnormalities seen in the hypothalamic-pituitary-ovarian axis that lead to PCOS. Hyperinsulinemia increases GnRH pulse frequency, LH over FSH dominance, increased ovarian androgen production,[19] decreased follicular maturation, and decreased SHBG binding. Furthermore, excessive

insulin, acting through its cognate receptor in the presence of component cAMP signalling, upregulates 17α-hydroxylase activity via PI3K, 17α-hydroxylase activity being responsible for synthesising androgen precursors.[60] The combined effects of hyperinsulinemia contribute to an increased risk of PCOS.[61] Insulin resistance is a common finding among women with a normal weight as well as overweight women.[16][22][12]

Adipose tissue possesses aromatase, an enzyme that converts androstenedione to estrone and testosterone to estradiol. The excess of adipose tissue in obese women creates the paradox of having both excess androgens (which are responsible for hirsutism and virilization) and estrogens (which inhibits FSH via negative feedback).[62]

PCOS may be associated with chronic inflammation,[19][63] with several investigators correlating inflammatory mediators with anovulation and other PCOS symptoms.[64][65] Similarly, there seems to be a relation between PCOS and increased level of oxidative stress.[66]

It has previously been suggested that the excessive androgen production in PCOS could be caused by a decreased serum level of IGFBP-1, in turn increasing the level of free IGF-I, which stimulates ovarian androgen production, but recent data concludes this mechanism to be unlikely.[67]

PCOS has also been associated with a specific FMR1 sub-genotype. The research suggests that women with *heterozygous-normal/low* FMR1 have polycystic-like symptoms of excessive follicle-activity and hyperactive ovarian function.[68]

Transgender men may experience a higher than expected rate of PCOS due to increased testosterone, if they choose to take hormone therapy as part of their gender presentation.[69][70]

## Management [edit]

The primary treatments for PCOS include: lifestyle changes, medications and surgery.[71][*needs update*]

Goals of treatment may be considered under four categories:

- Lowering of insulin resistance levels
- Restoration of fertility
- Treatment of hirsutism or acne
- Restoration of regular menstruation, and prevention of endometrial hyperplasia and endometrial cancer

In each of these areas, there is considerable debate as to the optimal treatment. One of the major reasons for this is the lack of large-scale clinical trials comparing different treatments. Smaller trials tend to be less reliable and hence may produce conflicting results.

General interventions that help to reduce weight or insulin resistance can be beneficial for all these aims, because they address what is believed to be the underlying cause.

As PCOS appears to cause significant emotional distress, appropriate support may be useful.[72]

### Diet [edit]

Where PCOS is associated with overweight or obesity, successful weight loss is the most effective method of restoring normal ovulation/menstruation, but many women find it very difficult to achieve and sustain significant weight loss. A scientific review in 2013 found similar decreases in weight and body composition and improvements in pregnancy rate, menstrual regularity, ovulation, hyperandrogenism, insulin resistance, lipids, and quality of life to occur with weight loss independent of diet composition.[73] Still, a low GI diet, in which a significant part of total carbohydrates are obtained from fruit, vegetables, and whole-grain sources, has resulted in greater menstrual regularity than a macronutrient-matched healthy diet.[73]

Vitamin D deficiency may play some role in the development of the metabolic syndrome, so treatment of any such deficiency is indicated.[74][75] However, a systematic review of 2015 found no evidence that vitamin D supplementation reduced or mitigated metabolic and hormonal dysregulations in PCOS.[76] As of

2012, interventions using dietary supplements to correct metabolic deficiencies in people with PCOS had been tested in small, uncontrolled and nonrandomized clinical trials; the resulting data is insufficient to recommend their use.[77]

## Medications [edit]

Medications for PCOS include oral contraceptives and metformin. The oral contraceptives increase sex hormone binding globulin production, which increases binding of free testosterone. This reduces the symptoms of hirsutism caused by high testosterone and regulates return to normal menstrual periods. Metformin is a drug commonly used in type 2 diabetes to reduce insulin resistance, and is used off label (in the UK, US, AU and EU) to treat insulin resistance seen in PCOS. In many cases, metformin also supports ovarian function and return to normal ovulation.[19][74][78] Spironolactone can be used for its antiandrogenic effects, and the topical cream eflornithine can be used to reduce facial hair. A newer insulin resistance drug class, the thiazolidinediones (glitazones), have shown equivalent efficacy to metformin, but metformin has a more favorable side effect profile.[79][80] The United Kingdom's National Institute for Health and Clinical Excellence recommended in 2004 that women with PCOS and a body mass index above 25 be given metformin when other therapy has failed to produce results.[81][82] Metformin may not be effective in every type of PCOS, and therefore there is some disagreement about whether it should be used as a general first line therapy.[83] The use of statins in the management of underlying metabolic syndrome remains unclear.[84]

It can be difficult to become pregnant with PCOS because it causes irregular ovulation. Medications to induce fertility when trying to conceive include the ovulation inducer clomiphene or pulsatile leuprolide. Metformin improves the efficacy of fertility treatment when used in combination with clomiphene.[85] Metformin is thought to be safe to use during pregnancy (pregnancy category B in the US).[86] A review in 2014 concluded that the use of metformin does not increase the risk of major birth defects in women treated with metformin during the first trimester.[87]

## Infertility [edit]

*Main article: Infertility in polycystic ovary syndrome*

Not all women with PCOS have difficulty becoming pregnant. For those that do, anovulation or infrequent ovulation is a common cause. Other factors include changed levels of gonadotropins, hyperandrogenemia and hyperinsulinemia.[88] Like women without PCOS, women with PCOS that are ovulating may be infertile due to other causes, such as tubal blockages due to a history of sexually transmitted diseases.

For overweight, anovulatory women with PCOS, weight loss and diet adjustments, especially to reduce the intake of simple carbohydrates, are associated with resumption of natural ovulation.

For those women that after weight loss still are anovulatory or for anovulatory lean women, then the ovulation-inducing medications clomiphene citrate[74] and FSH are the principal treatments used to promote ovulation.[19] Previously, the anti-diabetes medication metformin was recommended treatment for anovulation,[19] but it appears less effective than clomiphene.[89]

For women not responsive to clomiphene and diet and lifestyle modification, there are options available including assisted reproductive technology procedures such as controlled ovarian hyperstimulation with follicle-stimulating hormone (FSH) injections followed by in vitro fertilisation (IVF).

Though surgery is not commonly performed, the polycystic ovaries can be treated with a laparoscopic procedure called "ovarian drilling" (puncture of 4–10 small follicles with electrocautery, laser, or biopsy needles), which often results in either resumption of spontaneous ovulations[74] or ovulations after adjuvant treatment with clomiphene or FSH.[*citation needed*] (Ovarian wedge resection is no longer used as much due to complications such as adhesions and the presence of frequently effective medications.) There are, however, concerns about the long-term effects of ovarian drilling on ovarian function.[74]

## Hirsutism and acne [edit]

*For more details on this topic, see Hirsutism.*

When appropriate (e.g., in women of child-bearing age who require contraception), a standard contraceptive pill is frequently effective in reducing hirsutism.[19][74] Progestogens such as norgestrel and levonorgestrel should be avoided due to their androgenic effects.[74]

Other drugs with anti-androgen effects include flutamide,[90] and spironolactone,[19][74] which can give some improvement in hirsutism. Metformin can reduce hirsutism, perhaps by reducing insulin resistance, and is often used if there are other features such as insulin resistance, diabetes, or obesity that should also benefit from metformin. Eflornithine (Vaniqa) is a drug that is applied to the skin in cream form, and acts directly on the hair follicles to inhibit hair growth. It is usually applied to the face.[74] 5-alpha reductase inhibitors (such as finasteride and dutasteride) may also be used;[91] they work by blocking the conversion of testosterone to dihydrotestosterone (the latter of which responsible for most hair growth alterations and androgenic acne).

Although these agents have shown significant efficacy in clinical trials (for oral contraceptives, in 60–100% of individuals[74]), the reduction in hair growth may not be enough to eliminate the social embarrassment of hirsutism, or the inconvenience of plucking or shaving. Individuals vary in their response to different therapies. It is usually worth trying other drug treatments if one does not work, but drug treatments do not work well for all individuals.

### Menstrual irregularity [edit]

If fertility is not the primary aim, then menstruation can usually be regulated with a contraceptive pill.[19][74] The purpose of regulating menstruation, in essence, is for the woman's convenience, and perhaps her sense of well-being; there is no medical requirement for regular periods, as long as they occur sufficiently often.

If a regular menstrual cycle is not desired, then therapy for an irregular cycle is not necessarily required. Most experts say that, if a menstrual bleed occurs at least every three months, then the endometrium (womb lining) is being shed sufficiently often to prevent an increased risk of endometrial abnormalities or cancer.[92] If menstruation occurs less often or not at all, some form of progestogen replacement is recommended.[91] An alternative is oral progestogen taken at intervals (e.g., every three months) to induce a predictable menstrual bleeding.[19]

### Alternative medicine [edit]

There is not enough evidence to conclude any beneficial effect from D-chiro-inositol.[93] Based on a systematic review, myo-inositol supplementation, however, appears to be effective in improving several of the hormonal disturbances of PCOS.[94] There is also not evidence to support the use of acupuncture for treatment of ovulation disorders in women with PCOS.[95]

## Prognosis [edit]

A diagnosis of PCOS suggests an increased risk of the following:

- Endometrial hyperplasia and endometrial cancer (cancer of the uterine lining) are possible, due to overaccumulation of uterine lining, and also lack of progesterone resulting in prolonged stimulation of uterine cells by estrogen.[19][41][96] It is not clear whether this risk is directly due to the syndrome or from the associated obesity, hyperinsulinemia, and hyperandrogenism.[97][98][99]
- Insulin resistance/Type II diabetes.[19] A review published in 2010 concluded that women with PCOS have an elevated prevalence of insulin resistance and type II diabetes, even when controlling for body mass index (BMI).[41][100] PCOS also makes a woman, particularly if obese, prone to gestational diabetes.[19]
- High blood pressure, in particular if obese or during pregnancy[19]

- Depression and anxiety[16][101]
- Dyslipidemia[19] – disorders of lipid metabolism — cholesterol and triglycerides. Women with PCOS show a decreased removal of atherosclerosis-inducing remnants, seemingly independent of insulin resistance/Type II diabetes.[102]
- Cardiovascular disease,[19][41] with a meta-analysis estimating a 2-fold risk of arterial disease for women with PCOS relative to women without PCOS, independent of BMI.[103]
- Strokes[41]
- Weight gain[19]
- Miscarriage[104][105]
- Sleep apnea, particularly if obesity is present[19]
- Non-alcoholic fatty liver disease, again particularly if obesity is present[19]
- Acanthosis nigricans (patches of darkened skin under the arms, in the groin area, on the back of the neck)[41]
- Autoimmune thyroiditis[106]

Early diagnosis and treatment may reduce the risk of some of these, such as type 2 diabetes and heart disease.[19]

The risk of ovarian cancer and breast cancer is not significantly increased overall.[96]

## Epidemiology [edit]

The prevalence of PCOS depends on the choice of diagnostic criteria. The World Health Organization estimates that it affects 116 million women worldwide as of 2010 (3.4% of women).[107] One community-based prevalence study using the Rotterdam criteria found that about 18% of women had PCOS, and that 70% of them were previously undiagnosed.[16]

One study in the United Kingdom concluded that the risk of PCOS development was higher in lesbian women than in heterosexuals.[108] However, two subsequent studies of women with PCOS have not replicated this finding.[109][110] Ultrasonographic findings of polycystic ovaries are found in 8-25% of normal women.[111][112][113][114] 14% women on oral contraceptives are found to have polycystic ovaries.[112] Ovarian cysts are also a common side effect of intrauterine devices (IUDs).[115]

## History [edit]

The condition was first described in 1935 by American gynecologists Irving F. Stein, Sr. and Michael L. Leventhal, from whom its original name of *Stein–Leventhal syndrome* is taken.[40][41]

The earliest published description of a person with what is now recognized as PCOS was in 1721 in Italy.[18] Cyst-related changes to the ovaries were described in 1844.[18]

### Names [edit]

Other names for this syndrome include polycystic ovary disease, functional ovarian hyperandrogenism, ovarian hyperthecosis, sclerocystic ovary syndrome, and Stein–Leventhal syndrome. The eponymous last option is the original name; it is now used, if at all, only for the subset of women with all the symptoms of amenorrhea with infertility, hirsutism, and enlarged polycystic ovaries.[40]

Most common names for this disease derive from a typical finding on medical images, called a polycystic ovary.[19] A polycystic ovary has an abnormally large number of developing eggs visible near its surface,[40] looking like many small cysts[116] or a string of pearls.
