# Dermatitis

From Wikipedia, the free encyclopedia

**Dermatitis**, also known as **eczema**, is a group of diseases that results in inflammation of the skin.[1] These diseases are characterized by itchiness, red skin, and a rash.[1] In cases of short duration there may be small blisters while in long-term cases the skin may become thickened.[1] The area of skin involved can vary from small to the entire body.[1][2]

Dermatitis is a group of skin conditions that includes atopic dermatitis, allergic contact dermatitis, irritant contact dermatitis, and stasis dermatitis.[1][2] The exact cause of dermatitis is often unclear.[2] Cases are believed to often involve a combination of irritation, allergy, and poor venous return. The type of dermatitis is generally determined by the person's history and the location of the rash. For example, irritant dermatitis often occurs on the hands of people who frequently get them wet. Allergic contact dermatitis, however, can occur following brief exposures to substances a person is sensitive to.[1]

Treatment of atopic dermatitis is typically with moisturizers and steroid creams.[3] The steroid creams should generally be of mid- to high strength and used for less than two weeks at a time as side effects can occur.[4] Antibiotics may be required if there are signs of skin infection.[2] Contact dermatitis is typically treated by avoiding the allergen or irritant.[5][6] Antihistamines may help with sleep and to decrease nighttime scratching.[2]

Dermatitis was estimated to affect 334 million people globally in 2013.[7] Atopic dermatitis is the most common type and generally starts in childhood.[1][2] In the United States it affects about 10-30% of people.[2] Contact dermatitis is two times more common in females than males.[8] Allergic contact dermatitis affects about 7% of people at some point in time.[9] Irritant contact dermatitis is common, especially among people who do certain jobs; exact rates are unclear.[10]

## Signs and symptoms [edit]

Rash symptomatic of dermatitis

Dermatitis symptoms vary with all different forms of the condition. They range from skin rashes to bumpy rashes or including blisters. Although every type of dermatitis has different symptoms, there are certain signs that are common for all of them, including redness of the skin, swelling, itching and skin lesions with sometimes oozing and scarring. Also, the area of the skin on which the symptoms appear tends to be different with every type of dermatitis, whether on the neck, wrist, forearm, thigh or ankle. Although the location may vary, the primary symptom of this condition is itchy skin. More rarely, it may appear on the genital area, such as the vulva or scrotum.[11] Symptoms of this type of dermatitis may be very intense and may come and go. Irritant contact dermatitis is usually more painful than itchy.

Although the symptoms of atopic dermatitis vary from person to person, the most common symptoms are dry, itchy, red skin. Typical affected skin areas include the folds of the arms, the back of the knees, wrists, face and hands.

Dermatitis herpetiformis symptoms include itching, stinging and a burning sensation. Papules and vesicles are commonly present. The small red bumps experienced in this type of dermatitis are usually about 1 cm in size, red in color and may be found symmetrically grouped or distributed on the upper or lower back, buttocks, elbows, knees, neck, shoulders, and scalp.[12] Less frequently, the rash may appear inside the mouth or near the hairline.

The symptoms of seborrheic dermatitis, on the other hand, tend to appear gradually, from dry or greasy scaling of the scalp (dandruff) to hair loss. In severe cases, pimples may appear along the hairline, behind the ears, on the eyebrows, on the bridge of the nose, around the nose, on the chest, and on the upper back.[13] In newborns, the condition causes a thick and yellowish scalp rash, often accompanied by a diaper rash.

Perioral dermatitis refers to a red bumpy rash around the mouth.[14]

## Cause [edit]

The cause of dermatitis is unknown but is presumed to be a combination of genetic and environmental factors.[2]

### Environmental [edit]

The hygiene hypothesis postulates that the cause of asthma, eczema, and other allergic diseases is an unusually clean environment. It is supported by epidemiologic studies for asthma.[15] The hypothesis states that exposure to bacteria and other immune system modulators is important during development, and missing out on this exposure increases risk for asthma and allergy.

While it has been suggested that eczema may sometimes be an allergic reaction to the excrement from house dust mites,[16] with up to 5% of people showing antibodies to the mites,[17] the overall role this plays awaits further corroboration.[18]

### Genetic [edit]

A number of genes have been associated with eczema, one of which is filaggrin.[3] Genome-wide studies found three new genetic variants associated with eczema: OVOL1, ACTL9 and IL4-KIF3A.[19]

Eczema occurs about three times more frequently in individuals with celiac disease and about two times more frequently in relatives of those with celiac disease, potentially indicating a genetic link between the conditions.[20][21]

## Diagnosis [edit]

Diagnosis of eczema is based mostly on the history and physical examination.[3] In uncertain cases, skin biopsy may be useful.[22] Those with eczema may be especially prone to misdiagnosis of food allergies.[23]

Patch tests are used in the diagnosis of allergic contact dermatitis.[24][25]

## Classification [edit]

The term "eczema" refers to a set of clinical characteristics. Classification of the underlying diseases has been haphazard with numerous different classification systems, and many synonyms being used to describe the same condition.

A type of dermatitis may be described by location (e.g., hand eczema), by specific appearance (eczema craquele or discoid), or by possible cause (varicose eczema). Further adding to the confusion, many sources use the term eczema interchangeably for the most common type: atopic dermatitis.

The European Academy of Allergology and Clinical Immunology (EAACI) published a position paper in 2001, which simplifies the nomenclature of allergy-related diseases, including atopic and allergic contact eczemas.[26] Non-allergic eczemas are not affected by this proposal.

## Terminology [edit]

There are several types of dermatitis including atopic dermatitis, contact dermatitis, stasis dermatitis, and seborrheic eczema.[2] Many use the term dermatitis and eczema synonymously.[1]

Others use the term eczema to specifically mean atopic dermatitis.[27][28][29] Atopic dermatitis is also known as atopic eczema.[3] In some languages, dermatitis and eczema mean the same thing, while in other languages dermatitis implies an acute condition and eczema a chronic one.[30]

## Common types [edit]

- Atopic dermatitis is an allergic disease believed to have a hereditary component and often runs in families whose members have asthma. Itchy rash is particularly noticeable on head and scalp, neck, inside of elbows, behind knees, and buttocks. It is very common in developed countries, and rising. Irritant contact dermatitis is sometimes misdiagnosed as atopic dermatitis.
- Contact dermatitis is of two types: allergic (resulting from a delayed reaction to an allergen, such as poison ivy, nickel, or Balsam of Peru),[31] and irritant (resulting from direct reaction to a detergent, such as sodium lauryl sulfate, for example).
  Some substances act both as allergen and irritant (wet cement, for example). Other substances cause a problem after sunlight exposure, bringing on phototoxic dermatitis. About three quarters of cases of contact eczema are of the irritant type, which is the most common occupational skin disease. Contact eczema is curable, provided the offending substance can be avoided and its traces removed from one's environment. (ICD-10 L23; L24; L56.1; L56.0)
- Xerotic eczema (asteatotic eczema, eczema craquele, eczema craquelatum, winter itch, pruritus hiemalis) is dry skin that becomes so serious it turns into eczema. It worsens in dry winter weather, and limbs and trunk are most often affected. The itchy, tender skin resembles a dry, cracked, river bed. This disorder is very common among the older population. Ichthyosis is a related disorder. (ICD-10 L30.8A; L85.0)
- Seborrhoeic dermatitis or seborrheic dermatitis ("cradle cap" in infants) is a condition sometimes classified as a form of eczema that is closely related to dandruff. It causes dry or greasy peeling of the scalp, eyebrows, and face, and sometimes trunk. In newborns it causes a thick, yellow, crusty scalp rash called cradle cap, which seems related to lack of biotin and is often curable. (ICD-10 L21; L21.0)

## Less common types [edit]

- Dyshidrosis (dyshidrotic eczema, pompholyx, vesicular palmoplantar dermatitis) only occurs on palms, soles, and sides of fingers and toes. Tiny opaque bumps called vesicles, thickening, and cracks are accompanied by itching, which gets worse at night. A common type of hand eczema, it worsens in warm weather. (ICD-10 L30.1)
- Discoid eczema (ummular eczema, exudative eczema, microbial eczema) is characterized by round spots of oozing or dry rash, with clear boundaries, often on lower legs. It is usually worse in winter. Cause is unknown, and the condition tends to come and go. (ICD-10 L30.0)

Venous eczema (gravitational eczema, stasis dermatitis, varicose eczema) occurs in people with impaired circulation, varicose veins, and edema, and is particularly common in the ankle area of people over 50. There is redness, scaling, darkening of the skin, and itching. The disorder predisposes to leg ulcers. (ICD-10 I83.1)
- Dermatitis herpetiformis (Duhring's disease) causes intensely itchy and typically symmetrical rash on arms, thighs, knees, and back. It is directly related to celiac disease, can often be put into remission with appropriate diet, and tends to get worse at night. (ICD-10 L13.0)
- Neurodermatitis (lichen simplex chronicus, localized scratch dermatitis) is an itchy area of thickened, pigmented eczema patch that results from habitual rubbing and scratching. Usually there is only one spot. Often curable through behavior modification and anti-inflammatory medication. Prurigo nodularis is a related disorder showing multiple lumps. (ICD-10 L28.0; L28.1)
- Autoeczematization (id reaction, autosensitization) is an eczematous reaction to an infection with parasites, fungi, bacteria, or viruses. It is completely curable with the clearance of the original infection that caused it. The appearance varies depending on the cause. It always occurs some distance away from the original infection. (ICD-10 L30.2)
- There are eczemas overlaid by viral infections (eczema herpeticum or vaccinatum), and eczemas resulting from underlying disease (e.g., lymphoma). Eczemas originating from ingestion of medications, foods, and chemicals, have not yet been clearly systematized. Other rare eczematous disorders exist in addition to those listed here.

## Prevention [edit]

There is no good evidence that a mother's diet during pregnancy, the formula used, or breastfeeding changes the risk.[32] There is tentative evidence that probiotics in infancy may reduce rates but it is insufficient to recommend its use.[33]

People with eczema should not get the smallpox vaccination due to risk of developing eczema vaccinatum, a potentially severe and sometimes fatal complication.[34]

## Management [edit]

There is no known cure for some types of dermatitis, with treatment aiming to control symptoms by reducing inflammation and relieving itching. Contact dermatitis is treated by avoiding what is causing it.

### Lifestyle [edit]

Bathing once or more a day is recommended.[3] It is a misconception that bathing dries the skin in people with eczema.[35] Soaps should be avoided as they tend to strip the skin of natural oils and lead to excessive dryness.[36] It is not clear whether dust mite reduction helps with eczema.

There has not been adequate evaluation of changing the diet to reduce eczema.[37][38] There is some evidence that infants with an established egg allergy may have a reduction in symptoms if eggs are eliminated from their diets.[37] Benefits have not been shown for other elimination diets, though the studies are small and poorly executed.[37][38] Establishing that there is a food allergy before dietary change could avoid unnecessary lifestyle changes.[37]

People can wear clothing designed to manage the itching, scratching and peeling.[39]

### Moisturizers [edit]

Moisturizing agents (also known as emollients) are recommended at least once or twice a day.[3] Oilier formulations appear to be better and water-based formulations are not recommended.[3] It is unclear if moisturizers that contain ceramides are more or less effective than others.[40] Products that contain dyes, perfumes, or peanuts should not be used.[3] Occlusive dressings at night may be useful.[3]

## Medications [edit]

There is little evidence for antihistamine; they are thus not generally recommended.[3] Sedative antihistamines, such as diphenhydramine, may be tried in those who are unable to sleep due to eczema.[3]

## Corticosteroids [edit]

If symptoms are well controlled with moisturizers, steroids may only be required when flares occur.[3] Corticosteroids are effective in controlling and suppressing symptoms in most cases.[41] Once daily use is generally enough.[3] For mild-moderate eczema a weak steroid may be used (e.g., hydrocortisone), while in more severe cases a higher-potency steroid (e.g., clobetasol propionate) may be used. In severe cases, oral or injectable corticosteroids may be used. While these usually bring about rapid improvements, they have greater side effects.

Long term use of topical steroids may result in skin atrophy, stria, telangiectasia.[3] Their use on delicate skin (face or groin) is therefore typically with caution.[3] They are, however, generally well tolerated.[42] Red burning skin, where the skin turns red upon stopping steroid use, has been reported among adults who use topical steroids at least daily for more than a year.[43]

## Immunosuppressants [edit]

Topical immunosuppressants like pimecrolimus and tacrolimus may be better in the short term and appear equal to steroids after a year of use.[44] Their use is reasonable in those who do not respond to or are not tolerant of steroids.[45] Treatments are typically recommended for short or fixed periods of time rather than indefinitely.[3] Tacrolimus 0.1% has generally proved more effective than picrolimus, and equal in effect to mid-potency topical steroids.[32]

Tacrolimus 0.1%

The United States Food and Drug Administration has issued a health advisory a possible risk of lymph node or skin cancer from these products,[46] however, subsequent research has not supported these concerns.[45] A major debate, in the UK, has been about the cost of these medications and, given only finite NHS resources, when they are most appropriate to use.[47]

When eczema is severe and does not respond to other forms of treatment, systemic immunosuppressants are sometimes used. Immunosuppressants can cause significant side effects and some require regular blood tests. The most commonly used are ciclosporin, azathioprine, and methotrexate.

## Light therapy [edit]

Light therapy using ultraviolet light has tentative support but the quality of the evidence is not very good.[48] A number of different types of light may be used including UVA and UVB;[49] in some forms of treatment, light sensitive chemicals such as psoralen are also used. Overexposure to ultraviolet light carries its own risks, particularly that of skin cancer.[50]

## Alternative medicine [edit]

Limited evidence suggests that acupuncture may reduce itching in those affected by atopic dermatitis.[51] There is currently no scientific evidence for the claim that sulfur treatment relieves eczema.[52] It is unclear whether Chinese herbs help or harm.[53] Dietary supplements are commonly used by people with eczema.[54] Neither evening primrose oil nor borage seed oil taken orally have been shown to be effective.[55] Both are associated with gastrointestinal upset.[55] Probiotics do not appear to be effective.[56] There is insufficient evidence to support the use of zinc, selenium, vitamin D, vitamin E, pyridoxine (vitamin [54]

B6), sea buckthorn oil, hempseed oil, sunflower oil, or fish oil as dietary supplements.

Chiropractic spinal manipulation lacks evidence to support its use for dermatitis.[57] There is little evidence supporting the use of psychological treatments.[58] While dilute bleach baths have been used for infected dermatitis there is little evidence for this practice.[59]

## Prognosis [edit]

Most cases are well managed with topical treatments and ultraviolet light.[3] About 2% of cases are not.[3] In more than 60% the condition goes away by adolescence.[3]

## Epidemiology [edit]

Globally dermatitis affected approximately 230 million people as of 2010 (3.5% of the population).[60] Dermatitis is most commonly seen in infancy, with female predominance of eczema presentations occurring during the reproductive period of 15–49 years.[61] In the UK about 20% of children have the condition, while in the United States about 10% are affected.[3]

Although little data on the rates of eczema over time exists prior to the 1940s, the rate of eczema has been found to have increased substantially in the latter half of the 20th Century, with eczema in school-aged children being found to increase between the late 1940s and 2000.[62] In the developed world there has been rise in the rate of eczema over time. The incidence and lifetime prevalence of eczema in England has been seen to increase in recent times.[3][63]

Dermatitis affected about 10% of U.S. workers in 2010, representing over 15 million workers with dermatitis. Prevalence rates were higher among females than among males, and among those with some college education or a college degree compared to those with a high school diploma or less. Workers employed in healthcare and social assistance industries and life, physical, and social science occupations had the highest rates of reported dermatitis. About 6% of dermatitis cases among U.S. workers were attributed to work by a healthcare professional, indicating that the prevalence rate of work-related dermatitis among workers was at least 0.6%.[64]

## History [edit]

The term "atopic dermatitis" was coined in 1933 by Wise and Sulzberger.[66] Sulfur as a topical treatment for eczema was fashionable in the Victorian and Edwardian eras.[52]

The word dermatitis is from the Greek δέρμα *derma* "skin" and -ῖτις *-itis* "inflammation" and eczema is from Greek: ἔκζεμα *ekzema* "eruption".[67]

from Ancient Greek ἔκζεμα *ékzema*,[65]
from ἐκζέ-ειν *ekzé-ein*,
from ἐκ *ek* "out" + ζέ-ειν *zé-ein* "to boil"
(OED)

## Society and culture [edit]

The terms "hypoallergenic" and "doctor tested" are not regulated,[68] and no research has been done showing that products labeled "hypoallergenic" are less problematic than any others.

# Hair loss

From Wikipedia, the free encyclopedia

*"Bald" redirects here. For other uses, see Bald (disambiguation).*
*"Alopecia" redirects here. For an album by Why?, see Alopecia (album).*

**Hair loss**, also known as **alopecia** or **baldness**, refers to a loss of hair from part of the head or body.[1] Typically at least the head is involved.[2] The severity of hair loss can vary from a small area to the entire body.[3] Typically inflammation or scarring is not present.[2] Hair loss in some people causes psychological distress.[4]

Common types include: male-pattern hair loss, female-pattern hair loss, alopecia areata, and a thinning of hair known as telogen effluvium. The cause of male-pattern hair loss is a combination of genetics and male hormones, the cause of female pattern hair loss is unclear, the cause of alopecia areata is autoimmune, and the cause of is telogen effluvium is typically a physically or psychologically stressful event. Telogen effluvium is very common following pregnancy.[2]

Less common causes of hair loss without inflammation or scarring include the pulling out of hair, certain medications including chemotherapy, HIV/AIDS, hypothyroidism, and malnutrition including iron deficiency. Causes of hair loss that occurs with scarring or inflammation include fungal infection, lupus erythematosus, radiation therapy, and sarcoidosis.[2][4] Diagnosis of hair loss is partly based on the areas affected.[2]

Treatment of pattern hair loss may simply involve accepting the condition.[2] Intervention that can be tried include the medications minoxidil or finasteride, and hair transplant surgery.[5][6] Alopecia areata may be treated by steroid injections in the affected area but these need to be frequently repeated to be effective. Hair loss is a common problem. Pattern hair loss by age 50 affects about half of males and a quarter of females. About 2% of people develop alopecia areata at some point in time.[2]

# Terminology

Baldness is the partial or complete lack of hair growth, and part of the wider topic of "hair thinning". The degree and pattern of baldness varies, but its most common cause is androgenic alopecia, *alopecia androgenetica*, or *alopecia seborrheica*, with the last term primarily used in Europe.[*citation needed*]

# Signs and symptoms

Symptoms of hair loss include hair loss in patches usually in circular patterns, dandruff, skin lesions, and scarring. Alopecia areata (mild - medium level) usually shows in unusual hair loss areas e.g. eyebrows, backside of the head or above the ears where usually the male pattern baldness does not affect. In male-pattern hair loss, loss and thinning begin at the temples and the crown and either thins out or falls out. Female-pattern hair loss occurs at the frontal and parietal.

People have between 100,000 and 150,000 hairs on their head. The number of strands normally lost in a day varies, but on average is 100.[7] In order to maintain a normal volume, hair must be replaced at the same rate at which it is lost. The first signs of hair thinning that people will often notice are more hairs than usual left in the hairbrush after brushing or in the basin after shampooing. Styling can also reveal areas of thinning, such as a wider parting or a thinning crown.[*citation needed*]

A case of mid-frontal baldness:

## Skin conditions

A substantially blemished face, back and limbs could point to cystic acne. The most severe form of the condition, cystic acne arises from the same hormonal imbalances that cause hair loss, and is associated with dihydrotestosterone production.[8] Seborrheic dermatitis, a condition in which an excessive amount of sebum is produced and builds up on the scalp (looking like an adult cradle cap) is also a symptom of hormonal imbalances, as is an excessively oily or dry scalp. Both can cause hair

thinning.

## Psychological

Hair thinning and baldness cause psychological stress due to their effect on appearance. Although societal interest in appearance has a long history, this particular branch of psychology came into its own during the 1960s and has gained momentum as messages associating physical attractiveness with success and happiness grow more prevalent.[9]

The psychology of hair thinning is a complex issue. Hair is considered an essential part of overall identity: especially for women, for whom it often represents femininity and attractiveness. Men typically associate a full head of hair with youth and vigor. Although they may be aware of pattern baldness in their family, many are uncomfortable talking about the issue. Hair thinning is therefore a sensitive issue for both sexes. For sufferers, it can represent a loss of control and feelings of isolation. People experiencing hair thinning often find themselves in a situation where their physical appearance is at odds with their own self-image and commonly worry that they appear older than they are or less attractive to others. Psychological problems due to baldness, if present, are typically most severe at the onset of symptoms.[10]

Hair loss induced by cancer chemotherapy has been reported to cause changes in self-concept and body image. Body image does not return to the previous state after regrowth of hair for a majority of patients. In such cases, patients have difficulties expressing their feelings (alexithymia) and may be more prone to avoiding family conflicts. Family therapy can help families to cope with these psychological problems if they arise.[11]

# Causes

Although not completely understood,[*citation needed*] hair loss can have many causes:

## Pattern hair loss

*Main article: Pattern hair loss*

Male pattern hair loss is believed to be due to a combination of genetics and the male hormone dihydrotestosterone.[2] The cause in female pattern hair remains unclear.[2]

## Infection

- Dissecting cellulitis
- Fungal infections (such as tinea capitis)
- Folliculitis
- Secondary syphilis[12]
- *Demodex folliculorum*, a microscopic mite that feeds on the sebum produced by the sebaceous glands, denies hair essential nutrients and can cause thinning. *Demodex folliculorum* is not present on every scalp and is more likely to live in an excessively oily scalp environment.

## Drugs

- Temporary or permanent hair loss can be caused by several medications, including those for blood pressure problems, diabetes, heart disease and cholesterol.[13] Any that affect the body's hormone balance can have a pronounced effect: these include the contraceptive pill, hormone replacement therapy, steroids and acne medications.[14]
- Some treatments used to cure mycotic infections can cause massive hair loss.[15]
- Medications (side effects from drugs, including chemotherapy, anabolic steroids, and birth control pills[16][17])

## Trauma

- Traction alopecia is most commonly found in people with ponytails or cornrows who pull on their hair with excessive force. In addition, rigorous brushing and heat styling, rough scalp massage can damage the cuticle, the hard outer casing of the hair. This causes individual strands to become weak and break off, reducing overall hair volume.
- Trichotillomania is the loss of hair caused by compulsive pulling and bending of the hairs. Onset of this disorder tends to begin around the onset of puberty and usually continues through adulthood. Due to the constant extraction of the hair roots, permanent hair loss can occur.
- Traumas such as childbirth, major surgery, poisoning, and severe stress may cause a hair loss condition known as telogen effluvium,[18] in which a large number of hairs enter the resting phase at the same time, causing shedding and subsequent thinning. The condition also presents as a side effect of chemotherapy – while targeting dividing cancer cells, this treatment also affects hair's growth phase with the result that almost 90% of hairs fall out soon after chemotherapy starts.[19]
- Radiation to the scalp, as when radiotherapy is applied to the head for the treatment of certain cancers there, can cause baldness of the irradiated areas.

## Pregnancy

Hair loss often follows childbirth without causing baldness[*citation needed*]. In this situation, the hair is actually thicker during pregnancy due to increased circulating oestrogens. After the baby is born, the oestrogen levels fall back to normal prepregnancy levels, and the additional hair foliage drops out. A similar situation occurs in women taking the fertility-stimulating drug clomiphene.

## Other causes

- Alopecia areata is an autoimmune disorder also known as "spot baldness" that can result in hair loss ranging from just one location (*Alopecia areata monolocularis*) to every hair on the entire body (*Alopecia areata universalis*). Although thought to be caused by hair follicles becoming dormant, what triggers alopecia areata is not known. In most cases the condition corrects itself, but it can also spread to the entire scalp (alopecia totalis) or to the entire body (alopecia universalis).
- Localized or diffuse hair loss may also occur in cicatricial alopecia (lupus erythematosus, lichen plano pilaris, folliculitis decalvans, central centrifugal cicatricial alopecia, postmenopausal frontal fibrosing alopecia, etc.). Tumours and skin outgrowths also induce localized baldness (sebaceous nevus, basal cell carcinoma, squamous cell carcinoma).
- Hypothyroidism (an under-active thyroid) and the side effects of its related medications can cause hair loss, typically frontal, which is particularly associated with thinning of the outer third of the eyebrows (also seen with syphilis). Hyperthyroidism (an over-active thyroid) can also cause hair loss, which is parietal rather than frontal.[20][*unreliable medical source?*]
- Temporary loss of hair can occur in areas where sebaceous cysts are present for considerable duration (normally one to several weeks).
- Congenital triangular alopecia – It is a triangular, or oval in some cases, shaped patch of hair loss in the temple area of the scalp that occurs mostly in young children. The affected area mainly contains vellus hair follicles or no hair follicles at all, but it does not expand. Its causes are unknown, and although it is a permanent condition, it does not have any other effect on the affected individuals.[21]
- Gradual thinning of hair with age is a natural condition known as involutional alopecia. This is caused by an increasing number of hair follicles switching from the growth, or anagen, phase into a resting phase, or telogen phase, so that remaining hairs become shorter and fewer in number.
- An unhealthy scalp environment can play a significant role in hair thinning by contributing to miniaturization or causing damage[*citation needed*]. Air and water pollutants[*citation needed*], environmental toxins[*citation needed*], conventional styling products and excessive amounts of sebum have the potential to build up on the scalp[*citation needed*]. This debris can block hair follicles and cause their deterioration and consequent miniaturization of hair[*citation needed*]. It can also physically restrict hair growth or damage the hair cuticle[*citation needed*], leading to hair that is weakened and easily broken off before its natural lifecycle has ended.[*citation needed*]

Other causes of hair loss include:

- Alopecia mucinosa
- Biotinidase deficiency
- Chronic inflammation
- Diabetes[22]
- Lupus erythematosus
- Pseudopelade of Brocq
- Telogen effluvium
- Tufted folliculitis

The port-wine stain of Mikhail Gorbachev (pictured here with Ronald Reagan) would have remained unknown if he had not been bald.

## Pathophysiology

Hair follicle growth occurs in cycles. Each cycle consists of a long growing phase (anagen), a short transitional phase (catagen) and a short resting phase (telogen). At the end of the resting phase, the hair falls out (exogen) and a new hair starts growing in the follicle beginning the cycle again.

Normally, about 40 (0–78 in men) hairs reach the end of their resting phase each day and fall out.[23] When more than 100 hairs fall out per day, clinical hair loss (telogen effluvium) may occur.[*citation needed*] A disruption of the growing phase causes abnormal loss of anagen hairs (anagen effluvium).

## Diagnosis

Because they are not usually associated with an increased loss rate, male-pattern and female-pattern hair loss do not generally require testing. If hair loss occurs in a young man with no family history, drug use could be the cause.

- **The pull test** helps to evaluate diffuse scalp hair loss. Gentle traction is exerted on a group of hairs (about 40–60) on three different areas of the scalp. The number of extracted hairs is counted and examined under a microscope. Normally, fewer than three hairs per area should come out with each pull. If more than ten hairs are obtained, the pull test is considered positive.[24]
- **The pluck test** is conducted by pulling hair out "by the roots". The root of the plucked hair is examined under a microscope to determine the phase of growth, and is used to diagnose a defect of telogen, anagen, or systemic disease. Telogen hairs have tiny bulbs without sheaths at their roots. Telogen effluvium shows an increased percentage of hairs upon examination. Anagen hairs have sheaths attached to their roots. Anagen effluvium shows a decrease in telogen-phase hairs and an increased number of broken hairs.
- **Scalp biopsy** is used when the diagnosis is unsure; a biopsy allows for differing between scarring and nonscarring forms. Hair samples are taken from areas of inflammation, usually around the border of the bald patch.
- **Daily hair counts** are normally done when the pull test is negative. It is done by counting the number of hairs lost. The hair from the first morning combing or during washing should be counted. The hair is collected in a clear plastic bag for 14 days. The strands are recorded. If the hair count is >100/day, it is considered abnormal except after shampooing, where hair counts will be up to 250 and be normal.[*citation needed*]
- **Trichoscopy** is a noninvasive method of examining hair and scalp. The test may be performed with the use of a handheld dermoscope or a video dermoscope. It allows differential diagnosis of hair loss in most cases.[25]

There are two types of identification tests for female pattern baldness: the Ludwig Scale and the Savin Scale. Both track the progress of diffused thinning, which typically begins on the crown of the head behind the hairline, and becomes gradually more pronounced. For male pattern baldness, the Hamilton–Norwood scale tracks the progress of a receding hairline and/or a thinning crown, through to a horseshoe-shaped ring of hair around the head and on to total baldness.

In almost all cases of thinning, and especially in cases of severe hair loss, it is recommended to seek advice

from a doctor or dermatologist. Many types of thinning have an underlying genetic or health-related cause, which a qualified professional will be able to diagnose.

## Medications

Treatments for the various forms of hair loss have limited success. Three medications have evidence to support their use in male pattern hair loss: finasteride, dutasteride and minoxidil.[26][27] They typically work better to prevent further hair loss than to regrow lost hair.[26]

- Minoxidil (Rogaine) is a nonprescription medication approved for male pattern baldness and alopecia areata. In a liquid or foam, it is rubbed into the scalp twice a day. Some people have an allergic reaction to the propylene glycol in the minoxidil solution and a minoxidil foam was developed without propylene glycol. Not all users will regrow hair. The longer the hair has stopped growing, the less likely minoxidil will regrow hair. Minoxidil is not effective for other causes of hair loss. Hair regrowth can take 1 to 6 months to begin. Treatment must be continued indefinitely. If the treatment is stopped, hair loss resumes. Any regrown hair and any hair susceptible to being lost, while Minoxidil was used, will be lost. Most frequent side effects are mild scalp irritation, allergic contact dermatitis, and unwanted hair in other parts of the body.[27]
- Finasteride (Propecia) is used in male-pattern hair loss in a pill form, taken 1 milligram per day. It is not indicated for women and is not recommended in pregnant women. Treatment is effective starting within 6 weeks of treatment. Finasteride causes an increase in hair retention, the weight of hair, and some increase in regrowth. Side effects in about 2% of males, include decreased sex drive, erectile dysfunction, and ejaculatory dysfunction. Treatment should be continued as long as positive results occur. Once treatment is stopped, hair loss resumes.[27]
- Corticosteroids injections into the scalp can be used to treat alopecia areata. This type of treatment is repeated on a monthly basis. Oral pills for extensive hair loss may be used for alopecia areata. Results may take up to a month to be seen.
- Immunosuppressants applied to the scalp have been shown to temporarily reverse alopecia areata, though the side effects of some of these drugs make such therapy questionable.[28]
- There is some tentative evidence that anthralin maybe useful alopecia areata.[29]
- Hormonal modulators (oral contraceptives or antiandrogens such as spironolactone and flutamide) can be used for female-pattern hair loss associated with hyperandrogenemia.

## Surgery

Hair transplantation is usually carried out under local anaesthetic. A surgeon will move healthy hair from the back and sides of the head to areas of thinning. The procedure can take between four and eight hours, and additional sessions can be carried out to make hair even thicker. Transplanted hair falls out within a few weeks, but regrows permanently within months. Hair transplants, takes tiny plugs of skin, each which contains a few hairs, and implants the plugs into bald sections. The plugs are generally taken from the back or sides of the scalp. Several transplant sessions may be necessary.[30]

- Surgical options, such as follicle transplants, scalp flaps, and hair loss reduction, are available. These procedures are generally chosen by those who are self-conscious about their hair loss, but they are expensive and painful, with a risk of infection and scarring. Once surgery has occurred, six to eight months are needed before the quality of new hair can be assessed.
  - Scalp reduction is the process is the decreasing of the area of bald skin on the head. In time, the skin on the head becomes flexible and stretched enough that some of it can be surgically removed. After the hairless scalp is removed, the space is closed with hair-covered scalp. Scalp reduction is generally done in combination with hair transplantation to provide a natural-looking hairline, especially those with extensive hair loss.
  - Hairline lowering can sometimes be used to lower a high hairline secondary to hair loss, although

there may be a visible scar after further hair loss.
- Wigs are an alternative to medical and surgical treatment; some patients wear a wig or hairpiece. They can be used permanently or temporarily to cover the hair loss. High-quality, natural-looking wigs and hairpieces are available.

## Hiding hair loss

### Head

One method of hiding hair loss is the "comb over", which involves restyling the remaining hair to cover the balding area. It is usually a temporary solution, useful only while the area of hair loss is small. As the hair loss increases, a comb over becomes less effective.

Another method is to wear a hat or a hairpiece—a wig or toupee. The wig is a layer of artificial or natural hair made to resemble a typical hair style. In most cases the hair is artificial. Wigs vary widely in quality and cost. In the United States, the best wigs—those that look like real hair—cost up to tens of thousands of dollars. Organizations also collect individuals' donations of their own natural hair to be made into wigs for young cancer patients who have lost their hair due to chemotherapy or other cancer treatment in addition to any type of hair loss.

General Douglas MacArthur wearing a comb over.

### Eyebrows

Though not as common as the loss of hair on the head, chemotherapy, hormone imbalance, forms of hair loss, and other factors can also cause loss of hair in the eyebrows. Loss of growth in the outer one third of the eyebrow is often associated with hypothyroidism. Artificial eyebrows are available to replace missing eyebrows or to cover patchy eyebrows. Eyebrow embroidery is another option which involves the use of a blade to add pigment to the eyebrows. This gives a natural 3D look for those who are worried about an artificial look and it lasts for two years. Micropigmentation (permanent makeup tattooing) is also available for those who want the look to be permanent.

## Chemotherapy

Hypothermia caps may be useful to prevent hair loss during some kinds of chemotherapy, specifically when tazanes or anthracyclines are used.[31] It should not be used when cancer is present in the skin of the scalp or for lymphoma or leukemia.[32] There are generally only minor side effects from treatment.[33]

## Embracing baldness

Instead of concealing hair loss, some may embrace it by shaving their head. A shaved head will grow stubble in the same manner and at the same rate as a shaved face. The general public has become accepting of the shaved head as well, though female baldness can be considered less socially acceptable in various parts of the world.

## Alternative medicine

Dietary supplements are not typically recommended.[27] There is only one small trial of saw palmetto which shows tentative benefit in those with mild to moderate androgenetic alopecia.[27] There is no evidence for biotin.[27] Evidence for most other produces is also insufficient.[34] There was no good evidence for gingko, aloe vera, ginseng, bergamot, hibiscus, or sorphora as of 2011.[34]

Many people use unproven treatments.[26] Egg oil, in Indian,[35] Japanese, Unani (Roghan Baiza Murgh)[36] and Chinese[37] traditional medicine, was traditionally used as a treatment for hair loss.[*medical citation needed*]

# Research

Research is looking into connections between hair loss and other health issues. While there has been speculation about a connection between early-onset male pattern hair loss and heart disease, a review of articles from 1954 to 1999 found no conclusive connection between baldness and coronary artery disease. The dermatologists who conducted the review suggested further study was needed.[38]

Environmental factors are under review. A 2007 study indicated that smoking may be a factor associated with age-related hair loss among Asian men. The study controlled for age and family history, and found statistically significant positive associations between moderate or severe male pattern hairloss and smoking status.[39]

Vertex baldness is associated with an increased risk of coronary heart disease (CHD) and the relationship depends upon the severity of baldness, while frontal baldness is not. Thus, vertex baldness might be a marker of CHD and is more closely associated with atherosclerosis than frontal baldness.[23]

## Hair follicle aging

A key aspect of hair loss with age is the aging of the hair follicle.[40] Ordinarily, hair follicle renewal is maintained by the stem cells associated with each follicle. Aging of the hair follicle appears to be primed by a sustained cellular response to the DNA damage that accumulates in renewing stem cells during aging.[41] This damage response involves the proteolysis of type XVII collagen by neutrophil elastase in response to the DNA damage in the hair follicle stem cells. Proteolysis of collagen leads to elimination of the damaged cells and then to terminal hair follicle miniaturization.

# Etymology

The term *alopecia* (/ˌæləˈpiːʃiə/) is from the Classical Greek ἀλώπηξ, *alōpēx*, meaning "fox". The origin of this usage is because this animal sheds its coat twice a year, or because in ancient Greece foxes often lost hair because of mange.

The term *bald* likely derives from the English word *balde*, which means "white, pale" or Celtic *ball*, which means "white patch or blaze", such as on a horse's head.[42]

# Head lice infestation

From Wikipedia, the free encyclopedia

*This article is about the infestation. For the animal, see Head louse.*

**Head lice infestation** (also known as **pediculosis capitis**,[1] **nits**,[2] or **cooties**[3]) is the infection of the head hair and scalp by the head louse (*Pediculus humanus capitis*).[4] Itching from lice bites is common.[5] During a person's first infection, the itch may not develop for up to six weeks.[5] If a person is infected again, symptoms may begin much more quickly.[5] The itch may cause problems with sleeping.[6] Generally, however, it is not a serious condition.[7] While head lice appear to spread some other diseases in Africa, they do not appear to do so in Europe or North America.[4][6]

Head lice are spread by direct contact with the hair of someone who is infected.[6] The cause of head lice infestations are not related to cleanliness.[5] Other animals, such as cats and dogs, do not play a role in transmission.[6] Head lice feed only on human blood and are only able to survive on human head hair.[4][5] When adults, they are about 2 to 3 mm long.[8] When not attached to a human, they are unable to live beyond three days.[5] Humans can also become infected with two other lice – the body louse and the crab louse. To make the diagnosis, live lice must be found.[5] Using a comb can help with detection.[5] Empty eggshells (known as nits) are not sufficient for the diagnosis.[5]

Possible treatments include: combing the hair frequently with a fine tooth comb or shaving the head completely. A number of topical medications are also effective, including malathion, ivermectin, and dimethicone.[7] Dimethicone, which is a silicone oil, is often preferred due to the low risk of side effects.[7] Pyrethroids such as permethrin have been commonly used; however, have become less effective due to increasing pesticide resistance.[7] There is little evidence for alternative medicines.[9]

Head-lice infestations are common, especially in children.[5] In Europe, they infect between 1 and 20% of different groups of people.[4] In the United States, between 6 and 12 million children are infected a year.[6] They occur more often in girls than boys.[5] It has been suggested that historically, head lice

## Signs and symptoms [edit]

Head lice are generally uncomfortable, but typically do not constitute a serious condition.[7] The most common symptom is itching of the head, which normally worsens 3 to 4 weeks after the initial infestation.[*citation needed*] The bite reaction is very mild, and it can be rarely seen between the hairs. Bites can be seen, especially in the neck of long-haired individuals when the hair is pushed aside. Swelling of the local lymph nodes and fever are rare. Itching may cause skin breakdown and uncommonly result in a bacterial infection.[7]

Adult male (left) and female (right) head lice

In Ethiopia, head lice appear to be able to spread louse-born epidemic typhus and *Bartonella quintana*.[4] In Europe, the head lice do not appear to carry these infections.[4]

## Cause [edit]

Head lice are generally spread through direct head-to-head contact with an infested person.[5] Transmission by sharing bedding or clothing such as headwear is much less common.[11] The cause of head lice infestations is not related to cleanliness.[5] Neither hair length nor how often the hair is brushed affect the risk of infection.[12]

Body lice are spread through direct contact with the body, clothing, or other personal items of a person already carrying lice. Pubic lice are most often spread by intimate contact with an infested person. Head lice occur on the head hair, body lice on the clothing, and pubic lice mainly on the hair near the groin. Lice cannot burrow into the skin.

## Diagnosis [edit]

The condition is diagnosed by finding live lice in the hair. Finding empty eggs is not enough.[5] This is made easier by using a magnifying glass or running a comb through the child's hair. In questionable cases, a

child can be referred to a health professional. However, the condition is overdiagnosed, with extinct infestations being mistaken for active ones. As a result, lice-killing treatments are more often used on noninfested than infested children.[13] The use of a louse comb is the most effective way to detect living lice.[14] With both methods, special attention should be paid to the area near the ears and the nape of the neck. The use of a magnifying glass to examine the material collected between the teeth of the comb could prevent misdiagnosis.

The presence of nits alone, however, is not an accurate indicator of an active head louse infestation. Generally, white nits are empty egg casings, while brown nits may still contain viable louse larva. One way of determining the nit is to squeeze it between two fingernails; it gives a characteristic snapping pop sound as the egg bursts. Children with nits on their hair have a 35–40% chance of also being infested with living lice and eggs.[14][15] If lice are detected, the entire family needs to be checked (especially children up to the age of 13 years) with a louse comb, and only those who are infested with living lice should be treated. As long as no living lice are detected, the child should be considered negative for head louse infestation. Accordingly, a child should be treated with a pediculicide only when living lice are detected on their hair (not because he/she has louse eggs/nits on the hair and not because the scalp is itchy).[16]

## Prevention [edit]

Examination of the child's head at regular intervals using a louse comb allows the diagnosis of louse infestation at an early stage. Early diagnosis makes treatment easier and reduces the possibility of infesting others. In times and areas when louse infestations are common, weekly examinations of children, especially those 4–15 years old, carried out by their parents, will aid control. Additional examinations are necessary if the child came in contact with infested individuals, if the child frequently scratches his/her head, or if nits suddenly appear on the child's hair. Keeping long hair tidy could be helpful in the prevention of infestations with head lice.

Clothes, towels, bedding, combs, and brushes, which came in contact with the infested individual, can be disinfected either by leaving them outside for at least two days or by washing them at 60 °C (140 degrees F) for 30 minutes.[17] This is because adult lice can survive only one to two days without a blood meal and are highly dependent on human body warmth.[18] An insecticidal treatment of the house and furniture is not necessary.

## Treatment [edit]

*Main article: Treatment of human head lice*

There are a number of treatments effective for head lice. These methods include combs, shaving, medical creams, and hot air.[19] Medical creams usually require two treatments a week apart.[7] Head lice are not justification to keep children home from school as the risk of spread is low.[12]

### Mechanical measures [edit]

[7]

Shaving the head can effectively treat lice. Wet combing a few times a day for a few weeks may also get rid of the infestation in half of people.[7] This requires the use of a special lice comb with extra fine teeth.[7] This is the recommended method for infants and women who are pregnant.[7]

Another treatment is the use of heated air applied by a hair dryer.[19]

### Medications [edit]

There are many medications which can kill lice. Dimethicone is between 70 and 97% effective with a low rate of side effects, and thus is seen as the preferred treatment.[7] It works by physical means and there is no evidence of pesticide resistance.[4] Ivermectin is around 80% effective, but can cause local skin irritation. Malathion has an effectiveness around 90%, but there's the possibility of toxicity.[7] Pyrethroids such as permethrin, while commonly used, have lower rates of effectiveness due to the resistance among lice.[7] Effectiveness varies from 10 to 80%, depending on the population studied.[5][7] Medications within a lotions appear to work better than those within a shampoo.[7] Benzyl alcohol appears effective but it is unclear if it is better than standard treatments.[20]

### Alternative medicine [edit]

Tea tree oil has been promoted as a treatment for head lice; however, there is no clear evidence of its effectiveness.[21][22] A 2012 review of head lice treatment recommended against the use of tea tree oil for children because it could cause skin irritation or allergic reactions, because of contraindications, and because of a lack of knowledge about the oil's safety and effectiveness.[23] Other home remedies, such as putting vinegar, isopropyl alcohol, olive oil, mayonnaise, or melted butter under a shower cap, have been disproven.[9] The CDC states that swimming has no effect on lice, and can decrease the effectiveness of some treatments.[24]

### Environment [edit]

After treatment, people are often instructed to wash all bedding and vacuum all areas the head may have been, such as car seats, coat hoods, and sofas, but this is not always necessary, since adult lice will die within 2 days without a blood meal, and newly hatched lice die within minutes of hatching.[19] Combs and brushes may be deloused in boiling water for 5–10 minutes. Items may also be frozen for 24 hours well below the freezing point of water to ensure that ice crystals form within the cells of the lice.[25]

## Epidemiology [edit]

The number of cases of human louse infestations (or pediculosis) has increased worldwide since the mid-1960s, reaching hundreds of millions annually.[27] It is estimated between 1 and 20% of specific groups in Europe are infected.[4]

Despite improvements in medical treatment and prevention of human diseases during the 20th century, head louse infestation remains stubbornly prevalent. In 1997, 80% of American elementary schools reported at least one outbreak of lice.[28] Lice infestation during that same period was more prevalent than chickenpox.[28]

> “Reliable data describing the usual incidence of infestation in the general public, in the average school community, or during specific times of the year are lacking.”
>
> — Janis Hootman, 2002[26]

About 6–12 million children between the ages of 3 and 11 are treated annually for head lice in the United States alone.[11] High levels of louse infestations have also been reported from all over the world, including Israel, Denmark, Sweden, U.K., France, and Australia.[16][29]

The number of children per family, the sharing of beds and closets, hair washing habits, local customs and social contacts, healthcare in a particular area (e.g. school), and socioeconomic status were found to be [*citation needed*]

significant factors in head louse infestation. Children between 4 and 13 years of age are the most frequently infested group.[30] In the U.S., African-American children have lower rates of infestation.[11]

The United Kingdom's National Health Service[*citation needed*] and many American health agencies report that lice "prefer" clean hair because it's easier to attach eggs and to cling to the strands; however, this is often contested.

Head lice (*Pediculus humanus capitis*) infestation is most frequent on children aged 3–10 and their families.[31] Females get head lice twice as often as males,[31] and infestation in persons of Afro-Caribbean or other black descent is rare because of hair consistency.[31] But these children may have nits that hatch and the live lice could be transferred by head contact to other children.[32]

## Society and culture [edit]

- To a Louse (on a lady's bonnet). Perhaps the most widely known cultural reference to pediculosis capitis, occurring in a noted poem by Robert Burns.

## Other animals [edit]

Lice infestation in general is known as pediculosis, and occurs in many mammalian and bird species.[33] They are not the same organism as that which causes head lice infestations in humans.

# Herpes simplex

From Wikipedia, the free encyclopedia

*"Herpes" redirects here. For the medical journal, see Herpes (journal). For the virus that causes herpes simplex, see Herpes simplex virus. For all types of herpes viruses, see Herpesviridae.*

**Herpes simplex** (Greek: ἕρπης *herpēs*, "creeping" or "latent") is a viral disease caused by the herpes simplex virus.[1] Infections are categorized based on the part of the body infected. Oral herpes involves the face or mouth. It may result in small blisters in groups often called cold sores or fever blisters or may just cause a sore throat.[2][3] Genital herpes, often simply known as herpes, may have minimal symptoms or form blisters that break open and result in small ulcers. These typically heal over two to four weeks. Tingling or shooting pains may occur before the blisters appear. Herpes cycles between periods of active disease followed by periods without symptoms. The first episode is often more severe and may be associated with fever, muscle pains, swollen lymph nodes and headaches. Over time, episodes of active disease decrease in frequency and severity.[1] Other disorders caused by herpes simplex include: herpetic whitlow when it involves the fingers,[4] herpes of the eye,[5] herpes infection of the brain,[6] and neonatal herpes when it affects a newborn, among others.[7]

There are two types of herpes simplex virus, type 1 (HSV-1) and type 2 (HSV-2).[1] HSV-1 more commonly causes oral infections while HSV-2 more commonly causes genital infections.[2] They are transmitted by direct contact with body fluids or lesions of an infected individual. Transmission may still occur when symptoms are not present. Genital herpes is classified as a sexually transmitted infection. It may be spread to an infant during childbirth.[1] After infection, the viruses are transported along sensory nerves to the nerve cell bodies, where they reside lifelong.[2] Causes of recurrence may include: decreased immune function, stress, and sunlight exposure.[2][8] Oral and genital herpes is usually diagnosed based on the presenting symptoms.[2] The diagnosis may be confirmed by viral culture or detecting herpes DNA in fluid from blisters. Testing the blood for antibodies against the virus can confirm a previous infection but will be negative in new infections.[1]

The most effective method of avoiding genital infections is by avoiding vaginal, oral, and anal sex. Condom use decreases the risk somewhat. Daily antiviral medication taken by someone who has the infection can also reduce spread. There is no available vaccine and once infected, there is no cure.[1] Paracetamol (acetaminophen) and topical lidocaine may be used to help with the symptoms.[2] Treatments with antiviral medication such as aciclovir or valaciclovir can lessen the severity of symptomatic episodes.[1][2]

Worldwide rates of either HSV-1 or HSV-2 are between 60% and 95% in adults.[9] HSV-1 is usually acquired during childhood.[1] Rates of both increase as people age.[9] Rates of HSV-1 are between 70% and 80% in populations of low socioeconomic status and 40% to 60% in populations of improved socioeconomic status.[9] An estimated 536 million people worldwide (16% of the population) were infected with HSV-2 as of 2003 with greater rates among women and those in the developing world.[10] Most people with HSV-2 do not realize that they are [1]

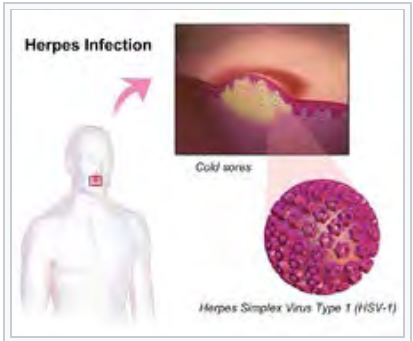
infected.

## Classification

Herpes simplex is divided into two types; HSV-1 causes primarily mouth, throat, face, eye, and central nervous system infections, whereas HSV-2 causes primarily anogenital infections. However, each may cause infections in all areas.[9]

## Signs and symptoms

HSV infection causes several distinct medical disorders. Common infection of the skin or mucosa may affect the face and mouth (orofacial herpes), genitalia (genital herpes), or hands (herpetic whitlow). More serious disorders occur when the virus infects and damages the eye (herpes keratitis), or invades the central nervous system, damaging the brain (herpes encephalitis). People with immature or suppressed immune systems, such as newborns, transplant recipients, or people with AIDS, are prone to severe complications from HSV infections. HSV infection has also been associated with cognitive deficits of bipolar disorder,[11] and Alzheimer's disease, although this is often dependent on the genetics of the infected person.



Herpes infection

In all cases, HSV is never removed from the body by the immune system. Following a primary infection, the virus enters the nerves at the site of primary infection, migrates to the cell body of the neuron, and becomes latent in the ganglion.[12] As a result of primary infection, the body produces antibodies to the particular type of HSV involved, preventing a subsequent infection of that type at a different site. In HSV-1-infected individuals, seroconversion after an oral infection prevents additional HSV-1 infections such as whitlow, genital herpes, and herpes of the eye. Prior HSV-1 seroconversion seems to reduce the symptoms of a later HSV-2 infection, although HSV-2 can still be contracted.

Many people infected with HSV-2 display no physical symptoms—individuals with no symptoms are described as asymptomatic or as having subclinical herpes.[13]

| Herpes labialis | Infection occurs when the virus comes into contact with oral mucosa or abraded skin. |  |
| Herpes genitalis | When symptomatic, the typical manifestation of a primary HSV-1 or HSV-2 genital infection is clusters of inflamed papules and vesicles on the outer surface of the genitals resembling cold sores. |  |
| Herpetic whitlow and herpes gladiatorum | Herpes whitlow is a painful infection that typically affects the fingers or thumbs. On occasion, infection occurs on the toes or on the nail cuticle. Individuals who participate in contact sports such as wrestling, rugby, and football(soccer), sometimes acquire a condition caused by HSV-1 known as herpes gladiatorum, scrumpox, wrestler's herpes, or mat herpes, which presents as skin ulceration on the face, ears, and neck. Symptoms include fever, headache, sore throat, and swollen glands. It occasionally affects the eyes or eyelids. |  |
| Herpesviral encephalitis and herpesviral meningitis | A herpetic infection of the brain thought to be caused by the transmission of virus from a peripheral site on the face following HSV-1 reactivation, along the trigeminal nerve axon, to the brain. HSV is the most common cause of viral encephalitis. When infecting the brain, the virus shows a preference for the temporal lobe.[14] HSV-2 is the most common cause of Mollaret's meningitis, a type of recurrent viral meningitis. |  |
| Herpes esophagitis | Symptoms may include painful swallowing (odynophagia) and difficulty swallowing (dysphagia). It is often associated with impaired immune function (e.g. HIV/AIDS, immunosuppression in solid organ transplants). |  |

## Other

Neonatal herpes simplex is a HSV infection in an infant. It is a rare but serious condition, usually caused by vertical transmission of HSV-1 or -2) from mother to newborn. During immunodeficiency, herpes simplex can cause unusual lesions in the skin. One of the most striking is the appearance of clean linear erosions in skin creases, with the appearance of a knife cut.[15] Herpetic sycosis is a recurrent or initial herpes simplex infection affecting primarily the hair follicles.[16]:369 Eczema herpeticum is an infection with herpesvirus in patients with chronic atopic dermatitis may result in spread of herpes simples throughout the eczematous areas.[16]:373

Herpetic keratoconjunctivitis, a primary infection, typically presents as swelling of the conjunctiva and eyelids (blepharoconjunctivitis), accompanied by small white itchy lesions on the surface of the cornea.

Herpetic sycosis is a recurrent or initial herpes simplex infection affecting primarily the hair follicle.[16]:369[17]

### Bell's palsy

Although the exact cause of Bell's palsy—a type of facial paralysis—is unknown, it may be related to reactivation of HSV-1.[18] This theory has been contested, however, since HSV is detected in large numbers of individuals having never experienced facial paralysis, and higher levels of antibodies for HSV are not found in HSV-infected individuals with Bell's palsy compared to those without.[19] Regardless antivirals have been found to not improve outcomes.[20]

### Alzheimer's disease

HSV-1 has been proposed as a possible cause of Alzheimer's disease.[21][22] In the presence of a certain gene variation (APOE-epsilon4 allele carriers), HSV-1 appears to be particularly damaging to the nervous system and increases one's risk of developing Alzheimer's disease. The virus interacts with the components and receptors of lipoproteins, which may lead to its development.[23][24]

## Pathophysiology

Herpes is contracted through direct contact with an active lesion or body fluid of an infected person.[26] Herpes transmission occurs between discordant partners; a person with a history of infection (HSV seropositive) can pass the virus to an HSV seronegative person. Herpes simplex virus 2 is typically contracted through direct skin-to-skin contact with an infected individual, but can also be contracted by exposure to infected saliva, semen, vaginal fluid, or the fluid from herpetic blisters.[27] To infect a new individual, HSV travels through tiny breaks in the skin or mucous membranes in the mouth or genital areas. Even microscopic abrasions on mucous membranes are sufficient to allow viral entry.

**Herpes shedding**[25]

| | |
|---|---|
| HSV-2 genital | 15–25% of days |
| HSV-1 oral | 6–33% of days |
| HSV-1 genital | 5% of days |
| HSV-2 oral | 1% of days |

HSV asymptomatic shedding occurs at some time in most individuals infected with herpes. It can occur more than a week before or after a symptomatic recurrence in 50% of cases.[28] Virus enters into susceptible cells by entry receptors[29] such as nectin-1, HVEM and 3-O sulfated heparan sulfate.[30] Infected people who show no visible symptoms may still shed and transmit viruses through their skin; asymptomatic shedding may represent the most common form of HSV-2 transmission.[28] Asymptomatic shedding is more frequent within the first 12 months of acquiring HSV. Concurrent infection with HIV increases the frequency and duration of asymptomatic shedding.[31] Some individuals may have much lower patterns of shedding, but evidence supporting this is not fully verified; no significant differences are seen in the frequency of asymptomatic shedding when comparing persons with one to 12 annual recurrences to those with no recurrences.[28]

Antibodies that develop following an initial infection with a type of HSV prevents reinfection with the same virus type—a person with a history of orofacial infection caused by HSV-1 cannot contract herpes whitlow or a genital infection caused by HSV-1.[*citation needed*] In a monogamous couple, a seronegative female runs a greater than 30% per year risk of contracting an HSV infection from a seropositive male partner.[32] If an oral HSV-1 infection is contracted first, seroconversion will have occurred after 6 weeks to provide protective antibodies against a future genital HSV-1 infection. Herpes simplex is a double-stranded DNA virus.[33]

## Diagnosis

Primary orofacial herpes is readily identified by clinical examination of persons with no previous history of lesions and contact with an individual with known HSV-1 infection. The appearance and distribution of sores in these individuals typically presents as multiple, round, superficial oral ulcers, accompanied by acute gingivitis.[34] Adults with atypical presentation are more difficult to diagnose. Prodromal symptoms that occur before the appearance of herpetic lesions help differentiate HSV symptoms from the similar symptoms of other disorders, such as allergic stomatitis. When lesions do not appear inside the mouth, primary orofacial herpes is sometimes mistaken for impetigo, a bacterial infection. Common mouth ulcers (aphthous ulcer) also resemble intraoral herpes, but do not present a vesicular stage.[34]

Genital herpes can be more difficult to diagnose than oral herpes, since most HSV-2-infected persons have no classical symptoms.[34] Further confusing diagnosis, several other conditions resemble genital herpes, including fungal infection, lichen planus, atopic dermatitis, and urethritis.[34] Laboratory testing is often used to confirm a

diagnosis of genital herpes. Laboratory tests include culture of the virus, direct fluorescent antibody (DFA) studies to detect virus, skin biopsy, and polymerase chain reaction to test for presence of viral DNA. Although these procedures produce highly sensitive and specific diagnoses, their high costs and time constraints discourage their regular use in clinical practice.[34]

Until the 1980s serological tests for antibodies to HSV were rarely useful to diagnosis and not routinely used in clinical practice.[34] The older IgM serologic assay could not differentiate between antibodies generated in response to HSV-1 or HSV-2 infection. However, a glycoprotein G-specific (IgG) HSV test introduced in the 1980s is more than 98% specific at discriminating HSV-1 from HSV-2.[35]

It should not be confused with conditions caused by other viruses in the *herpesviridae* family such as herpes zoster, which is caused by varicella zoster virus. The differential diagnosis includes hand, foot and mouth disease due to similar lesions on the skin.

# Prevention

As with almost all sexually transmitted infections, women are more susceptible to acquiring genital HSV-2 than men.[36] On an annual basis, without the use of antivirals or condoms, the transmission risk of HSV-2 from infected male to female is about 8–11%.[32][37] This is believed to be due to the increased exposure of mucosal tissue to potential infection sites. Transmission risk from infected female to male is around 4–5% annually.[37] Suppressive antiviral therapy reduces these risks by 50%.[38] Antivirals also help prevent the development of symptomatic HSV in infection scenarios, meaning the infected partner will be seropositive but symptom-free by about 50%. Condom use also reduces the transmission risk significantly.[39][40] Condom use is much more effective at preventing male-to-female transmission than *vice versa*.[39] Previous HSV-1 infection may reduce the risk for acquisition of HSV-2 infection among women by a factor of three, although the one study that states this has a small sample size of 14 transmissions out of 214 couples.[41]

Barrier protection, such as a condom, can reduce the risk of herpes transmission.

However, asymptomatic carriers of the HSV-2 virus are still contagious. In many infections, the first symptom people will have of their own infections is the horizontal transmission to a sexual partner or the vertical transmission of neonatal herpes to a newborn at term. Since most asymptomatic individuals are unaware of their infection, they are considered at high risk for spreading HSV.[42]

In October 2011, the anti-HIV drug tenofovir, when used topically in a microbicidal vaginal gel, was reported to reduce herpes virus sexual transmission by 51%.[43]

## Barrier methods

Condoms offer moderate protection against HSV-2 in both men and women, with consistent condom users having a 30%-lower risk of HSV-2 acquisition compared with those who never use condoms.[44] A female condom can provide greater protection than the male condom, as it covers the labia.[45] The virus cannot pass through a synthetic condom, but a male condom's effectiveness is limited[46] because herpes ulcers may appear on areas not covered by it. Neither type of condom prevents contact with the scrotum, anus, buttocks, or upper thighs, areas that may come in contact with ulcers or genital secretions during sexual activity. Protection against herpes simplex depends on the site of the ulcer; therefore, if ulcers appear on areas not covered by condoms, abstaining from sexual activity until the ulcers are fully healed is one way to limit risk of transmission.[47] The risk is not eliminated, however, as viral shedding capable of transmitting infection may still occur while the infected partner is asymptomatic.[48] The use of condoms or dental dams also limits the transmission of herpes from the genitals of one partner to the mouth of the other (or *vice versa*) during oral sex. When one partner has a herpes simplex infection and the other does not, the use of antiviral medication, such as valaciclovir, in conjunction with a condom, further decreases the chances of transmission to the uninfected partner.[12] Topical microbicides that contain chemicals that directly inactivate the virus and block viral entry are being investigated.[12]

## Antivirals

Antivirals may reduce asymptomatic shedding; asymptomatic genital HSV-2 viral shedding is believed to occur on 20% of days per year in patients not undergoing antiviral treatment, *versus* 10% of days while on antiviral therapy.[28]

### Pregnancy

The risk of transmission from mother to baby is highest if the mother becomes infected around the time of delivery (30% to 60%),[49][50] since insufficient time will have occurred for the generation and transfer of protective maternal antibodies before the birth of the child. In contrast, the risk falls to 3% if the infection is recurrent,[51] and is 1–3% if the woman is seropositive for both HSV-1 and HSV-2,[51][52] and is less than 1% if no lesions are visible.[51] Women seropositive for only one type of HSV are only half as likely to transmit HSV as infected seronegative mothers. To prevent neonatal infections, seronegative women are recommended to avoid unprotected oral-genital contact with an HSV-1-seropositive partner and conventional sex with a partner having a genital infection during the last trimester of pregnancy. Mothers infected with HSV are advised to avoid procedures that would cause trauma to the infant during birth (e.g. fetal scalp electrodes, forceps, and vacuum extractors) and, should lesions be present, to elect caesarean section to reduce exposure of the child to infected secretions in the birth canal.[12] The use of antiviral treatments, such as acyclovir, given from the 36th week of pregnancy, limits HSV recurrence and shedding during childbirth, thereby reducing the need for caesarean section.[12]

Acyclovir is the recommended antiviral for herpes suppressive therapy during the last months of pregnancy. The use of valaciclovir and famciclovir, while potentially improving compliance, have less-well-determined safety in pregnancy.

## Management

No method eradicates herpes virus from the body, but antiviral medications can reduce the frequency, duration, and severity of outbreaks. Analgesics such as ibuprofen and paracetamol (acetaminophen) can reduce pain and fever. Topical anesthetic treatments such as prilocaine, lidocaine, benzocaine, or tetracaine can also relieve itching and pain.[53][54][55]

### Antiviral

Several antiviral drugs are effective for treating herpes, including acyclovir, valaciclovir (valacyclovir), famciclovir, and penciclovir. Acyclovir was the first discovered and is now available in generic.[56] Valacyclovir is also available as a generic.[57]

Evidence supports the use of acyclovir and valacyclovir in the treatment of herpes labialis[58] as well as herpes infections in people with cancer.[59] The evidence to support the use of acyclovir in primary herpetic gingivostomatitis is weaker.[60]

The antiviral medication acyclovir

### Topical

A number of topical antivirals are effective for herpes labialis, including acyclovir, penciclovir, and docosanol.[58][61]

### Alternative medicine

Certain dietary supplements and alternative remedies are claimed to be beneficial in the treatment of herpes.[62] Evidence is insufficient, though, to support use of many of these compounds, including echinacea, eleuthero, L-lysine, zinc, monolaurin bee products, and aloe vera.[63] While a number of small studies show possible benefit from monolaurin, L-lysine, aspirin, lemon balm, topical zinc, or licorice root cream in treatment, these preliminary studies have not been confirmed by higher-quality randomized controlled studies.[64]

## Prognosis

Following active infection, herpes viruses establish a latent infection in sensory and autonomic ganglia of the nervous system. The double-stranded DNA of the virus is incorporated into the cell physiology by infection of the nucleus of a nerve's cell body. HSV latency is static; no virus is produced; and is controlled by a number of viral genes, including latency-associated transcript.[65]

Many HSV-infected people experience recurrence within the first year of infection.[12] Prodrome precedes development of lesions. Prodromal symptoms include tingling (paresthesia), itching, and pain where lumbosacral

nerves innervate the skin. Prodrome may occur as long as several days or as short as a few hours before lesions develop. Beginning antiviral treatment when prodrome is experienced can reduce the appearance and duration of lesions in some individuals. During recurrence, fewer lesions are likely to develop and are less painful and heal faster (within 5–10 days without antiviral treatment) than those occurring during the primary infection.[12] Subsequent outbreaks tend to be periodic or episodic, occurring on average four or five times a year when not using antiviral therapy.

The causes of reactivation are uncertain, but several potential triggers have been documented. A 2009 study showed the protein VP16 plays a key role in reactivation of the dormant virus.[66] Changes in the immune system during menstruation may play a role in HSV-1 reactivation.[67][68] Concurrent infections, such as viral upper respiratory tract infection or other febrile diseases, can cause outbreaks. Reactivation due to other infections is the likely source of the historic terms 'cold sore' and 'fever blister'.

Other identified triggers include local injury to the face, lips, eyes, or mouth; trauma; surgery; radiotherapy; and exposure to wind, ultraviolet light, or sunlight.[69][70][71][72][73]

The frequency and severity of recurrent outbreaks vary greatly between people. Some individuals' outbreaks can be quite debilitating, with large, painful lesions persisting for several weeks, while others experience only minor itching or burning for a few days. Some evidence indicates genetics play a role in the frequency of cold sore outbreaks. An area of human chromosome 21 that includes six genes has been linked to frequent oral herpes outbreaks. An immunity to the virus is built over time. Most infected individuals experience fewer outbreaks and outbreak symptoms often become less severe. After several years, some people become perpetually asymptomatic and no longer experience outbreaks, though they may still be contagious to others. Immunocompromised individuals may experience longer, more frequent, and more severe episodes. Antiviral medication has been proven to shorten the frequency and duration of outbreaks.[74] Outbreaks may occur at the original site of the infection or in proximity to nerve endings that reach out from the infected ganglia. In the case of a genital infection, sores can appear at the original site of infection or near the base of the spine, the buttocks, or the back of the thighs. HSV-2-infected individuals are at higher risk for acquiring HIV when practicing unprotected sex with HIV-positive persons, in particular during an outbreak with active lesions.[75]

## Epidemiology

*Main article: Epidemiology of herpes simplex*

Worldwide rates of either HSV-1 and/or HSV-2 are between 60 and 95% in adults.[9] HSV-1 is more common than HSV-2, with rates of both increasing as people age.[9] HSV-1 rates are between 70% and 80% in populations of low socioeconomic status and 40% to 60% in populations of improved socioeconomic status.[9] An estimated 536 million people or 16% of the population worldwide were infected with HSV-2 as of 2003 with greater rates among women and in those in the developing world.[10] Rates of infection are determined by the presence of antibodies against either viral species.[76]

In the US, 57.7% of the population is infected with HSV-1[77] and 16.2% are infected with HSV-2. Among those HSV-2-seropositive, only 18.9% were aware they were infected.[78] During 2005–2008, the prevalence of HSV-2 was 39.2% in blacks and 20.9% in women.[79]

The annual incidence in Canada of genital herpes due to HSV-1 and HSV-2 infection is not known (for a review of HSV-1/HSV-2 prevalence and incidence studies worldwide, see Smith and Robinson 2002). As many as one in seven Canadians [80] aged 14 to 59 may be infected with herpes simplex type 2 virus and more than 90 per cent of them may be unaware of their status, a new study suggests.[81] In the United States, it is estimated that about 1,640,000 HSV-2 seroconversions occur yearly (730,000 men and 910,000 women, or 8.4 per 1,000 persons).[82]

In British Columbia in 1999, the seroprevalence of HSV-2 antibody in leftover serum submitted for antenatal testing revealed a prevalence of 17.3%, ranging from 7.1% in women 15–19 years old to 28.2% in those 40–44 years.[83]

In Norway, a study published in 2000 found that 90% of genital initial infections were due to HSV-1.[84]

In Nova Scotia, 58.1% of 1,790 HSV isolates from genital lesion cultures in women were HSV-1; in men, 36.7% of 468 isolates were HSV-1.[85]

## History

Herpes has been known for at least 2,000 years. Emperor Tiberius is said to have banned kissing in Rome for a

time due to so many people having cold sores. In the 16th-century *Romeo and Juliet*, blisters "o'er ladies' lips" are mentioned. In the 18th century, it was so common among prostitutes that it was called "a vocational disease of women".[86] The term 'herpes simplex' appeared in Richard Boulton's *A System of Rational and Practical Chirurgery* in 1713, where the terms 'herpes miliaris' and 'herpes exedens' also appeared. Herpes was not found to be a virus until the 1940s.[86]

Herpes antiviral therapy began in the early 1960s with the experimental use of medications that interfered with viral replication called deoxyribonucleic acid (DNA) inhibitors. The original use was against normally fatal or debilitating illnesses such as adult encephalitis,[87] keratitis,[88] in immunocompromised (transplant) patients,[89] or disseminated herpes zoster.[90] The original compounds used were 5-iodo-2'-deoxyuridine, AKA idoxuridine, IUdR, or(IDU) and 1-β-D-arabinofuranosylcytosine or ara-C,[91] later marketed under the name cytosar or cytorabine. The usage expanded to include topical treatment of herpes simplex,[92] zoster, and varicella.[93] Some trials combined different antivirals with differing results.[87] The introduction of 9-β-D-arabinofuranosyladenine, (ara-A or vidarabine), considerably less toxic than ara-C, in the mid-1970s, heralded the way for the beginning of regular neonatal antiviral treatment. Vidarabine was the first systemically administered antiviral medication with activity against HSV for which therapeutic efficacy outweighed toxicity for the management of life-threatening HSV disease. Intravenous vidarabine was licensed for use by the U.S. Food and Drug Administration in 1977. Other experimental antivirals of that period included: heparin,[94] trifluorothymidine (TFT),[95] Ribivarin,[96] interferon,[97] Virazole,[98] and 5-methoxymethyl-2'-deoxyuridine (MMUdR).[99] The introduction of 9-(2-hydroxyethoxymethyl)guanine, AKA acyclovir, in the late 1970s[100] raised antiviral treatment another notch and led to vidarabine vs. acyclovir trials in the late 1980s.[101] The lower toxicity and ease of administration over vidarabine has led to acyclovir becoming the drug of choice for herpes treatment after it was licensed by the FDA in 1998.[102] Another advantage in the treatment of neonatal herpes included greater reductions in mortality and morbidity with increased dosages, which did not occur when compared with increased dosages of vidarabine.[102] However, acyclovir seems to inhibit antibody response, and newborns on acyclovir antiviral treatment experienced a slower rise in antibody titer than those on vidarabine.[102]

# Society and culture

Genital herpes simplex was not always stigmatised. It was merely a cold sore in an unusual place until the 1970s. As late as 1975, a study of "Psychological morbidity in a clinic for sexually transmitted disease" does not mention herpes simplex because at that time, no significant morbidity problem (i.e. mental anxiety or illness) was associated with the virus.[103]

Pedro Cuatrecasas states, "during the R&D of acyclovir (Zovirax), marketing [department of Burroughs Wellcome] insisted that there were 'no markets' for this compound. Most had hardly heard of genital herpes..." Thus, marketing the medical condition – separating the 'normal cold sore' from the 'stigmatized genital infection' was to become the key to marketing the drug, a process now known as 'disease mongering'.[104][105]

Since the creation of the herpes hype, some people experience negative feelings related to the condition following diagnosis, in particular if they have acquired the genital form of the disease. Feelings can include depression, fear of rejection, feelings of isolation, fear of being found out, and self-destructive feelings.[106] These feelings usually lessen over time. Much of the hysteria and stigma surrounding herpes stems from a media campaign beginning in the late 1970s and peaking in the early 1980s. Multiple articles were worded in fear-mongering and anxiety-provoking terminology, such as the now-ubiquitous "attacks", "outbreaks", "victims", and "sufferers". At one point, the term "herpetic" even entered the popular lexicon. The articles were published by *Reader's Digest*, *U.S. News*, and *Time* magazine, among others. A made-for-TV movie was named *Intimate Agony*. The peak was when *Time* magazine had 'Herpes: The New Scarlet Letter' on the cover in August 1982, forever stigmatizing the word in the public mind.[86] Herpes support groups have been formed in the United States and the UK, providing information about herpes and running message forums and dating websites for sufferers. People with the herpes virus are often hesitant to divulge to other people, including friends and family, that they are infected. This is especially true of new or potential sexual partners whom they consider casual.[107]

In a 2007 study, 1900 people (25% of which had herpes) ranked genital herpes second for social stigma, out of all sexually transmitted diseases (HIV took the top spot for STD stigma).[108][109][110]

## Support groups

### USA

An important source of support is the *National Herpes Resource Center* which arose from the work of the American

Social Health Association (ASHA).[111] The ASHA was created in 1914 to in response to the increase in social diseases that had spread during World War 1.[112] During the 1970s, there was an increase in sexually transmitted diseases. One of the diseases that increased dramatically was genital herpes. In response, ASHA created the National Herpes Resource Center in 1979. The HRC was designed to meet the growing need for education and awareness about the virus. One of the projects of The Herpes Resource Center (HRC) was to create a network of local support (HELP) groups. The goal of these HELP groups was to provide a safe, confidential environment where participants can get accurate information and share experiences, fears, and feelings with others who are concerned about herpes.[113][114]

### UK

In the UK, the Herpes Association (now the Herpes Viruses Association) was started in 1982, becoming a registered charity with a Dept of Health grant in 1985. The charity started as a string of local group meetings before acquiring an office and a national spread.[115]

## Research

*Main article: Herpes simplex research*

Research has gone into vaccines for both prevention and treatment of herpes infections. Unsuccessful clinical trials have been conducted for glycoprotein subunit vaccines. For therapy, only a single replication-competent HSV vaccine has undergone human testing. As of 2011, the future pipeline includes several promising replication-incompetent vaccine proposals while two replication-competent vaccine proposals require further animal testing.[116]

Another possibility to eradicate the HSV-1 variant is being pursued by a team at Duke University. By figuring out how to switch all copies of the virus in the host from latency to their active stage at the same time, rather than the way the virus copies normally stagger their activity stage, leaving some dormant somewhere at all times, conventional antiviral drugs might kill the entire virus population, since they can no longer hide in the nerve cells. One class of drugs called antagomir could serve this purpose. These are chemically engineered oligonucleotides or short segments of RNA that can be made to mirror their target genetic material, namely herpes microRNAs. They could be engineered to attach and thus 'silence' the microRNA, thus rendering the virus incapable of remaining latent in its host.[117] Professor Cullen believes a drug could be developed to block the microRNA whose job it is to suppress HSV-1 into latency.[118]

A genomic study of the herpes simplex type 1 virus confirmed the human migration pattern theory called 'out-of-Africa hypothesis'.[119]

# Shingles

From Wikipedia, the free encyclopedia
(Redirected from Herpes zoster)

*For other uses, see Shingle (disambiguation).*
*"Zoster" redirects here. For the ancient Greek article of dress, see Zoster (costume).*

**Shingles**, also known as **herpes zoster**, is a viral disease characterized by a painful skin rash with blisters in a localized area.[1][2] Typically the rash occurs in a single stripe either on the left or right of the body or face.[3] Two to four days before the rash occurs there may be tingling or local pain in the area.[3][4] Otherwise there are typically few symptoms.[3] The rash usually heals within two to four weeks;[1] however, some people develop ongoing nerve pain which can last for months or years, a condition called postherpetic neuralgia. In those with poor immune function the rash may occur widely.[3] If the rash involves the eye, vision loss may occur.[1]

Shingles is due to a reactivation of varicella zoster virus (VZV) within a person's body. Chickenpox is due to an initial infection with VZV. Once chickenpox has resolved, the virus may remain inactive in nerve cells.[3] When it reactivates it travels from the nerve body to the endings in the skin producing blisters.[4] Risk factors for reactivation include old age, poor immune function, and having had chickenpox before 18 months of age. How the virus remains in the body or subsequently re-activates, is not well understood.[3] Exposure to the virus in the blisters can cause chickenpox in someone who has not had it before but will not trigger shingles.[5] Diagnosis is typically based on a person's signs and symptoms.[6] Varicella zoster virus is not the same as herpes simplex virus, however, they belong to the same family of viruses.[7]

The shingles vaccine decreases the chance of shingles by about half in those between the ages of 50 and 80. It also decreases rates of postherpetic neuralgia, and if an outbreak occurs, its severity. After 80 the vaccine is still effective, just less so. It contains the same material as the varicella vaccine, just at a higher dose.[3] If shingles develops, antiviral medications such as aciclovir can reduce the severity and duration of disease if started within 72 hours of the appearance of the rash.[6] Evidence does not show a significant effect of antivirals or steroids on rates of postherpetic neuralgia.[8][9] Paracetamol, NSAIDs, or opioids may be used to help with the acute pain.[6]

It is estimated that about a third of people develop shingles at some point in their life.[3] While more common among older [7]

people, children may also get the disease. The number of new cases per year ranges from 1.2–3.4 per 1,000 among healthy individuals to 3.9–11.8 per 1,000 among those older than 65 years of age.[10] About half of those living to age 85 will have at least one attack, and less than 5% will have more than one attack.[3][11] The disease has been recognized since ancient times.[3]

## Signs and symptoms [edit]

The earliest symptoms of shingles, which include headache, fever, and malaise, are nonspecific, and may result in an incorrect diagnosis.[10][12] These symptoms are commonly followed by sensations of burning pain, itching, hyperesthesia (oversensitivity), or paresthesia ("pins and needles": tingling, pricking, or numbness).[13] Pain can be mild to extreme in the affected dermatome, with sensations that are often described as stinging, tingling, aching, numbing or throbbing, and can be interspersed with quick stabs of agonizing pain.[14]

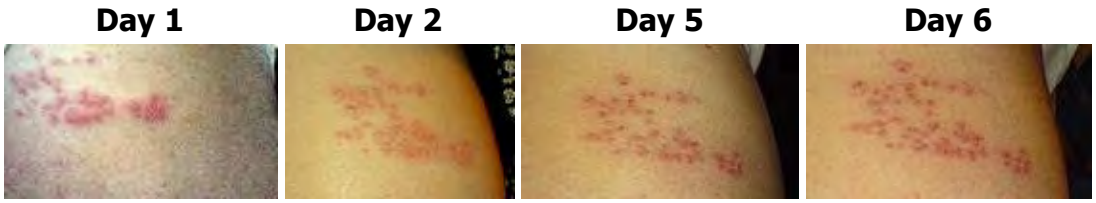
A case of shingles that demonstrates the typical dermatomal distribution, in this case C8/T1

Shingles in children is often painless, but people are more likely to get shingles as they age, and the disease tends to be more severe.[15]

In most cases after one to two days, but sometimes as long as three weeks, the initial phase is followed by the appearance of the characteristic skin rash. The pain and rash most commonly occurs on the torso, but can appear on the face, eyes or other parts of the body. At first the rash appears similar to the first appearance of hives; however, unlike hives, shingles causes skin changes limited to a dermatome, normally resulting in a stripe or belt-like pattern that is limited to one side of the body and does not cross the midline.[13] *Zoster sine herpete* ("zoster without herpes") describes a person who has all of the symptoms of shingles except this characteristic rash.[16]

Later the rash becomes vesicular, forming small blisters filled with a serous exudate, as the fever and general malaise continue. The painful vesicles eventually become cloudy or darkened as they fill with blood, and crust over within seven to ten days; usually the crusts fall off and the skin heals, but sometimes, after severe blistering, scarring and discolored skin remain.[13]

**Development of the shingles rash**



## Face [edit]

Shingles may have additional symptoms, depending on the dermatome involved. The trigeminal nerve is the most commonly involved nerve.[17]

The ophthalmic division of the trigeminal nerve is the most commonly involved branch.[18] When the virus is reactivated in this nerve branch it is termed *zoster ophthalmicus*. The skin of the forehead, upper eyelid and orbit of the eye may be involved. Zoster ophthalmicus occurs in approximately 10% to 25% of cases. In some people, symptoms may include conjunctivitis, keratitis, uveitis, and optic nerve palsies that can sometimes cause chronic ocular inflammation, loss of vision, and debilitating pain.[19]

*Shingles oticus*, also known as Ramsay Hunt syndrome type II, involves the ear. It is thought to result from the virus spreading from the facial nerve to the vestibulocochlear nerve. Symptoms include hearing loss and vertigo (rotational dizziness).[20]

Shingles may occur in the mouth if the maxillary or mandibular division of the trigeminal nerve is affected,[21] in which the rash may appear on the mucous membrane of the upper jaw (usually the palate, sometimes the gums of the upper teeth) or the lower jaw (tongue or gums of the lower teeth) respectively.[22] Oral involvement may occur alone or in combination with a rash on the skin over the cutaneous distribution of the same trigeminal branch.[21] As with shingles of the skin, the lesions tend to only involve one side, distinguishing it from other oral blistering conditions.[22] In the mouth, shingles appears initially as 1–4 mm opaque blisters (vesicles),[21] which break down quickly to leave ulcers that heal within 10–14 days.[22] The prodromal pain (before the rash) may be confused with toothache.[21] Sometimes this leads to unnecessary dental treatment.[22] Post herpetic neuralgia uncommonly is associated with shingles in the mouth.[22] Unusual complications may occur with intra-oral shingles that are not seen elsewhere. Due to the close relationship of blood vessels to nerves, the virus can spread to involve the blood vessels and compromise the blood supply, sometimes causing ischemic necrosis.[21] Therefore, oral involvement rarely causes complications such as osteonecrosis, tooth loss, periodontitis (gum disease), pulp calcification, pulp necrosis, periapical lesions and tooth developmental anomalies.[17]

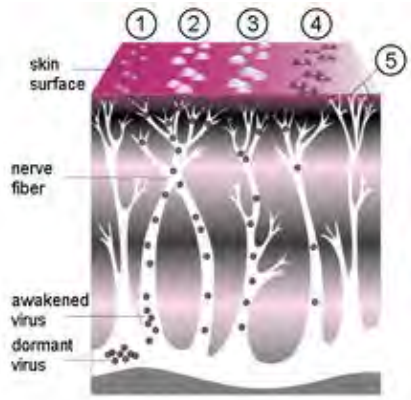
## Disseminated shingles [edit]

In those with poor immune function, *disseminated shingles* may occur (wide rash).[3] It is defined as more than twenty skin lesions appearing outside either the primarily affected dermatome or dermatomes directly adjacent to it. Besides the skin, other organs, such as the liver or brain, may also be affected (causing hepatitis or encephalitis[23][24] respectively), making the condition potentially lethal.[25]:380

# Pathophysiology [edit]

The causative agent for shingles is the varicella zoster virus (VZV)—a double-stranded DNA virus related to the Herpes simplex virus. Most individuals are infected with this virus as children which causes an episode of chickenpox. The immune system eventually eliminates the virus from most locations, but it remains dormant (or latent) in the ganglia adjacent to the spinal cord (called the dorsal root ganglion) or the trigeminal ganglion in the base of the skull.[26]

Shingles occurs only in people who have been previously infected with VZV; although it can occur at any age, approximately half of the cases in the USA occur in those aged 50 years or older.[27] Repeated attacks of shingles are rare,[13] and it is extremely rare for a person to have more than three recurrences.[26]



Progression of shingles. A cluster of small bumps (1) turns into blisters (2). The blisters fill with lymph, break open (3), crust over (4), and finally disappear. Postherpetic neuralgia can sometimes occur due to nerve damage (5).

The disease results from virus particles in a single sensory ganglion switching from their latent lysogenic cycles to their active lytic cycles.[28] In contrast to the herpes simplex virus, the latency of VZV is poorly understood. The virus has never been successfully recovered from human nerve cells by cell culture. The complete sequence of the viral genome was published in 1986.[29] Virus-specific proteins continue to be made by the infected cells during the latent period, so true latency, as opposed to chronic, low-level, active infection, has not been proven to occur in VZV infections.[30][31] Although VZV has been detected in autopsies of nervous tissue,[32] there are no methods to find dormant virus in the ganglia of living people.

Unless the immune system is compromised, it suppresses reactivation of the virus and prevents shingles outbreaks. Why this suppression sometimes fails is poorly understood,[33] but shingles is more likely to occur in people whose immune systems are impaired due to aging, immunosuppressive therapy, psychological stress, or other factors.[34] Upon reactivation, the virus replicates in neuronal cell bodies, and virions are shed from the cells and carried down the axons to the area of skin innervated by that ganglion. In the skin, the virus causes local inflammation and blistering. The short- and long-term pain caused by shingles outbreaks originates from inflammation of affected nerves due to the widespread growth of the virus in those areas.[35]

As with chickenpox and/or other forms of herpes, direct contact with an active rash can spread VZV to a person who has no immunity to the virus. This newly infected individual may then develop chickenpox, but will not immediately develop shingles.[13]

## Diagnosis [edit]

Shingles on the chest

If the rash has appeared, identifying this disease (making a differential diagnosis) requires only a visual examination, since very few diseases produce a rash in a dermatomal pattern (see map). However, herpes simplex virus (HSV) can occasionally produce a rash in such a pattern (zosteriform herpes simplex).[36][37] The Tzanck smear is helpful for diagnosing acute infection with a herpes virus, but does not distinguish between HSV and VZV.[38]

When the rash is absent (early or late in the disease, or in the case of zoster sine herpete), shingles can be difficult to diagnose.[39] Apart from the rash, most symptoms can occur also in other conditions.

Laboratory tests are available to diagnose shingles. The most popular test detects VZV-specific IgM antibody in blood; this appears only during chickenpox or shingles and not while the virus is dormant.[40] In larger laboratories, lymph collected from a blister is tested by polymerase chain reaction for VZV DNA, or examined with an electron microscope for virus particles.[41] Molecular biology tests based on in vitro nucleic acid amplification (PCR tests) are currently considered the most reliable. Nested PCR test has high sensitivity, but is susceptible to contamination leading to false positive results. The latest real-time PCR tests are rapid, easy to perform, and as sensitive as nested PCR, and have a lower risk of contamination. They also have more sensitivity than viral cultures.[42]

## Differential diagnosis [edit]

Shingles can be confused with herpes simplex, dermatitis herpetiformis and impetigo, and skin reactions caused by contact dermatitis, candidiasis, certain drugs and insect bites.[43]

# Prevention [edit]

There is a live vaccine for VZV, known as the zoster vaccine.[44] It must be maintained at a temperature not exceeding −15 °C during shipping and storage, although it can be stored and transported at refrigerator temperature for up to 72 continuous hours before reconstitution. The incidence of side effects is low. There is no recommended upper age limit.[45]

A systematic review by Cochrane concluded that the herpes zoster vaccine was useful for preventing herpes zoster for at least three years.[4] This equates to about 50% relative risk reduction. The vaccine reduced incidence of persistent, severe pain after shingles (i.e., PHN) by 66% in people who contracted shingles despite vaccination.[45]

In the Shingles Prevention Study (SPS), vaccine efficacy was maintained through four years of follow-up.[45] Following one dose of live attenuated vaccine 69% were protected in the first year and 4% after eight years. Two doses of a adjuvanted herpes zoster subunit vaccine had levels of protection of about 90% at 3.5 years.[46]

An episode of HZ has an immunizing effect, reducing the probability of a subsequent recurrence. However, individuals with a history of severe HZ are often insistent on receiving the vaccine, and there have been concerns about the validity of people's histories of HZ. Both the Centers for Disease Control and Prevention and the ACIP recommended the vaccination of adults regardless of a previous episode of HZ.[45]

It has been recommended that people with primary or acquired immunodeficiency should not receive the vaccine.[45]

The likelihood of vaccination causing a case of HZ appears to be very low.[45]

A 2007 study found that the shingles vaccine is likely to be cost-effective in the U.S., projecting an annual savings of $82 to $103 million in healthcare costs with cost-effectiveness ratios ranging from $16,229 to $27,609 per quality-adjusted life year gained.[47] In October 2007 the vaccine was officially recommended in the U.S. for healthy adults aged 60 and over.[44][48] The Centers for Disease Control and Prevention recommends shingle vaccine for use in people 60 years old and older to prevent shingles, but it is not recommended to treat active shingles or postherpetic neuralgia (pain after the rash is gone) once it develops.[49] Adults also receive an immune boost from contact with children infected with varicella (chicken pox), a boosting method that prevents about a quarter of shingles cases among unvaccinated adults, but that is becoming less common in the U.S. now that children are routinely vaccinated against varicella.[50][51]

In the United Kingdom and other parts of Europe, population-based varicella immunization is not practiced. The rationale is that until the entire population could be immunized, adults who have previously contracted VZV would instead derive benefit from occasional exposure to VZV (from children), which serves as a booster to their immunity to the virus, and may reduce the risk of shingles later on in life.[52] The UK Health Protection Agency states that, while the vaccine is licensed in the UK, there are no plans to introduce it into the routine childhood immunization scheme, although it may be offered to healthcare workers who have no immunity to VZV.[53]

From 2013 the UK National Health Service started offering shingles vaccination, with Zostavax, to elderly people. People aged either 70 or 79 on 1 September 2013 were offered the vaccine. People aged 71 to 78 on that date would only have an opportunity to have the shingles vaccine after reaching the age of 79.[54] The original intention was for people aged *between* 70 and 79 to be vaccinated, but the NHS later said that the vaccination programme was being staggered as it would be impractical to vaccinate everyone in their 70s in a single year.[55]

# Treatment [edit]

The aims of treatment are to limit the severity and duration of pain, shorten the duration of a shingles episode,

and reduce complications. Symptomatic treatment is often needed for the complication of postherpetic neuralgia.[56] However, a study on untreated shingles shows that, once the rash has cleared, postherpetic neuralgia is very rare in people under 50 and wears off in time; in older people the pain wore off more slowly, but even in people over 70, 85% were pain free a year after their shingles outbreak.[57]

### Analgesics [edit]

People with mild to moderate pain can be treated with over-the-counter pain medications. Topical lotions containing calamine can be used on the rash or blisters and may be soothing. Occasionally, severe pain may require an opioid medication, such as morphine. Once the lesions have crusted over, capsaicin cream (Zostrix) can be used. Topical lidocaine and nerve blocks may also reduce pain.[58] Administering gabapentin along with antivirals may offer relief of postherpetic neuralgia.[56]

### Antivirals [edit]

Antiviral drugs may reduce the severity and duration of shingles;[59] however, they do not prevent postherpetic neuralgia.[60] Of these drugs, acyclovir has been the standard treatment, but the new drugs valaciclovir and famciclovir demonstrate similar or superior efficacy and good safety and tolerability.[56] The drugs are used both for prevention (for example in HIV/AIDS) and as therapy during the acute phase. Complications in immunocompromised individuals with shingles may be reduced with intravenous acyclovir. In people who are at a high risk for repeated attacks of shingles, five daily oral doses of acyclovir are usually effective.[20]

### Steroids [edit]

Corticosteroids do not appear to decrease the risk of long term pain.[61] Side effects however appear to be minimal. Their use in Ramsay Hunt syndrome has not been properly studied as of 2008.[62]

### Zoster ophthalmicus [edit]

Treatment for zoster ophthalmicus is similar to standard treatment for shingles at other sites. A recent trial comparing acyclovir with its prodrug, valaciclovir, demonstrated similar efficacies in treating this form of the disease.[63] The significant advantage of valciclovir over aciclovir is its dosing of only 3 times/day (compared with aciclovir's 5 times/day dosing), which could make it more convenient for people and improve adherence with therapy.[64]

## Prognosis [edit]

The rash and pain usually subside within three to five weeks, but about one in five people develop a painful condition called postherpetic neuralgia, which is often difficult to manage. In some people, shingles can reactivate presenting as *zoster sine herpete*: pain radiating along the path of a single spinal nerve (a *dermatomal distribution*), but without an accompanying rash. This condition may involve complications that affect several levels of the nervous system and cause many cranial neuropathies, polyneuritis, myelitis, or aseptic meningitis. Other serious effects that may occur in some cases include partial facial paralysis (usually temporary), ear damage, or encephalitis.[20] During pregnancy, first infections with VZV, causing chickenpox, may lead to infection of the fetus and complications in the newborn, but chronic infection or reactivation in shingles are not associated with fetal infection.[65][66]

Trigeminal shingles with uveitis

There is a slightly increased risk of developing cancer after a shingles infection. However, the mechanism is unclear and mortality from cancer did not appear to increase as a direct result of the presence of the virus.[67] Instead, the increased risk may result from the immune suppression that

and keratitis

allows the reactivation of the virus.[68]

Although shingles typically resolves within 3–5 weeks, certain complications may arise:

- Secondary bacterial infection
- Motor involvement, including weakness especially in "motor herpes zoster"
- Eye involvement: trigeminal nerve involvement (as seen in herpes ophthalmicus) should be treated early and aggressively as it may lead to blindness. Involvement of the tip of the nose in the zoster rash is a strong predictor of herpes ophthalmicus.[69]
- Postherpetic neuralgia, a condition of chronic pain following shingles

## Epidemiology [edit]

Varicella zoster virus (VZV) has a high level of infectivity and has a worldwide prevalence.[70] Shingles is a re-activation of latent VZV infection: zoster can only occur in someone who has previously had chickenpox (varicella).

Shingles has no relationship to season and does not occur in epidemics. There is, however, a strong relationship with increasing age.[15][34] The incidence rate of shingles ranges from 1.2 to 3.4 per 1,000 person years among younger healthy individuals, increasing to 3.9–11.8 per 1,000 person years among those older than 65 years,[10][15] and incidence rates worldwide are similar.[10][71] This relationship with age has been demonstrated in many countries,[10][71][72][73][74][75] and is attributed to the fact that cellular immunity declines as people grow older.

Another important risk factor is immunosuppression, as in people with HIV.[76][77] Other risk factors include psychological stress.[14][78][79] According to a study in North Carolina, "black subjects were significantly less likely to develop zoster than were white subjects."[80][81] It is unclear whether the risk is different by gender. Other potential risk factors include mechanical trauma and exposure to immunotoxins.[34][79]

There is no strong evidence for a genetic link or a link to family history. A 2008 study showed that people with close relatives who had had shingles were twice as likely to develop it themselves,[82] but a 2010 study found no such link.[79]

Adults with latent VZV infection who are exposed intermittently to children with chickenpox receive an immune boost.[15][79] This periodic boost to the immune system helps to prevent shingles in older adults. When routine chickenpox vaccination was introduced in the United States, there was concern that, because older adults would no longer receive this natural periodic boost, there would be an increase in the incidence of shingles.

Multiple studies and surveillance data, at least when viewed superficially, demonstrate no consistent trends in incidence in the U.S. since the chickenpox vaccination program began in 1995.[83] However, upon closer inspection, the two studies that showed no increase in shingles incidence were conducted among populations where varicella vaccination was not as yet widespread in the community.[84][85] A later study by Patel *et al.* concluded that since the introduction of the chickenpox vaccine, hospitalization costs for complications of shingles increased by more than $700 million annually for those over age 60.[86] Another study by Yih *et al*. reported that as varicella vaccine coverage in children increased, the incidence of varicella decreased, and the occurrence of shingles among adults increased by 90%.[87] The results of a further study by Yawn *et al*. showed a 28% increase in shingles incidence from 1996 to 2001.[88] It is likely that incidence rate will change in the future, due to the aging of the population, changes in therapy for malignant and autoimmune diseases, and changes in chickenpox vaccination rates; a wide adoption of zoster vaccination could dramatically reduce the incidence rate.[10]

In one study, it was estimated that 26% of those who contract shingles eventually present complications.

Postherpetic neuralgia arises in approximately 20% of people with shingles.[89] A study of 1994 California data found hospitalization rates of 2.1 per 100,000 person-years, rising to 9.3 per 100,000 person-years for ages 60 and up.[90] An earlier Connecticut study found a higher hospitalization rate; the difference may be due to the prevalence of HIV in the earlier study, or to the introduction of antivirals in California before 1994.[91]

## History [edit]

Shingles has a long recorded history, although historical accounts fail to distinguish the blistering caused by VZV and those caused by smallpox,[27] ergotism, and erysipelas. In the late 18th century William Heberden established a way to differentiate between shingles and smallpox,[92] and in the late 19th century shingles was differentiated from erysipelas. In 1831 Richard Bright hypothesized that the disease arose from the dorsal root ganglion, and an 1861 paper by Felix von Bärensprung confirmed this.[93]

The first indications that chickenpox and shingles were caused by the same virus were noticed at the beginning of the 20th century. Physicians began to report that cases of shingles were often followed by chickenpox in the younger people who lived with the person with shingles. The idea of an association between the two diseases gained strength when it was shown that lymph from a person with shingles could induce chickenpox in young volunteers. This was finally proved by the first isolation of the virus in cell cultures, by the Nobel laureate Thomas Huckle Weller, in 1953.[94]

Until the 1940s the disease was considered benign, and serious complications were thought to be very rare.[95] However, by 1942, it was recognized that shingles was a more serious disease in adults than in children, and that it increased in frequency with advancing age. Further studies during the 1950s on immunosuppressed individuals showed that the disease was not as benign as once thought, and the search for various therapeutic and preventive measures began.[96] By the mid-1960s, several studies identified the gradual reduction in cellular immunity in old age, observing that in a cohort of 1,000 people who lived to the age of 85, approximately 500 (i.e., 50%) would have at least one attack of shingles, and 10 (i.e., 1%) would have at least two attacks.[97]

In historical shingles studies, shingles incidence generally increased with age. However, in his 1965 paper, Dr. Hope-Simpson suggested that the "peculiar age distribution of zoster may in part reflect the frequency with which the different age groups encounter cases of varicella and because of the ensuing boost to their antibody protection have their attacks of zoster postponed".[15] Lending support to this hypothesis that contact with children with chickenpox boosts adult cell-mediated immunity to help postpone or suppress shingles, a study by Thomas et al. reported that adults in households with children had lower rates of shingles than households without children.[98] Also, the study by Terada et al. indicated that pediatricians reflected incidence rates from 1/2 to 1/8 that of the general population their age.[99]

### Etymology [edit]

The family name of all the herpesviridae derives from the Greek word *herpein* ("to creep"),[100] referring to the latent, recurring infections typical of this group of viruses. *Zoster* comes from Greek *zōstēr*, meaning "belt" or "girdle", after the characteristic belt-like dermatomal rash.[101] The common name for the disease, *shingles*, derives from the Latin *cingulus*, a variant of Latin *cingulum* meaning "girdle".[102]

In Arabic its name means "belt of fire", while in Spanish it means "small snake"; in Hindi it means "big rash"[103] and in Norwegian its name is *helvetesild*, literally "hell's fire".[104]

## Research [edit]

Until the mid 1990s, infectious complications of the Central Nervous System (CNS) caused by VZV reactivation were regarded as rare. The presence of rash, as well as specific neurological symptoms, were required to diagnose a CNS infection caused by VZV. Since 2000, PCR testing has become more widely used, and the number of diagnosed cases of CNS infection has increased.[105]

Classic textbook descriptions state that VZV reactivation in the CNS is restricted to immunocompromised individuals and the elderly, however, recent studies have found that most patients are immunocompetent, and less than 60 years old. Old references cite vesicular rash as a characteristic finding, however, recent studies have

found that rash is only present in 45% of cases.[105] In addition, systemic inflammation is not as reliable an indicator as previously thought: the mean level of C-reactive protein and mean white blood cell count are within the normal range in patients with VZV meningitis.[106] MRI and CT scans are usually normal in cases of VZV reactivation in the CNS. CSF pleocytosis, previously thought to be a strong indicator of VZV encephalitis, was absent in half of a group of patients diagnosed with VZV encephalitis by PCR.[105]

The frequency of CNS infections presented at the emergency room of a community hospital is not negligible, so a means of diagnosing cases is needed. PCR is not a foolproof method of diagnosis, but because so many other indicators have turned out to not be reliable in diagnosing VZV infections in the CNS, screening for VZV by PCR is recommended. Negative PCR does not rule out VZV involvement, but a positive PCR can be used for diagnosis, and appropriate treatment started (for example, antivirals can be prescribed rather than antibiotics).[105]

The introduction of DNA analysis techniques has shown some complications of varicella-zoster to be more common than previously thought. For example, sporadic meningoencephalitis (ME) caused by varicella-zoster was regarded as rare disease, mostly related to childhood chickenpox. However, meningoencephalitis caused by varicella-zoster is increasingly recognized as a predominant cause of ME among immunocompetent adults in non-epidemic circumstances.[107]

Diagnosis of complications of varicella-zoster, particularly in cases where the disease reactivates after years or decades of latency, are difficult. A rash (shingles) can be present or absent. Symptoms vary, and there is significant overlap in symptoms with herpes-simplex symptoms.[107]

Although DNA analysis techniques such as polymerase chain reaction can be used to look for DNA of herpesviruses in spinal fluid or blood, the results may be negative, even in cases where other definitive symptoms exist.[108] Notwithstanding these limitations, the use of PCR has resulted in an advance in the state of the art in our understanding of herpesviruses, including VZV, during the 1990s and 2000s. For example, in the past, clinicians believed that encephalitis was caused by herpes simplex, and that patients always died or developed serious long term function problems. People were diagnosed at autopsy or by brain biopsy. Brain biopsy is not undertaken lightly: it is reserved only for serious cases that cannot be diagnosed by less invasive methods. For this reason, knowledge of these herpes virus conditions was limited to severe cases. DNA techniques have made it possible to diagnose "mild" cases, caused by VZV or HSV, in which the symptoms include fever, headache, and altered mental status. Mortality rates in treated patients are decreasing.[107]

# Measles

From Wikipedia, the free encyclopedia

**Measles** is a highly contagious infection caused by the measles virus.[1][2] Initial signs and symptoms typically include fever, often greater than 40 °C (104.0 °F), cough, runny nose, and inflamed eyes.[1][3] Two or three days after the start of symptoms, small white spots may form inside the mouth, known as Koplik's spots. A red, flat rash which usually starts on the face and then spreads to the rest of the body typically begins three to five days after the start of symptoms.[3] Symptoms usually develop 10–12 days after exposure to an infected person and last 7–10 days.[4][5] Complications occur in about 30% and may include diarrhea, blindness, inflammation of the brain, and pneumonia among others.[4][6] Rubella (German measles) and roseola are different diseases.[7]

Measles is an airborne disease which spreads easily through the coughs and sneezes of those infected. It may also be spread through contact with saliva or nasal secretions.[4] Nine out of ten people who are not immune and share living space with an infected person will catch it. People are infectious to others from four days before to four days after the start of the rash.[6] People usually do not get the disease more than once.[4] Testing for the virus in suspected cases is important for public health efforts.[6]

The measles vaccine is effective at preventing the disease. Vaccination has resulted in a 75% decrease in deaths from measles between 2000 and 2013 with about 85% of children globally being currently vaccinated. No specific treatment is available. Supportive care may improve outcomes.[4] This may include giving oral rehydration solution (slightly sweet and salty fluids), healthy food, and medications to control the fever.[4][5] Antibiotics may be used if a secondary bacterial infection such as pneumonia occurs. Vitamin A supplementation is also recommended in the developing world.[4]

Measles affects about 20 million people a year,[1] primarily in the developing areas of Africa and Asia.[4] It causes the most vaccine-preventable deaths of any disease.[8] It resulted in about 96,000 deaths in 2013, down from 545,000 deaths in 1990.[9] In 1980, the disease was estimated to have caused 2.6 million deaths per year.[4] Most of those who are infected [4]

and who die are less than five years old. The risk of death among those infected is usually 0.2%,[6] but may be up to 10% in those who have malnutrition.[4] It is not believed to affect other animals.[4] Before immunization in the United States, between three and four million cases occurred each year.[7] As a result of widespread vaccination, the disease was eliminated from the Americas by 2016.[10]

## Signs and symptoms [edit]

The classic signs and symptoms of measles include four-day fevers (the 4 D's) and the three C's — cough, coryza (head cold, fever, sneezing), and conjunctivitis (red eyes) — along with fever and rashes.[11] Fever is common and typically lasts for about one week; the fever seen with measles is often as high as 40 °C (104 °F).[12] Koplik's spots seen inside the mouth are pathognomonic (diagnostic) for measles, but are temporary and therefore rarely seen.[11] Recognizing these spots before a person reaches their maximum infectiousness can help physicians reduce the spread of the disease.[13]

The characteristic measles rash is classically described as a generalized red maculopapular rash that begins several days after the fever starts. It starts on the back of the ears and, after a few hours, spreads to the head and neck before spreading to cover most of the body, often causing itching. The measles rash appears two to four days after the initial symptoms and lasts for up to eight days. The rash is said to "stain", changing color from red to dark brown, before disappearing.[14] Overall, the disease from infection with the measles virus usually resolves after about three weeks.[12]

## Complications [edit]

Complications with measles are relatively common, ranging from mild complications such as diarrhea to serious complications such as pneumonia (either direct viral pneumonia or secondary bacterial pneumonia), bronchitis (either direct viral bronchitis or secondary bacterial bronchitis), otitis media,[15] acute brain inflammation[16] (and very rarely SSPE — subacute sclerosing panencephalitis),[17] and corneal ulceration (leading to corneal scarring).[18] Complications are usually

more severe in adults who catch the virus.[19] The death rate in the 1920s was around 30% for measles pneumonia.[20] People that are at high risk for complications are: Infants and children aged <5 years, adults aged >20 years, pregnant women, and people with compromised immune systems, such as from leukemia and HIV infection.[21]

Between 1987 and 2000, the case fatality rate across the United States was three measles-attributable deaths per 1000 cases, or 0.3%.[22] In underdeveloped nations with high rates of malnutrition and poor healthcare, fatality rates have been as high as 28%.[22] In immunocompromised persons (e.g., people with AIDS) the fatality rate is approximately 30%.[23] Risk factors for severe measles and its complications include malnutrition,[24] underlying immunodeficiency,[24] pregnancy,[24] and vitamin A deficiency.[24][25] Even in previously healthy children, measles can cause serious illness requiring hospitalization.[26] One out of every 1,000 measles cases will develop acute encephalitis, which often results in permanent brain damage.[26] One or two out of every 1,000 children who become infected with measles will die from respiratory and neurologic complications.[21]

## Cause [edit]

Measles is caused by the measles virus, a single-stranded, negative-sense, enveloped RNA virus of the genus *Morbillivirus* within the family *Paramyxoviridae*.[27] The virus was first isolated in 1954 by Nobel Laureate John F. Enders and Thomas Peebles, who were careful to point out that the isolations were made from patients who had Koplik's spots.[28] Humans are the only natural hosts of the virus, and no other animal reservoirs are known to exist. This highly contagious virus is spread by coughing and sneezing via close personal contact or direct contact with secretions. Risk factors for measles virus infection include immunodeficiency caused by HIV or AIDS,[29] immunosuppression following receipt of an organ or a stem cell transplant,[30] alkylating agents, or corticosteroid therapy, regardless of immunization status;[24] travel to areas where measles is endemic or contact with travelers to endemic areas;[24] and the loss of passive, inherited antibodies before the age of routine immunization.[31]

## Diagnosis [edit]

Clinical diagnosis of measles requires a history of fever of at least three days, with at least one of the three C's (cough, coryza, conjunctivitis). Observation of Koplik's spots is also diagnostic of measles.[13][32][33]

### Laboratory testing [edit]

Alternatively, laboratory diagnosis of measles can be done with confirmation of positive measles IgM antibodies or isolation of measles virus RNA from respiratory specimens.[34] For people unable to have their blood drawn, saliva can be collected for salivary measles-specific IgA testing.[35] Positive contact with other patients known to have measles adds strong epidemiological evidence to the diagnosis. Any contact with an infected person, including semen through sex, saliva, or mucus, can cause infection.[33]

## Prevention [edit]

Rates of measles vaccination worldwide

In developed countries, children are immunized against measles at 12 months, generally as part of a three-part MMR vaccine (measles, mumps, and rubella). The vaccination is generally not given before this age because such infants respond inadequately to the vaccine due to an immature immune system.[31] Anti-measles antibodies are transferred from mothers who have been vaccinated against measles or have been previously infected with measles to their newborn children.[31] However, such antibodies are transferred in low amounts and usually last six months or less.[31] Infants under one year of age whose maternal anti-measles antibodies have disappeared become susceptible to infection with the measles virus.[31] A second dose of the vaccine is usually given to children between the ages of four and five, to increase rates of immunity. Vaccination rates have been high enough to make measles relatively uncommon. Adverse reactions to vaccination are rare, with fever and pain at the injection site being the most common. Life-threatening adverse reactions occur in less than one per million vaccinations (<0.0001%).[36]

In developing countries where measles is highly endemic, WHO doctors recommend two doses of vaccine be given at six and nine months of age. The vaccine should be given whether the child is HIV-infected or not.[37] The vaccine is less effective in HIV-infected infants than in the general population, but early treatment with antiretroviral drugs can increase its effectiveness.[38] Measles vaccination programs are often used to deliver other child health interventions, as well, such as bed nets to protect against malaria, antiparasite medicine and vitamin A supplements, and so contribute to the reduction of child deaths from other causes.[39]

## Treatment [edit]

There is no specific treatment for measles. Most people with uncomplicated measles will recover with rest and supportive treatment.

Patients who become sicker may be developing medical complications. Some people will develop pneumonia as a consequence of infection with the measles virus. Other complications include ear infections, bronchitis (either viral bronchitis or secondary bacterial bronchitis), and brain inflammation.[40] Brain inflammation from measles has a mortality rate of 15%. While there is no specific treatment for brain inflammation from measles, antibiotics are required for bacterial pneumonia, sinusitis, and bronchitis that can follow measles.

All other treatment addresses symptoms, with ibuprofen or paracetamol to reduce fever and pain and, if required, a fast-acting medication to dilate the airways for cough. As for aspirin, some research has suggested a correlation between children who take aspirin and the development of Reye syndrome.[41] Some research has shown aspirin may not be the only medication associated with Reye, and even antiemetics have been implicated.[42] The link between aspirin use in children and Reye syndrome development is weak at best, if not actually nonexistent.[43] Nevertheless, most health authorities still caution against the use of aspirin for any fevers in children under 16.[44][45][46][47]

The use of vitamin A during treatment is recommended by the World Health Organization to decrease the risk of blindness.[48] A systematic review of trials into its use found no significant reduction in overall mortality, but it did reduce mortality in children aged under two years.[49][50][*needs update*][51]

It is unclear if zinc supplementation in children with measles affects outcomes.[52]

## Prognosis [edit]

The majority of people survive measles, though in some cases, complications may occur. Possible consequences of measles virus infection include bronchitis, sensorineural hearing loss,[27] and — in about 1 in 10,000 to 1 in 300,000 cases[53] — panencephalitis, which is usually fatal.[54] Acute measles encephalitis is another serious risk of measles virus infection. It typically occurs two days to one week after the breakout of the measles rash and begins with very high fever, severe headache, convulsions and altered mentation. A person with measles encephalitis may become comatose, and death or brain injury may occur.[55]

## Epidemiology [edit]

*Main article: Epidemiology of measles*

Measles is extremely infectious and its continued circulation in a community depends on the generation of susceptible hosts by birth of children. In communities which generate insufficient new hosts the disease will die out. This concept was first recognized in measles by Bartlett in 1957, who referred to the minimum number supporting measles as the critical community size (CCS).[56] Analysis of outbreaks in island communities suggested that the CCS for measles is around 250,000.[57] To achieve herd immunity, more than 95% of the community must be vaccinated due to the ease with which measles is transmitted from person to person.[12] The disease was eliminated from the Americas in 2016.[10]

In 2011, the WHO estimated that 158,000 deaths were caused by measles. This is down from 630,000 deaths in 1990.[58] As of 2013, measles remains the leading cause of vaccine-preventable deaths in the world.[8] In developed countries, death occurs in 1 to 2 cases out of every 1,000 (0.1% - 0.2%).[59] In populations with high levels of malnutrition and a lack of adequate healthcare, mortality can be as high as 10%. In cases with complications, the rate may rise to 20–30%.[60] In 2012, the number of deaths due to measles was 78% lower than in 2000 due to increased rates of immunization among UN member states.[12]

Even in countries where vaccination has been introduced, rates may remain high. Measles is a leading cause of vaccine-preventable childhood mortality. Worldwide, the fatality rate has been significantly reduced by a vaccination campaign led by partners in the Measles Initiative: the American Red Cross, the United States' Centers for Disease Control and Prevention (CDC), the United Nations Foundation, UNICEF and the WHO. Globally, measles fell 60% from an estimated 873,000 deaths in 1999 to 345,000 in 2005.[67] Estimates for 2008 indicate deaths fell further to 164,000 globally, with 77% of the remaining measles deaths in 2008 occurring within the Southeast Asian region.[68]

In 2013–14 there were almost 10,000 cases in 30 European countries. Most cases occurred

in unvaccinated individuals and over 90% of cases occurred in the five European nations: Germany, Italy, the Netherlands, Romania, and the United Kingdom.[12] In the Vietnamese measles epidemic in spring of 2014, an estimated 8,500 measles cases were reported as of April 19, with 114 fatalities;[69] as of May 30, 21,639 suspected measles cases had been reported, with 142 measles-related fatalities.[70]

Five out of six WHO regions have set goals to eliminate measles, and at the 63rd World Health Assembly in May 2010, delegates agreed on a global target of a 95% reduction in measles mortality by 2015 from the level seen in 2000, as well as to move towards eventual eradication. However, no specific global target date for eradication has yet been agreed to as of May 2010.[71][72]

In 2014, a review by the Centers for Disease Control reported a total of 911 cases of measles from 2001 to 2011, with an annual median number of 61 cases and concluded that "the elimination of endemic measles, rubella, and CRS has been sustained in the United States."[73] However, in 2015, a measles outbreak occurred in the U.S. and spread rather farther than it should have, because misguided ideas about anti-vaccination and vaccination delaying have decreased the community immunity afforded by proper public health programs. In 2015, a U.S. woman died of pneumonia, as a result of measles. She was the first fatality in the USA from measles since 2003.[74] The woman had been vaccinated for measles and was taking immune suppression drugs for another condition. The drugs suppressed the measles immunity, the woman became infected with measles, did not develop a rash, and contracted pneumonia which caused her death.[75]

Between October 2014 and March 2015, a measles outbreak in the German capital of Berlin resulted in at least 782 cases.[76]

From January 4 to April 2, 2015, there were 159 reported cases of measles to the CDC. Of those 159 cases, 111 (70%) were determined to have come from an earlier exposure in late December 2014. This outbreak was believed to have originated from the Disney theme parks in California. The initial exposure to the virus was never found. There have been cases associated with this outbreak in seven states, Mexico, and Canada. Of the cases 48% were unvaccinated and 38% were unsure of their vaccination status.[77]

In the Naga Self-Administered Zone in a remote northern region of Myanmar, at least 40 children died during a measles outbreak in August 2016 that was probably caused by lack of vaccination in an area of poor health infrastructure.[78][79]

## History [edit]

16th-century Aztec drawing of someone with measles

Estimates based on modern molecular biology place the emergence of measles as a human disease sometime after 500 AD[80] (the former speculation that the Antonine Plague of 165–180 AD was caused by measles is now discounted). The first systematic description of measles, and its distinction from smallpox and chickenpox, is credited to the Persian physician Rhazes (860–932), who published *The Book of Smallpox and Measles*.[81] Given what is now known about the evolution of measles, Rhazes' account is remarkably timely, as recent work that examined the mutation rate of the virus indicates the measles virus emerged from rinderpest (cattle plague) as a zoonotic disease between 1100 and 1200 AD, a period that may have been preceded by limited outbreaks involving a virus not yet fully acclimated to humans.[80] This

agrees with the observation that measles requires a susceptible population of >500,000 to sustain an epidemic, a situation that occurred in historic times following the growth of medieval European cities.[82]

Measles is an endemic disease, meaning it has been continually present in a community, and many people develop resistance. In populations not exposed to measles, exposure to the new disease can be devastating. In 1529, a measles outbreak in Cuba killed two-thirds of those natives who had previously survived smallpox. Two years later, measles was responsible for the deaths of half the population of Honduras, and it had ravaged Mexico, Central America, and the Inca civilization.[84]

Between roughly 1855 and 2005, measles has been estimated to have killed about 200 million people worldwide.[85] Measles killed 20 percent of Hawaii's population in the 1850s.[86] In 1875, measles killed over 40,000 Fijians, approximately one-third of the population.[87] In the 19th century, the disease killed 50% of the Andamanese population.[88] Seven to eight million children are thought to have died from measles each year before the vaccine was introduced.[12]

In 1954, the virus causing the disease was isolated from a 13-year-old boy from the United States, David Edmonston, and adapted and propagated on chick embryo tissue culture.[89] To date, 21 strains of the measles virus have been identified.[90] While at Merck, Maurice Hilleman developed the first successful vaccine.[91] Licensed vaccines to prevent the disease became available in 1963.[92] An improved measles vaccine became available in 1968.[93] Measles as an endemic disease was eliminated from the United States in 2000, but continues to be reintroduced by international travelers.

Maurice Hilleman's measles vaccine is estimated to prevent 1 million deaths per year.[83]

## Society and culture [edit]

German anti-vaccination campaigner and HIV/AIDS denialist[94] Stefan Lanka posed a challenge on his website in 2011, offering a sum of €100,000 for anyone who could scientifically prove that measles is caused by a virus and determine the diameter of the virus.[95] He posits that the illness is psychosomatic and that the measles virus does not exist. When provided with overwhelming scientific evidence from various medical studies by German physician David Barden, Lanka did not accept the findings, forcing Barden to appeal in court. The legal case ended with the ruling that Lanka was to pay the prize.[76][96] The case received wide international coverage that prompted many to comment on it, including clinical neurologist, well-known skeptic and science-based medicine advocate Dr. Steven Novella, who called Lanka "a crank".[97]

## Research [edit]

In May 2015, the journal *Science*, published a report in which researchers found that the measles infection can leave a population at increased risk for mortality from other diseases for 2 to 3 years.[98][99]

A specific drug treatment for measles ERDRP-0519 has shown promising results in animal studies, but has not yet been tested in humans.[100][101][102]

# Psoriasis

From Wikipedia, the free encyclopedia

**Psoriasis** is a long-lasting [autoimmune disease](#) which is characterized by patches of abnormal skin.[3] These skin patches are typically red, itchy, and scaly. They may vary in severity from small and localized to complete body coverage.[4] Injury to the skin can trigger psoriatic skin changes at that spot, which is known as Koebner phenomenon.[5]

There are five main types of psoriasis: plaque, guttate, inverse, pustular, and erythrodermic.[3] Plaque psoriasis, also known as psoriasis vulgaris, makes up about 90% of cases. It typically presents with red patches with white scales on top. Areas of the body most commonly affected are the back of the forearms, shins, around the navel, and the scalp.[6] Guttate psoriasis has drop-shaped lesions.[3] Pustular psoriasis presents with small non-infectious pus-filled blisters.[7] Inverse psoriasis forms red patches in skin folds.[3] Erythrodermic psoriasis occurs when the rash becomes very widespread, and can develop from any of the other types. Fingernails and toenails are affected in most people at some point in time. This may include pits in the nails or changes in nail color.[6]

Psoriasis is generally thought to be a genetic disease which is triggered by environmental factors.[4] In twin studies, identical twins are three times more likely to both be affected compared to non-identical twins; this suggests that genetic factors predispose to psoriasis. Symptoms often worsen during winter and with certain medications such as beta blockers or NSAIDs.[6] Infections and psychological stress may also play a role.[3][4] Psoriasis is not contagious. The underlying mechanism involves the immune system reacting to skin cells. Diagnosis is typically based on the signs and symptoms.[6]

There is no cure for psoriasis. However, various treatments can help control the symptoms.[6] These treatments may include steroid creams, vitamin D3 cream, ultraviolet light, and immune system suppressing medications such as methotrexate.[3] About 75% of cases can be managed with creams alone.[6] The disease affects 2–4% of the population.[8] Men and women are affected with equal frequency.[3] The disease may begin at any age.[9] Psoriasis is associated with an increased risk of psoriatic arthritis, lymphomas, cardiovascular disease, Crohn's disease, and depression.[6] Psoriatic arthritis affects up to 30% of

## Signs and symptoms [edit]

### Plaque [edit]

Psoriasis vulgaris (also known as chronic stationary psoriasis or plaque-like psoriasis) is the most common form and affects 85%–90% of people with psoriasis.[10] Plaque psoriasis typically appears as raised areas of inflamed skin covered with silvery-white scaly skin. These areas are called plaques and are most commonly found on the elbows, knees, scalp, and back.[10][11] Psoriatic erythroderma (erythrodermic psoriasis) involves widespread inflammation and exfoliation of the skin over most of the body surface. It may be accompanied by severe itching, swelling, and pain. It is often the result of an exacerbation of unstable plaque psoriasis, particularly following the abrupt withdrawal of systemic glucocorticoids.[12] This form of psoriasis can be fatal as the extreme inflammation and exfoliation disrupt the body's ability to regulate temperature and perform barrier functions.[13]

## Pustular [edit]

*See also: Generalized pustular psoriasis*

Severe pustular psoriasis.

Pustular psoriasis appears as raised bumps filled with noninfectious pus (pustules).[14] The skin under and surrounding the pustules is red and tender.[15] Pustular psoriasis can be localized, commonly to the hands and feet (palmoplantar pustulosis), or generalized with widespread patches occurring randomly on any part of the body. Acrodermatitis continua is a form of localized psoriasis limited to the fingers and toes that may spread to the hands and feet.[15] Pustulosis palmaris et plantaris is another form of localized pustular psoriasis similar to acrodermatitis continua with pustules erupting from red, tender, scaly skin found on the palms of the hands and the soles of the feet.[15]

Generalized pustular psoriasis (pustular psoriasis of von Zumbusch), also known as impetigo herpetiformis during pregnancy,[16] is a rare and severe form of psoriasis that may require hospitalization. The development of generalized pustular psoriasis is often caused by an infection, abrupt withdrawal of topical corticosteroid treatment, pregnancy, hypocalcemia, medications, or following an irritating topical treatment for plaque psoriasis.[15] This form of psoriasis is characterized by an acute onset of numerous pustules on top of tender red skin. This skin eruption is often accompanied by a fever, muscle aches, nausea, and an elevated white blood cell count.[15] Annular pustular psoriasis (APP), a rare form of generalized pustular psoriasis, is the most common type seen during childhood.[16] APP tends to occur in women more frequently than in men, and is usually less severe than other forms of generalized pustular psoriasis such as impetigo herpetiformis.[16] This form of psoriasis is characterized by ring-shaped plaques with pustules around the edges and yellow crusting.[16] APP most often affects the torso, neck, arms, and legs.[16]

## Other skin lesions [edit]

Additional types of psoriasis affecting the skin include inverse psoriasis, guttate psoriasis, oral psoriasis, and seborrheic-like psoriasis.[17]

Inverse psoriasis (also known as flexural psoriasis) appears as smooth, inflamed patches of skin. The patches frequently affect skin folds, particularly around the genitals (between the thigh and groin), the armpits, in the skin folds of an overweight abdomen (known as panniculus), between the buttocks in the intergluteal cleft, and under the breasts in the inframammary fold. Heat, trauma, and infection are thought to play a role in the development of this atypical form of psoriasis.[18] Napkin psoriasis is a subtype of psoriasis common in infants characterized by red papules with silver scale in the diaper area that may extend to the torso or limbs.[19] Napkin psoriasis is often misdiagnosed as napkin dermatitis (diaper rash).[20]

Guttate psoriasis is characterized by numerous small, scaly, red or pink, droplet-like lesions (papules). These numerous spots of psoriasis appear over

Example of guttate psoriasis

large areas of the body, primarily the trunk, but also the limbs and scalp. Guttate psoriasis is often triggered by a streptococcal infection, typically streptococcal pharyngitis.[18] The reverse is not true.

Oral psoriasis is very rare,[21] in contrast to lichen planus, another common papulosquamous disorder that commonly involves both the skin and mouth. When psoriasis involves the oral mucosa (the lining of the mouth), it may be asymptomatic,[21] but it may appear as white or grey-yellow plaques.[21] Fissured tongue is the most common finding in those with oral psoriasis and has been reported to occur in 6.5–20% of people with psoriasis affecting the skin. The microscopic appearance of oral mucosa affected by geographic tongue (migratory stomatitis) is very similar to the appearance of psoriasis.[22] However, modern studies have failed to demonstrate any link between the two conditions.[23]

Seborrheic-like psoriasis is a common form of psoriasis with clinical aspects of psoriasis and seborrheic dermatitis, and may be difficult to distinguish from the latter. This form of psoriasis typically manifests as red plaques with greasy scales in areas of higher sebum production such as the scalp, forehead, skin folds next to the nose, skin surrounding the mouth, skin on the chest above the sternum, and in skin folds.[19]

## Psoriatic arthritis [edit]

*See also: Psoriatic arthritis*

Psoriatic arthritis is a form of chronic inflammatory arthritis that has a highly variable clinical presentation and frequently occurs in association with skin and nail psoriasis.[24][25] It typically involves painful inflammation of the joints and surrounding connective tissue and can occur in any joint, but most commonly affects the joints of the fingers and toes. This can result in a sausage-shaped swelling of the fingers and toes known as dactylitis.[24] Psoriatic arthritis can also affect the hips, knees, spine (spondylitis), and sacroiliac joint (sacroiliitis).[26] About 30% of individuals with psoriasis will develop psoriatic arthritis.[10] Skin manifestations of psoriasis tend to occur before arthritic manifestations in about 75% of cases.[25]

## Nail changes [edit]

Psoriasis can affect the nails and produces a variety of changes in the appearance of finger and toe nails. Nail psoriasis occurs in 40–45% of people with psoriasis affecting the skin and has a lifetime incidence of 80–90% in those with psoriatic arthritis.[27] These changes include pitting of the nails (pinhead-sized depressions in the nail is seen in 70% with nail psoriasis), whitening of the nail, small areas of bleeding from capillaries under the nail, yellow-reddish discoloration of the nails known as the oil drop or salmon spot, thickening of the skin under the nail (subungual hyperkeratosis), loosening and separation of the nail (onycholysis), and crumbling of the nail.[27]

## Medical signs [edit]

Psoriasis of a fingernail, with visible pitting.

In addition to the appearance and distribution of the rash, specific medical signs may be used by medical practitioners to assist with diagnosis. These may include Auspitz's sign (pinpoint bleeding when scale is removed), Koebner phenomenon (psoriatic skin lesions induced by trauma to the skin),[19] and itching and pain localized to papules and plaques.[18][19]

## Causes [edit]

The cause of psoriasis is not fully understood, but a number of theories exist.

### Genetics [edit]

*See also: List of human leukocyte antigen alleles associated with cutaneous conditions*

Around one-third of people with psoriasis report a family history of the disease, and researchers have identified genetic loci associated with the condition. Identical twin studies suggest a 70% chance of a twin developing psoriasis if the other twin has the disorder. The risk is around 20% for nonidentical twins. These findings suggest both a genetic susceptibility and an environmental response in developing psoriasis.[28]

Psoriasis has a strong hereditary component, and many genes are associated with it, but it is unclear how those genes work together. Most of the identified genes relate to the immune system, particularly the major histocompatibility complex (MHC) and T cells. Genetic studies are valuable due to their ability to identify molecular mechanisms and pathways for further study and potential drug targets.[29]

Classic genome-wide linkage analysis has identified nine loci on different chromosomes associated with psoriasis. They are called psoriasis susceptibility 1 through 9 (*PSORS1* through *PSORS9*). Within those loci are genes on pathways that lead to inflammation. Certain variations (mutations) of those genes are commonly found in psoriasis.[29] Genome-wide association scans have identified other genes that are altered to characteristic variants in psoriasis. Some of these genes express inflammatory signal proteins, which affect cells in the immune system that are also involved in psoriasis. Some of these genes are also involved in other autoimmune diseases.[29]

The major determinant is *PSORS1*, which probably accounts for 35%–50% of psoriasis heritability.[30] It controls genes that affect the immune system or encode skin proteins that are overabundant with psoriasis. *PSORS1* is located on chromosome 6 in the major histocompatibility complex (MHC), which controls important immune functions. Three genes in the *PSORS1* locus have a strong association with psoriasis vulgaris: *HLA-C* variant *HLA-Cw6*,[31] which encodes a MHC class I protein; *CCHCR1*, variant WWC, which encodes a coiled protein that is overexpressed in psoriatic epidermis; and *CDSN*, variant allele 5, which encodes corneodesmosin, a protein which is expressed in the granular and cornified layers of the epidermis and upregulated in psoriasis.[29]

Two major immune system genes under investigation are interleukin-12 subunit beta (*IL12B*) on chromosome 5q, which expresses interleukin-12B; and *IL23R* on chromosome 1p, which expresses the interleukin-23 receptor, and is involved in T cell differentiation. Interleukin-23 receptor and *IL12B* have both been strongly linked with psoriasis.[31] T cells are involved in the inflammatory process that leads to psoriasis.[29] These genes are on the pathway that up-regulate tumor necrosis factor-α and nuclear factor κB, two genes involved in inflammation.[29]

Recently, the first gene directly linked to psoriasis has been identified. A rare mutation in the gene encoding for the *CARD14* protein plus an environmental trigger was enough to cause plaque psoriasis (the most common form of psoriasis).[32][33]

### Lifestyle [edit]

Conditions reported as accompanying a worsening of the disease include chronic infections, stress, and changes in season and climate.[31] Others include hot water, scratching psoriasis skin lesions, skin dryness, excessive alcohol consumption, cigarette smoking, and obesity.[31][34][35]

### HIV [edit]

The rate of psoriasis in HIV-positive individuals is comparable to that of HIV-negative individuals, however, psoriasis tends to be more severe in people infected with HIV.[36] A much higher rate of psoriatic arthritis occurs in HIV-positive individuals with psoriasis than in those without the infection.[36] The immune response in those infected with HIV is typically characterized by cellular signals from Th2 subset of CD4+ helper T cells,[37] whereas the immune response in psoriasis vulgaris is characterized by a pattern of cellular signals typical of Th1 subset of CD4+ helper T cells and Th17 helper T cells.[38][39] It is hypothesized that the diminished CD4+-T cell presence causes an overactivation of CD8+-T cells, which are responsible for the exacerbation of psoriasis in HIV-positive people. Psoriasis in those with HIV/AIDS is often severe and may be untreatable with conventional therapy.[40]

### Microbes [edit]

Psoriasis has been described as occurring after strep throat, and may be worsened by skin or gut colonization with *Staphylococcus aureus*, *Malassezia*, and *Candida albicans*.[41]

### Medications [edit]

Drug-induced psoriasis may occur with beta blockers,[7] lithium,[7] antimalarial medications,[7] non-steroidal anti-inflammatory drugs,[7] terbinafine, calcium channel blockers, captopril, glyburide, granulocyte colony-stimulating factor,[7] interleukins, interferons,[7] lipid-lowering drugs,[17]:197 and paradoxically TNF inhibitors such as infliximab or adalimumab.[42] Withdrawal of corticosteroids (topical steroid cream) can aggravate psoriasis due to the rebound effect.[43]

## Mechanism [edit]

Psoriasis is characterized by an abnormally excessive and rapid growth of the epidermal layer of the skin.[44] Abnormal production of skin cells (especially during wound repair) and an overabundance of skin cells result from the sequence of pathological events in psoriasis.[15] Skin cells are replaced every 3–5 days in psoriasis rather than the usual 28–30 days.[45] These changes are believed to stem from the premature maturation of keratinocytes induced by an inflammatory cascade in the dermis involving dendritic cells, macrophages, and T cells (three subtypes of white blood cells).[10][36] These immune cells move from the dermis to the epidermis and secrete inflammatory chemical signals (cytokines) such as tumor necrosis factor-α, interleukin-1β, interleukin-6, interleukin-36 and interleukin-22.[29][46] These secreted inflammatory signals are believed to stimulate keratinocytes to proliferate.[29] One hypothesis is that psoriasis involves a defect in regulatory T cells, and in the regulatory cytokine interleukin-10.[29]

Gene mutations of proteins involved in the skin's ability to function as a barrier have been identified as markers of susceptibility for the development of psoriasis.[47][48]

DNA released from dying cells acts as an inflammatory stimulus in psoriasis[49] and stimulates the receptors on certain dendritic cells, which in turn produce the cytokine interferon-α.[49] In response to these chemical messages from dendritic cells and T cells, keratinocytes also secrete cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor-α, which signal downstream inflammatory cells to arrive and stimulate additional [29]

inflammation.

Dendritic cells bridge the innate immune system and adaptive immune system. They are increased in psoriatic lesions[44] and induce the proliferation of T cells and type 1 helper T cells (Th1). Targeted immunotherapy as well as psoralen and ultraviolet A (PUVA) therapy can reduce the number of dendritic cells and favors a Th2 cell cytokine secretion pattern over a Th1/Th17 cell cytokine profile.[29][38] Psoriatic T cells move from the dermis into the epidermis and secrete interferon-γ and interleukin-17.[50] Interleukin-23 is known to induce the production of interleukin-17 and interleukin-22.[44][50] Interleukin-22 works in combination with interleukin-17 to induce keratinocytes to secrete neutrophil-attracting cytokines.[50]

## Diagnosis [edit]

A diagnosis of psoriasis is usually based on the appearance of the skin. Skin characteristics typical for psoriasis are scaly, erythematous plaques, papules, or patches of skin that may be painful and itch.[18] No special blood tests or diagnostic procedures are needed to make the diagnosis.[15][51]

The differential diagnosis of psoriasis includes dermatological conditions similar in appearance such as discoid eczema, seborrhoeic eczema, pityriasis rosea (may be confused with guttate psoriasis), nail fungus (may be confused with nail psoriasis) or cutaneous T cell lymphoma (50% of individuals with this cancer are initially misdiagnosed with psoriasis).[43] Dermatologic manifestations of systemic illnesses such as the rash of secondary syphilis may also be confused with psoriasis.[43]

If the clinical diagnosis is uncertain, a skin biopsy or scraping may be performed to rule out other disorders and to confirm the diagnosis. Skin from a biopsy will show clubbed epidermal projections that interdigitate with dermis on microscopy. Epidermal thickening is another characteristic histologic finding of psoriasis lesions.[15][52] The stratum granulosum layer of the epidermis is often missing or significantly decreased in psoriatic lesions; the skin cells from the most superficial layer of skin are also abnormal as they never fully mature. Unlike their mature counterparts, these superficial cells keep their nucleus.[15] Inflammatory infiltrates can typically be visualized on microscopy when examining skin tissue or joint tissue affected by psoriasis. Epidermal skin tissue affected by psoriatic inflammation often has many CD8+ T cells while a predominance of CD4+ T cells makes up the inflammatory infiltrates of the dermal layer of skin and the joints.[15]

### Classification [edit]

### Morphological [edit]

| Psoriasis Type | ICD-10 Code |
|---|---|
| Psoriasis vulgaris | L40.0 |
| Generalized pustular psoriasis | L40.1 |
| Acrodermatitis continua | L40.2 |
| Pustulosis palmaris et plantaris | L40.3 |
| Guttate psoriasis | L40.4 |
| Psoriatic arthritis | L40.50 |
| Psoriatic spondylitis | L40.53 |
| Inverse psoriasis | L40.8 |

Psoriasis is classified as a papulosquamous disorder and is most commonly subdivided into different categories based on histological characteristics.[4][7] Variants include plaque, pustular, guttate, and flexural psoriasis. Each form has a dedicated ICD-10 code.[53] Psoriasis can also be classified into nonpustular and pustular types.[54]

### Pathogenetic [edit]

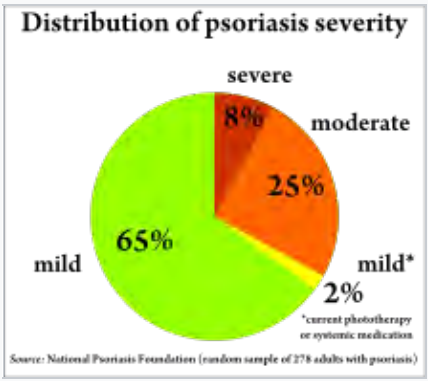
Another classification scheme considers genetic and demographic factors. Type 1 has a positive family history,

starts before the age of 40, and is associated with the human leukocyte antigen, *HLA-Cw6*. Conversely, type 2 does not show a family history, presents before age 40, and is not associated with *HLA-Cw6*.[55] Type 1 accounts for about 75% of persons with psoriasis.[56]

The classification of psoriasis as an autoimmune disease has sparked considerable debate. Researchers have proposed differing descriptions of psoriasis and psoriatic arthritis; some authors have classified them as autoimmune diseases[15][31][57] while others have classified them as distinct from autoimmune diseases and referred to them as immune-mediated inflammatory diseases.[29][58][59]

### Severity [edit]

There is no consensus about how to classify the severity of psoriasis. Mild psoriasis has been defined as a percentage of body surface area (BSA)≤10, a Psoriasis Area Severity Index (PASI) score ≤10, and a dermatology life quality index (DLQI) score ≤10.[60] Moderate to severe psoriasis was defined by the same group as BSA >10 or PASI score >10 and a DLQI score >10.[60] The DLQI is a 10 question tool used to measure the impact of several dermatologic diseases on daily functioning. The DLQI score ranges from 0 (minimal impairment) to 30 (maximal impairment) and is calculated with each answer being assigned 0–3 points with higher scores indicating greater social or occupational impairment.[61]

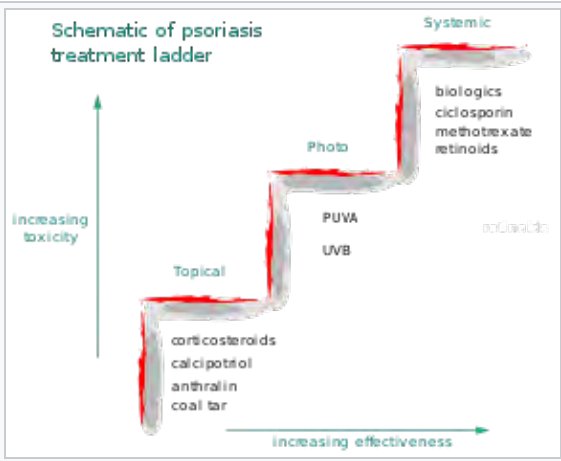


Distribution of severity

The psoriasis area severity index (PASI) is the most widely used measurement tool for psoriasis. PASI assesses the severity of lesions and the area affected and combines these two factors into a single score from 0 (no disease) to 72 (maximal disease).[62] Nevertheless, the PASI can be too unwieldy to use outside of research settings, which has led to attempts to simplify the index for clinical use.[63]

## Management [edit]

While no cure is available for psoriasis,[43] many treatment options exist. Topical agents are typically used for mild disease, phototherapy for moderate disease, and systemic agents for severe disease.[64]



Schematic of psoriasis treatment ladder

### Topical agents [edit]

Topical corticosteroid preparations are the most effective agents when used continuously for 8 weeks; retinoids and coal tar were found to be of limited benefit and may be no better than placebo.[65] Greater benefit has been observed with very potent corticosteroids when compared to potent corticosteroids. Vitamin D analogues such as paricalcitol were found to be significantly superior to placebo. Combination therapy with vitamin D and a corticosteroid was superior to either treatment alone and vitamin D was found to be superior to coal tar for chronic plaque psoriasis.[66]

Moisturizers and emollients such as mineral oil, petroleum jelly, calcipotriol, and decubal (an oil-in-water emollient) were found to increase the clearance of psoriatic plaques. Emollients have been shown to be even more effective at clearing psoriatic plaques when combined with phototherapy.[67] However, certain emollients have no impact on psoriasis plaque clearance or may even decrease the clearance achieved with phototherapy. The emollient salicylic acid is structurally similar to para-aminobenzoic acid (PABA), commonly found in sunscreen, and is known to interfere with phototherapy in psoriasis. Coconut oil, when used as an emollient in psoriasis, has been found to decrease plaque clearance with phototherapy.[67] Medicated creams and ointments applied directly to psoriatic plaques can help reduce inflammation, remove built-up scale, reduce skin turnover, and clear affected skin of plaques. Ointment and creams containing coal tar, dithranol, corticosteroids (i.e. desoximetasone), fluocinonide, vitamin D analogs (for example, calcipotriol), and retinoids are routinely used.

The use of the finger tip unit may be helpful in guiding how much topical treatment to use.[34][68]

Vitamin D analogues may be useful with steroids; however, alone have a higher rate of side effects.[69] They may allow less steroids to be used.[70]

Another topical therapy used to treat psoriasis is a form of balneotherapy, which involves daily baths in the Dead Sea. This is usually done for four weeks with the benefit attributed to sun exposure and specifically UVB light. This is cost-effective and it has been propagated as an effective way to treat psoriasis without medication.[71] Decreases of PASI scores greater than 75% and remission for several months have commonly been observed.[71] Side-effects may be mild such as itchiness, folliculitis, sunburn, poikiloderma, and a theoretical risk of nonmelanoma skin cancer or melanoma has been suggested.[71] However, more recent studies have determined that there does not appear to be increased risk of melanoma in the long-term.[72] Data are inconclusive with respect to nonmelanoma skin cancer risk, but support the idea that the therapy is associated with an increased risk of benign forms of sun-induced skin damage such as, but not limited to, actinic elastosis or liver spots.[72] Dead Sea balneotherapy is also effective for psoriatic arthritis.[72]

## Light exposure [edit]

Phototherapy in the form of sunlight has long been used for psoriasis.[64] Wavelengths of 311–313 nanometers are most effective, and special lamps have been developed for this application.[64] The exposure time should be controlled to avoid over exposure and burning of the skin. The UVB lamps should have a timer that will turn off the lamp when the time ends. The amount of light used is determined by a person's skin type.[64] Increased rates of cancer from treatment appear to be small.[64] Narrow band UVB light (NBUVB) phototherapy has been demonstrated to have similar efficacy to PUVA.[73]

One of the problems with clinical phototherapy is the difficulty many patients have gaining access to a facility. Indoor tanning resources are almost ubiquitous today and could be considered as a means for patients to get UV exposure when dermatologist provided phototherapy is not available. Indoor tanning is already used by many people as a treatment for psoriasis; one indoor facility reported that 50% of its clients were using the center for psoriasis treatment; another reported 36% were doing the same thing. However, a concern with the use of commercial tanning is that tanning beds that primarily emit UVA might not effectively treat psoriasis. One study found that plaque psoriasis is responsive to erythemogenic doses of either UVA or UVB, as exposure to either can cause dissipation of psoriatic plaques. It does require more energy to reach erythemogenic dosing with UVA.[74]

UV light therapies all have risks; tanning beds are no exception, particularly in the link between UV light and the increased chance of skin cancer. There are increased risks of melanoma, squamous cell and basal cell carcinomas; younger psoriasis patients, particularly those under age 35, are at increased risk from melanoma from UV light treatment. The World Health Organization (WHO) listed tanning beds as carcinogens. A review of studies recommends that people who are susceptible to skin cancers exercise caution when using UV light therapy as a treatment.[74]

A major mechanism of NBUVB is the induction of DNA damage in the form of pyrimidine dimers. This type of phototherapy is useful in the treatment of psoriasis because the formation of these dimers interferes with the cell cycle and stops it. The interruption of the cell cycle induced by NBUVB opposes the characteristic rapid division of skin cells seen in psoriasis.[73] The activity of many types of immune cells found in the skin is also effectively suppressed by NBUVB phototherapy treatments. The most common short-term side effect of this form of phototherapy is redness of the skin; less common side effects of NBUVB phototherapy are itching and blistering of the treated skin, irritation of the eyes in the form of conjunctival inflammation or inflammation of the cornea, or cold sores due to reactivation of the herpes simplex virus in the skin surrounding the lips. Eye protection is usually given during phototherapy treatments.[73]

Psoralen and ultraviolet A phototherapy (PUVA) combines the oral or topical administration of psoralen with exposure to ultraviolet A (UVA) light. The mechanism of action of PUVA is unknown, but probably involves activation of psoralen by UVA light, which inhibits the abnormally rapid production of the cells in psoriatic skin. There are multiple mechanisms of action associated with PUVA, including effects on the skin's immune system. PUVA is associated with nausea, headache, fatigue, burning, and itching. Long-term treatment is associated with squamous cell carcinoma (but not with melanoma).[35][75] A combination therapy for moderate to severe

psoriasis using PUVA plus acitretin resulted in benefit, but acitretin use has been associated with birth defects and liver damage.[76]

## Systemic agents [edit]

Psoriasis resistant to topical treatment and phototherapy may be treated with systemic therapies including medications by mouth or injectable treatments.[77] People undergoing systemic treatment must have regular blood and liver function tests to check for medication toxicities.[77] Pregnancy must be avoided for most of these treatments. The majority of people experience a recurrence of psoriasis after systemic treatment is discontinued.

Pictures of a patient with psoriasis (and psoriatic arthritis) at baseline and 8 weeks after initiation of infliximab therapy.

Non-biologic systemic treatments frequently used for psoriasis include methotrexate, ciclosporin, hydroxycarbamide, fumarates such as dimethyl fumarate, and retinoids.[78] Methotrexate and ciclosporin are drugs that suppress the immune system; retinoids are synthetic forms of vitamin A. These agents are also regarded as first-line treatments for psoriatic erythroderma.[12]

Biologics are manufactured proteins that interrupt the immune process involved in psoriasis. Unlike generalised immunosuppressive drug therapies such as methotrexate, biologics target specific aspects of the immune system contributing to psoriasis.[78] These medications are generally well-tolerated and limited long-term outcome data have demonstrated biologics to be safe for long-term use in moderate to severe plaque psoriasis.[78][79] However, due to their immunosuppressive actions, biologics have been associated with a small increase in the risk for infection.[78] Guidelines regard biologics as third-line treatment for plaque psoriasis following inadequate response to topical treatment, phototherapy, and non-biologic systemic treatments.[79] The safety of biologics during pregnancy has not been assessed. European guidelines recommend avoiding biologics if a pregnancy is planned; anti-TNF therapies such as infliximab are not recommended for use in chronic carriers of the hepatitis B virus or individuals infected with HIV.[78]

Several monoclonal antibodies target cytokines, the molecules that cells use to send inflammatory signals to each other. TNF-α is one of the main executor inflammatory cytokines. Four monoclonal antibodies (MAbs) (infliximab, adalimumab, golimumab, and certolizumab pegol) and one recombinant TNF-α decoy receptor, etanercept, have been developed to inhibit TNF-α signaling. Additional monoclonal antibodies, such as ixekizumab,[80] have been developed against pro-inflammatory cytokines[81] and inhibit the inflammatory pathway at a different point than the anti-TNF-α antibodies.[29] IL-12 and IL-23 share a common domain, p40, which is the target of the recently FDA-approved ustekinumab.[31]

Two drugs that target T cells are efalizumab and alefacept. Efalizumab is a monoclonal antibody that specifically targets the CD11a subunit of LFA-1.[78] It also blocks the adhesion molecules on the endothelial cells that line blood vessels, which attract T cells. Efalizumab was voluntarily withdrawn from the European market in February 2009 and from the US market in June 2009 by the manufacturer due to the medication's association with cases of progressive multifocal leukoencephalopathy.[78] Alefacept also blocks the molecules that dendritic cells use to communicate with T cells and even causes natural killer cells to kill T cells as a way of controlling inflammation.[29] Apremilast may also be used.[10]

Individuals with psoriasis may develop neutralizing antibodies against monoclonal antibodies. Neutralization occurs when an antidrug antibody prevents a monoclonal antibody such as infliximab from binding antigen in a laboratory test. Specifically, neutralization occurs when the antidrug antibody binds to infliximab's antigen binding site instead of TNF-α. When infliximab no longer binds tumor necrosis factor alpha, it no longer decreases inflammation, and psoriasis may worsen. Neutralizing antibodies have not been reported against etanercept, a biologic drug that is a fusion protein composed of two TNF-α receptors. The lack of neutralizing antibodies against etanercept is probably secondary to the innate presence of the TNF-α receptor, and the development of immune tolerance.[82]

## Surgery [edit]

Limited evidence suggests removal of the tonsils may benefit people with chronic plaque psoriasis, guttate psoriasis, and palmoplantar pustulosis.[83][84]

### Diet [edit]

Uncontrolled studies have suggested that individuals with psoriasis or psoriatic arthritis may benefit from a diet supplemented with fish oil rich in eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).[85] Diet recommendations include consumption of cold water fish (preferably wild fish, not farmed) such as salmon, herring, and mackerel, extra virgin olive oil, legumes, vegetables, fruits, and whole grains; and avoid consumption of alcohol, red meat, and dairy products. The effect of consumption of caffeine (including coffee, black tea, mate, and dark chocolate) remains to be determined[86]

There is a higher rate of celiac disease among people with psoriasis.[86][87] Disease severity generally decreases in people with celiac disease and those with anti-gliadin antibodies after the adoption of a gluten-free diet.[88][89][85]

## Prognosis [edit]

Most people with psoriasis experience nothing more than mild skin lesions that can be treated effectively with topical therapies.[65]

Psoriasis is known to have a negative impact on the quality of life of both the affected person and the individual's family members.[31] Depending on the severity and location of outbreaks, individuals may experience significant physical discomfort and some disability. Itching and pain can interfere with basic functions, such as self-care and sleep.[45] Participation in sporting activities, certain occupations, and caring for family members can become difficult activities for those with plaques located on their hands and feet.[45] Plaques on the scalp can be particularly embarrassing, as flaky plaque in the hair can be mistaken for dandruff.[90]

Individuals with psoriasis may feel self-conscious about their appearance and have a poor self-image that stems from fear of public rejection and psychosexual concerns. Psoriasis has been associated with low self-esteem and depression is more common among those with the condition.[4] People with psoriasis often feel prejudiced against due to the commonly held incorrect belief that psoriasis is contagious.[45] Psychological distress can lead to significant depression and social isolation; a high rate of thoughts about suicide has been associated with psoriasis.[20] Many tools exist to measure the quality of life of patients with psoriasis and other dermatological disorders. Clinical research has indicated individuals often experience a diminished quality of life.[91] Children with psoriasis may encounter bullying.[92]

Several conditions are associated with psoriasis. These occur more frequently in older people. Nearly half of individuals with psoriasis over the age of 65 have at least three comorbidities, and two-thirds have at least two comorbidities.[93]

### Cardiovascular disease [edit]

Psoriasis has been associated with obesity[4] and several other cardiovascular and metabolic disturbances. The incidence of diabetes is 27% higher in people affected by psoriasis than in those without the condition.[94] Severe psoriasis may be even more strongly associated with the development of diabetes than mild psoriasis.[94] Younger people with psoriasis may also be at increased risk for developing diabetes.[93][95] Individuals with psoriasis or psoriatic arthritis have a slightly higher risk of heart disease and heart attacks when compared to the general population. Cardiovascular disease risk appeared to be correlated with the severity of psoriasis and its duration. There is no strong evidence to suggest that psoriasis is associated with an increased risk of death from cardiovascular events. Methotrexate may provide a degree of protection for the heart.[35][93]

The odds of having hypertension are 1.58 times higher in people with psoriasis than those without the condition; these odds are even higher with severe cases of psoriasis. A similar association was noted in people who have psoriatic arthritis—the odds of having hypertension were found to be 2.07 times greater when compared to odds of the general population. The link between psoriasis and hypertension is not currently understood. Mechanisms hypothesized to be involved in this relationship include the following: dysregulation of the renin-angiotensin [95][96]

system, elevated levels of endothelin 1 in the blood, and increased oxidative stress. The incidence of the heart rhythm abnormality atrial fibrillation is 1.31 times higher in people with mild psoriasis and 1.63 times higher in people with severe psoriasis.[97] There may be a slightly increased risk of stroke associated with psoriasis, especially in severe cases.[35][98] Treating high levels of cholesterol with statins has been associated with decreased psoriasis severity, as measured by PASI score, and has also been associated with improvements in other cardiovascular disease risk factors such as markers of inflammation.[99] These cardioprotective effects are attributed to ability of statins to improve blood lipid profile and because of their anti-inflammatory effects. Statin use in those with psoriasis and hyperlipidemia was associated with decreased levels of high-sensitivity C-reactive protein and TNFα as well as decreased activity of the immune protein LFA-1.[99] Compared to individuals without psoriasis, those affected by psoriasis are more likely to satisfy the criteria for metabolic syndrome.[15][97]

### Other diseases [edit]

The rates of Crohn's disease and ulcerative colitis are increased when compared with the general population, by a factor of 3.8 and 7.5 respectively.[4] People with psoriasis also have a higher risk of celiac disease.[86][89] Few studies have evaluated the association of multiple sclerosis with psoriasis, and the relationship has been questioned.[4][100] Psoriasis has been associated with a 16% increase in overall relative risk for non-skin cancer.[35] People with psoriasis have a 52% increased risk cancers of the lung and bronchus, a 205% increase in the risk of developing cancers of the upper gastrointestinal tract, a 31% increase in the risk of developing cancers of the urinary tract, a 90% increase in the risk of developing liver cancer, and a 46% increase in the risk of developing pancreatic cancer.[35] The risk for development of non-melanoma skin cancers is also increased. Psoriasis increases the risk of developing squamous cell carcinoma of the skin by 431% and increases the risk of basal cell carcinoma by 100%.[35] There is no increased risk of melanoma associated with psoriasis.[35]

## Epidemiology [edit]

Psoriasis is estimated to affect 2–4% of the population of the western world.[8] The rate of psoriasis varies according to age, gender, region and ethnicity; a combination of environmental and genetic factors is thought to be responsible for these differences.[8] It can occur at any age, although it most commonly appears for the first time between the ages of 15 and 25 years. Approximately one third of people with psoriasis report being diagnosed before age 20.[101] Psoriasis affects both sexes equally.[55]

Psoriasis affects about 7.5 million Americans and occurs more frequently between the ages of 15 and 50.[9]

People with inflammatory bowel disease such as Crohn's disease or ulcerative colitis are at an increased risk of developing psoriasis.[42] Psoriasis is more common in countries farther from the equator.[42] Persons of white European ancestry are more likely to have psoriasis and the condition is relatively uncommon in African Americans and extremely uncommon in Native Americans.[43]

## History [edit]

Scholars believe psoriasis to have been included among the various skin conditions called *tzaraath* (translated as leprosy) in the Hebrew Bible, a condition imposed as a punishment for slander. The patient was deemed "impure" (see tumah and taharah) during their afflicted phase and is ultimately treated by the kohen.[102] However, it is more likely that this confusion arose from the use of the same Greek term for both conditions. The Greeks used the term lepra (λεπρα) for scaly skin conditions. They used the term psora to describe itchy skin conditions.[102] It became known as *Willan's lepra* in the late 18th century when English dermatologists Robert Willan and Thomas Bateman differentiated it from other skin diseases. Leprosy, they said, is distinguished by the regular, circular form of patches, while psoriasis is always irregular. Willan identified two categories: *leprosa graecorum* and *psora leprosa*.[103]

Psoriasis is thought to have first been described in Ancient Rome by Cornelius Celsus. The disease was first classified by English physician Thomas Willan. The British dermatologist Thomas Bateman described a possible link between psoriasis and arthritic symptoms in 1813.[104]

The history of psoriasis is littered with treatments of dubious effectiveness and high toxicity. In the 18th and

19th centuries, Fowler's solution, which contains a poisonous and carcinogenic arsenic compound, was used by dermatologists as a treatment for psoriasis.[102] Mercury was also used for psoriasis treatment during this time period.[102] Sulfur, iodine, phenol were also commonly used treatments for psoriasis during this era when it was incorrectly believed that psoriasis was an infectious disease.[102] Coal tars were widely used with ultraviolet light irradiation as a topical treatment approach in the early 1900s.[102][105] During the same time period, psoriatic arthritis cases were treated with intravenously administered gold preparations in the same manner as rheumatoid arthritis.[105] All of these treatments have been replaced with modern topical and systemic therapies.

### Etymology [edit]

The word *psoriasis* is from Greek ψωρίασις, meaning "itching condition" or "being itchy"[106] from *psora*, "itch" and *-iasis*, "action, condition".

## Society and culture [edit]

The International Federation of Psoriasis Associations (IFPA) is the global umbrella organization for national and regional psoriasis patient associations and also gathers the leading experts in psoriasis and psoriatic arthritis research for scientific conferences every three years.[107] The Psoriasis International Network, a program of the Fondation René Touraine, gathers dermatologists, rheumatologists and other caregivers involved in the management of psoriasis. Non-profit organizations the National Psoriasis Foundation in the United States, the Psoriasis Association in the United Kingdom and Psoriasis Australia offer advocacy and education about psoriasis in their respective countries.

### Cost [edit]

The annual cost for treating psoriasis in the US is estimated as high as $32.5 billion - $12.2 billion in direct costs. Pharmacy costs are the main source of direct expense, with biologic therapy the most prevalent. These costs increase significantly when co-morbid conditions such as heart disease, hypertension, diabetes, lung disease and psychiatric disorders are factored in. Expenses linked to co-morbidities are estimated at an additional $23,000 per patient per year.[108]

## Research [edit]

The role of insulin resistance in the pathogenesis of psoriasis is currently under investigation. Preliminary research has suggested that antioxidants such as polyphenols may have beneficial effects on the inflammation characteristic of psoriasis.[109]

Many novel drugs being researched target the Th17/IL-23 axis,[109] particularly IL-23p19 inhibitors, as IL-23p19 is present in increased concentrations in psoriasis skin lesions while contributing less to protection against opportunistic infections.[110] Other cytokines such as IL-17 and IL-22 also have been targets for inhibition as they play important roles in the pathogenesis of psoriasis.[110] Another avenue of research has focused on the use of vascular endothelial growth factor inhibitors to treat psoriasis.[57] Oral agents being investigated as alternatives to medications administered by injection include Janus kinase inhibitors, protein kinase C inhibitors, mitogen-activated protein kinase inhibitors, and phosphodiesterase 4 inhibitors, all of which have proven effective in various phase 2 and 3 clinical trials.[109][110] However, these agents have potentially severe side-effects due to their immunosuppressive mechanisms.[110]

*For psychological condition, see The seven-year itch.*

**Scabies**, previously known as the seven-year itch, is a contagious skin infestation by the mite *Sarcoptes scabiei*.[1][2] The most common symptoms are severe itchiness and a pimple-like rash. Occasionally tiny burrows may be seen in the skin. When first infected, usually two to six weeks are required before symptoms occur. If a person develops a second infection later in life, symptoms may begin within a day. These symptoms can be present across most of the body or just certain areas such as the wrists, between fingers, or along the waistline. The head may be affected, but this is typically only in young children. The itch is often worse at night. Scratching may cause skin breakdown and an additional bacterial infection of the skin.[3]

Scabies is caused by infection with the female mite *Sarcoptes scabiei*.[1] The mites burrow into the skin to live and deposit eggs.[1] The symptoms of scabies are due to an allergic reaction to the mites.[3] Often only between ten and fifteen mites are involved in an infection.[3] Scabies is most often spread during a relatively long period of direct skin contact with an infected person such as that which may occur during sex.[1] Spread of disease may occur even if the person has not developed symptoms yet.[4] Crowded living conditions such as those found in child care facilities, group homes, and prisons increase the risk of spread.[1] Areas with a lack of access to water also have higher rates of disease.[5]

**Crusted scabies** is a more severe form of the disease. It typically only occurs in those with a poor immune system and people may have millions of mites, making them much more contagious. In these cases spread of infection may occur during brief contact or via contaminated objects. The mite is very small and usually not directly visible. Diagnosis is based on the signs and symptoms.[6]

A number of medications are available to treat those infected, including permethrin, crotamiton and lindane creams and ivermectin pills.[7] Sexual contacts within the last month and people who live in the same house should also be treated at the same time. Bedding and clothing used in the last three days should be washed in hot water and dried in a hot dryer. As the mite does not live for more than three days away from human skin more washing is not needed. Symptoms may continue for two to four weeks following treatment. If after this time there continue to be symptoms retreatment may be needed.[4]

[edit on Wikidata]

Scabies is one of the three most common skin disorders in children, along with ringworm and bacterial skin infections.[8] As of 2010 it affects approximately 100 million people (1.5% of the world population) and is equally common in both sexes.[9] The young and the old are more commonly affected. It also occurs more commonly in

the developing world and tropical climates.[6] The word scabies is from Latin: *scabere*, "to scratch".[10] Other animals do not spread human scabies.[1] Infection in other animals is typically caused by slightly different but related mites and is known as sarcoptic mange.[11]

## Signs and symptoms [edit]

The characteristic symptoms of a scabies infection include intense itching and superficial burrows.[12] The burrow tracks are often linear, to the point that a neat "line" of four or more closely placed and equally developed mosquito-like "bites" is almost diagnostic of the disease. Because the host develops the symptoms as a reaction to the mites' presence over time, there is typically a delay of four to six weeks between the onset of infestation and the onset of itching. Similarly, symptoms often persist for one to several weeks after successful eradication of the mites. As noted, those re-exposed to scabies after successful treatment may exhibit symptoms of the new infestation in a much shorter period—as little as one to four days.[13]

### Itching [edit]

In the classic scenario, the itch is made worse by warmth, and is usually experienced as being worse at night, possibly because there are fewer distractions.[12] As a symptom, it is less common in the elderly.[12]

### Rash [edit]

The superficial burrows of scabies usually occur in the area of the finger webs, feet, ventral wrists, elbows, back, buttocks, and external genitals.[12] Except in infants and the immunosuppressed, infection generally does not occur in the skin of the face or scalp. The burrows are created by excavation of the adult mite in the epidermis.[12]

In most people, the trails of the burrowing mites are linear or *s*-shaped tracks in the skin often accompanied by rows of small, pimple-like mosquito or insect bites. These signs are often found in crevices of the body, such as on the webs of fingers and toes, around the genital area, in stomach folds of the skin, and under the breasts of women.[15]

Commonly involved sites of rashes of scabies[14]

Symptoms typically appear two to six weeks after infestation for individuals never before exposed to scabies. For those having been previously exposed, the symptoms can appear within several days after infestation. However, it is not unknown for symptoms to appear after several months or years.[16] Acropustulosis, or blisters and pustules on the palms and soles of the feet, are characteristic symptoms of scabies in infants.[15]

## Crusted scabies [edit]

The elderly and people with an impaired immune system, such as HIV, cancer, or those on immunosuppressive medications, are susceptible to crusted scabies (formerly called Norwegian scabies).[12][16][17] On those with weaker immune systems, the host becomes a more fertile breeding ground for the mites, which spread over the host's body, except the face. Sufferers of crusted scabies exhibit scaly rashes, slight itching, and thick crusts of skin that contain thousands of mites.[18] Such areas make eradication of mites particularly difficult, as the crusts protect the mites from topical miticides/scabicides, necessitating prolonged treatment of these areas.

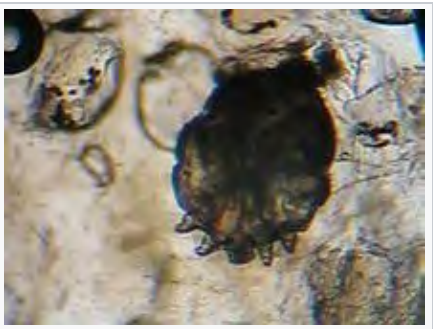
## Scabies mite [edit]

*Main article: Sarcoptes scabiei*

In the 18th century, Italian biologist Diacinto Cestoni (1637–1718) described the mite now called *Sarcoptes scabiei*, variety *hominis*, as the cause of scabies. *Sarcoptes* is a genus of skin parasites and part of the larger family of mites collectively known as scab mites. These organisms have eight legs as adults, and are placed in the same phylogenetic class (Arachnida) as spiders and ticks.



*Sarcoptes scabiei* mites are under 0.5 mm in size but are sometimes visible as pinpoints of white. Pregnant females tunnel into the dead, outermost layer (stratum corneum) of a host's skin and deposit eggs in the shallow burrows. The eggs hatch into larvae in three to ten days. These young mites move

about on the skin and molt into a "nymphal" stage, before maturing as adults, which live three to four weeks in the host's skin. Males roam on top of the skin, occasionally burrowing into the skin. In general, the total number of adult mites infesting a healthy hygienic person with non-crusted scabies is small; about 11 females in burrows, on average.[19]

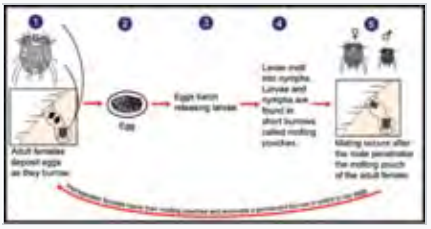
The movement of mites within and on the skin produces an intense itch, which has the characteristics of a delayed cell-mediated inflammatory response to allergens. IgE antibodies are present in the serum and the site of infection, which react to multiple protein allergens in the body of the mite. Some of these cross-react to allergens from house dust mites. Immediate antibody-mediated allergic reactions (wheals) have been elicited in infected persons, but not in healthy persons; immediate hypersensitivity of this type is thought to explain the observed far more rapid allergic skin response to reinfection seen in persons having been previously infected (especially having been infected within the previous year or two).[20]



Life cycle of scabies[14]

## Transmission [edit]

Scabies is contagious and can be contracted through prolonged physical contact with an infested person.[21] This includes sexual intercourse, although a majority of cases are acquired through other forms of skin-to-skin contact. Less commonly, scabies infestation can happen through the sharing of clothes, towels, and bedding, but this is not a major mode of transmission; individual mites can only survive for two to three days, at most, away from human skin.[22][23] As with lice, a latex condom is ineffective against scabies transmission during intercourse, because mites typically migrate from one individual to the next at sites other than the sex organs.[24]

Healthcare workers are at risk of contracting scabies from patients, because they may be in extended contact with them.[25]

# Pathophysiology [edit]

The symptoms are caused by an allergic reaction of the host's body to mite proteins, though exactly which proteins remains a topic of study. The mite proteins are also present from the gut, in mite feces, which are deposited under the skin. The allergic reaction is both of the delayed (cell-mediated) and immediate (antibody-mediated) type, and involves IgE (antibodies, it is presumed, mediate the very rapid symptoms on reinfection).[19] The allergy-type symptoms (itching) continue for some days, and even several weeks, after all mites are killed. New lesions may appear for a few days after mites are eradicated. Nodular lesions from scabies may continue to be symptomatic for weeks after the mites have been killed.[19]

A 2016 study found rates of scabies was negatively related to temperature and positively related with humidity.[26]

# Diagnosis [edit]

Scabies may be diagnosed clinically in geographical areas where it is common when diffuse itching presents along with either lesions in two typical spots or there is itchiness of another household member.[8] The classical sign of scabies is the burrows made by the mites within the skin.[8] To detect the burrow, the suspected area is rubbed with ink from a fountain pen or a topical tetracycline solution, which glows under a special light. The skin is then wiped with an alcohol pad. If the person is infected with scabies, the characteristic zigzag or *S* pattern of the burrow will appear across the skin; however, interpreting this test may be difficult as the burrows are scarce and may be obscured by scratch marks.[8] A definitive diagnosis is made by finding either the scabies mites or their eggs and fecal pellets.[8] Searches for these signs involve either scraping a suspected area, mounting the sample in

potassium hydroxide and examining it under a microscope, or using dermoscopy to examine the skin directly.[12]

trail of the scabies mite: The scaly patch on the left was caused by the scratching and marks the mite's entry point into the skin. The mite has burrowed to the top-right, where it can be seen as a dark spot at the end.

### Differential diagnosis [edit]

Symptoms of early scabies infestation mirror other skin diseases, including dermatitis, syphilis, erythema multiforme, various urticaria-related syndromes, allergic reactions, and other ectoparasites such as lice and fleas.[27]

## Prevention [edit]

Mass treatment programs that use topical permethrin or oral ivermectin have been effective in reducing the prevalence of scabies in a number of populations.[8] No vaccine is available for scabies. The simultaneous treatment of all close contacts is recommended, even if they show no symptoms of infection (asymptomatic), to reduce rates of recurrence.[8][8] Since mites can survive for only two to three days without a host, other objects in the environment pose little risk of transmission except in the case of crusted scabies, thus cleaning is of little importance.[8] Rooms used by those with crusted scabies require thorough cleaning.[28]

## Management [edit]

A number of medications are effective in treating scabies. Treatment should involve the entire household, and any others who have had recent, prolonged contact with the infested individual.[8] Options to control itchiness include antihistamines and prescription anti-inflammatory agents.[29] Bedding, clothing and towels used during the previous three days should be washed in hot water and dried in a hot dryer.[30]

### Permethrin [edit]

Permethrin is the most effective treatment for scabies,[31] and remains the treatment of choice.[8][32] It is applied from the neck down, usually before bedtime, and left on for about eight to 14 hours, then washed off in the morning.[8] Care should be taken to coat the entire skin surface, not just symptomatic areas; any patch of skin left untreated can provide a "safe haven" for one or more mites to survive. One application is normally sufficient, as permethrin kills eggs and hatchlings as well as adult mites, though many physicians recommend a second application three to seven days later as a precaution. Crusted scabies may require multiple applications, or supplemental treatment with oral ivermectin (below).[8][32][33] Permethrin may cause slight irritation of the skin that is usually tolerable.[12]

### Ivermectin [edit]

Oral Ivermectin is effective in eradicating scabies, often in a single dose.[5][8] It is the treatment of choice for crusted scabies, and is sometimes prescribed in combination with a topical agent.[8][12] It has not been tested on infants, and is not recommended for children under six years of age.[12]

Topical ivermectin preparations have been shown to be effective for scabies in adults, though only one such formulation is available in the United States at present, and it is not FDA approved as a scabies treatment.[34] It has also been useful for sarcoptic mange (the veterinary analog of human scabies).[35]

### Others [edit]

Other treatments include lindane, benzyl benzoate, crotamiton, malathion, and sulfur preparations.[8][12] Lindane is effective, but concerns over potential neurotoxicity has limited its availability in many countries.[12] It is banned in California,[36] but may be used in other states as a second-line treatment.[37] Sulfur ointments or benzyl benzoate are often used in the developing world due to their low cost;[12] 10% sulfur solutions have been shown to be effective,[38] and sulfur ointments are typically used for at least a week, though many people find the odor of sulfur products unpleasant.[12] Crotamiton has been found to be less effective than permethrin

in limited studies.[12] Crotamiton or sulfur preparations are sometimes recommended instead of permethrin for children, due to concerns over dermal absorption of permethrin.[8]

## Communities [edit]

Scabies is endemic in many developing countries,[39] where it tends to be particularly problematic in rural and remote areas. In such settings community wide control strategies are required to reduce the rate of disease, as treatment of only individuals is ineffective due to the high rate of reinfection. Large-scale mass drug administration strategies may be required where coordinated interventions aim to treat whole communities in one concerted effort.[40] Although such strategies have shown to be able to reduce the burden of scabies in these kinds of communities, debate remains about the best strategy to adopt, including the choice of drug.[40][41]

The resources required to implement such large-scale interventions in a cost-effective and sustainable way are significant. Furthermore, since endemic scabies is largely restricted to poor and remote areas, it is a public health issue that has not attracted much attention from policy makers and international donors.[40][41]

# Epidemiology [edit]

Scabies is one of the three most common skin disorders in children, along with tinea and pyoderma.[8] As of 2010 it affects approximately 100 million people (1.5% of the population) and is equally common in both genders.[9] The mites are distributed around the world and equally infect all ages, races, and socioeconomic classes in different climates.[18] Scabies is more often seen in crowded areas with unhygienic living conditions.[42] Globally as of 2009, an estimated 300 million cases of scabies occur each year, although various parties claim the figure is either over- or underestimated.[16][43] About 1–10% of the global population is estimated to be infected with scabies, but in certain populations, the infection rate may be as high as 50–80%.[8]

# History [edit]

Wax figurine of a man with Norwegian scabies

Scabies has been observed in humans since ancient times. Archeological evidence from Egypt and the Middle East suggests scabies was present as early as 494 BC.[13][44] The first recorded reference to scabies is believed to be from the Bible – it may be a type of "leprosy" mentioned in Leviticus *circa* 1200 BC[45] or be mentioned among the curses of Deuteronomy 28.[46] In the fourth century BC, Aristotle reported on "lice" that "escape from little pimples if they are pricked" – a description consistent with scabies.[47]

The Roman encyclopedist and medical writer Aulus Cornelius Celsus (c. 25 BC – c. 50 AD) is credited with naming the disease "scabies" and describing its characteristic features.[47] The parasitic etiology of scabies was documented by the Italian physician Giovanni Cosimo Bonomo (1663–1696) in his 1687 letter, "Observations concerning the fleshworms of the human body".[47] Bonomo's description established scabies as one of the first human diseases

with a well-understood cause.[13][44]

In Europe in the late 19th through mid-20th centuries, a sulfur-bearing ointment called by the medical eponym of Wilkinson's ointment was widely used for topical treatment of scabies. The contents and origins of several versions of the ointment were detailed in correspondence published in the *British Medical Journal* in 1945.[48]

## Society and culture [edit]

The International Alliance for the Control of Scabies (IACS) was started in 2012,[41][49][50] and brings together over 70 researchers, clinicians and public health experts from more than 15 different countries. It has managed to bring the global health implications of scabies to the attention of the World Health Organization.[41] Consequently, the WHO has included scabies on its official list of neglected tropical diseases and other neglected conditions.[51]

## Other animals [edit]

*Main articles: Sarcoptic mange and Acariasis*

Scabies may occur in a number of domestic and wild animals; the mites that cause these infestations are of different subspecies from the one typically causing the human form.[12] These subspecies can infest animals that are not their usual hosts, but such infections do not last long.[12] Scabies-infected animals suffer severe itching and secondary skin infections. They often lose weight and become frail.[19]

A street dog in Bali, Indonesia, suffers from sarcoptic mange.

The most frequently diagnosed form of scabies in domestic animals is sarcoptic mange, caused by the subspecies *Sarcoptes scabiei canis*, most commonly in dogs and cats. Sarcoptic mange is transmissible to humans who come into prolonged contact with infested animals,[52] and is distinguished from human scabies by its distribution on skin surfaces covered by clothing. Scabies-infected domestic fowl suffer what is known as "scaly leg". Domestic animals that have gone feral and have no veterinary care are frequently afflicted with scabies and a host of other ailments.[53] Nondomestic animals have also been observed to suffer from scabies. Gorillas, for instance, are known to be susceptible to infection via contact with items used by humans.[54]

## Research [edit]

Moxidectin is being evaluated as a treatment for scabies.[55] It is established in veterinary medicine to treat a range of parasites, including sarcoptic mange. Its advantage over ivermectin is its longer duration of action.[56]

## Intro page [edit]

This is the intro page for the WikiMed Medical Encyclopdia app as seen here https://play.google.com/store/apps/details?id=org.kiwix.kiwixcustomwikimed

Emmanuel Engelhart is the amazing programmer that has brought it to life.

**Doc James** (talk · contribs · email) 00:10, 12 June 2015 (UTC)

@Doc James: Looks interesting. Where is the source code for this app? Is there a particular reason it is not developed as a Wikimedia project?--Anders Feder (talk) 07:04, 12 June 2015 (UTC)

Emmanuel is with Wikimedia-CH and does Kiwix. Source code should be available. **Doc James** (talk · contribs · email) 08:04, 12 June 2015 (UTC)

Right, the source code for Kiwix can be found through kiwix.org. I was unable to find anything for this particular 'variant' (WikiMed Medical Encyclopedia), though. @Kelson: Is/will this project be hosted somewhere?--Anders Feder (talk) 08:12, 12 June 2015 (UTC)

Thank you for the praises, but this is mostly the work of two colleagues of the Kiwix project. Kiwix is a Wikimedia project and is sponsored by WikimediaCH. All the source code you need is in the Kiwix repo, have a look to the README file. Kelson (talk) 08:16, 12 June 2015 (UTC)

Excellent, thanks.--Anders Feder (talk) 09:51, 12 June 2015 (UTC)

I am not understanding: "this is mostly the work of two colleagues of the Kiwix project". How was this funded?96.52.0.249 (talk) 18:08, 12 June 2015 (UTC)

This was was done during our last one week hackathon which was funded (accomodation/travel costs) by WikimediaCH. Kelson (talk) 19:46, 12 June 2015 (UTC)

It was you, User:Kelson? And who else? How were you invited to the event (and your partner), if so? Why choose medical articles?96.52.0.249 (talk) 20:15, 12 June 2015 (UTC)

We have been collaborating on putting together an offline version of medical articles since London last year. A number of chip manufacturer are interested in shipping phones to the developed world pre loaded with this content / this app. Thus there is the potential for 350 million copies going out. The phone manufacturers are interested in medical articles as am I.

**Doc James** (talk · contribs · email) 22:54, 12 June 2015 (UTC)

Everyone are invited to the hackathons, AFAIK, i.e. it is public events. Still, it would be a good idea to make the source code behind the "WikiMed Medical Encyclopedia" version of Kiwix available somewhere, so others can contribute.--Anders Feder (talk) 01:30, 13 June 2015 (UTC)

Is it not here http://sourceforge.net/p/kiwix/kiwix/ci/master/tree/ **Doc James** (talk · contribs · email) 06:55, 13 June 2015 (UTC)

No, that appears to be the mainline Kiwix release. It is the same URL that one gets to if clicking "Browse repository" -> "Kiwix" from kiwix.org, and there is no mention of the medical encyclopedia in the README file.--Anders Feder (talk) 07:48, 13 June 2015 (UTC)

We obviously develop agnostic technologies and you need therefore to read the paragraph "Android Custom App". If you want to dive in the code, this is really welcome, but please use Kiwix traditional communication solutions. We focus here on the content part of the app. Kelson (talk) 09:29, 13 June 2015 (UTC)

That paragraph mentions "bundled zim files". Where is the bundled zim file for the WikiMed Medical Encyclopedia?--Anders Feder (talk) 10:03, 13 June 2015 (UTC)

Here [1] **Doc James** (talk · contribs · email) 11:13, 13 June 2015 (UTC)

That was the piece I was missing. Could it be added to the project page in some fashion? I found this address too, which has no timestamp, and so presumably always points to the latest version.--Anders Feder (talk) 11:29, 13 June 2015 (UTC)

Which project page? **Doc James** (talk · contribs · email) 11:57, 13 June 2015 (UTC)

The one labelled "Project page" above in the tab next to the "Talk" tab on the present page.--Anders Feder (talk) 12:19, 13 June 2015 (UTC)

This is the intro page to the app in question. Rather than a project page for the app in question. We should develop a project page. **Doc James** (talk · contribs · email) 12:22, 13 June 2015 (UTC)

Can I begin one at a subpage to the intro page or would there be a better location?--Anders Feder (talk) 12:25, 13 June 2015 (UTC)

Okay created a project page for the app here Wikipedia:WikiProject_Medicine/App **Doc James** (talk · contribs · email) 12:29, 13 June 2015 (UTC)

## For the sake of transparency [edit]

I recommend some sort of page explaining the development of this app. Many Apps require-payment/are-not-free; any potentional customer coming through an app store who happens on this app will wonder why the app was developed by wikipedia, a nonprofit, and what sort of financial arrangement existed to ensure the completion of the app.96.52.0.249 (talk) 16:04, 13 June 2015 (UTC)

> So that would go here than [2]?
>
> We already mention it is free here [3] **Doc James** (talk · contribs · email) 23:52, 13 June 2015 (UTC)

## German translation [edit]

Dear Doc James, I revised the German translation of the Textbook, see de:Wikipedia:Redaktion Medizin/Open Textbook of Medicine. However, there are some questions remaining. Andrea Kamphuis posted some further questions a while ago. Maybe you can help us.

- The order of chapters and links is strictly alphabetical in the English version. Do the different language versions have to overlap each other or are we free to change the order of entries on de.wikipedia?

  > You are free to change the order. **Doc James** (talk · contribs · email) 15:42, 6 October 2016 (UTC)

- Some attributions were disputed. Why is the Asperger syndrome listed as part of Children's health? This is clearly not limited to children. Shouldn't it be listed under Psychiatry, same as Autism?

  > Yes many conditions are within to subject matter areas. I am happy if you move them around. **Doc James** (talk · contribs · email) 15:42, 6 October 2016 (UTC)

- Low back pain is listed under Rheumatology. To my limited understanding most cases of Low back pain have nothing to do with Rheumatology.

  > Yes agree most cases are not. Typically it is emergency medicine or primary care. Sometimes it is however related to rheumatology which is why we placed it their. **Doc James** (talk · contribs · email) 15:42, 6 October 2016 (UTC)

- Who is the recipient of the content? Medical doctors, patients? We need to know since we have to decide whether to use medical or common terms.

  > In English we are using common terms as both physicians and patients will understand them. We are seeing a great deal of us by medical students and they appreciate the simple language. **Doc James** (talk · contribs · email) 15:42, 6 October 2016 (UTC)

- What is the criteria of an entry being chosen for this list? Availability of a featured or good article on en.wikipdia? Or a general overiew of important medical subjects regardless of article rating?

  > These were key diseases and conditions I pulled together. The list can be changed. All the ones listed on the English list have had their leads improved in English. **Doc James** (talk · contribs · email) 15:42, 6 October 2016 (UTC)

Best regards, --Gereon K. (talk) 06:26, 6 October 2016 (UTC)

> These are all great questions. I do not have answers. It seems that the set of books has an unintentional English-language bias and also some challenges with grouping issues into categories. I imagined that this book was an experimental prototype and only imagined for a general audience. Anyone may make wiki-changes to it and in the case of low back pain and asperger it sounds like there are reasons to consider rearranging categories. **Blue Rasberry** (talk) 13:38, 6 October 2016 (UTC)

User:Gereon K. answered the questions. User:Bluerasberry this page is the intro to the offline medical app. **Doc James** (talk · contribs · email) 15:42, 6 October 2016 (UTC)

## Tools - Snellen chart? (Related?) [edit]

I would like to incorporate this tool, as it is simple, and can detect immediate vision issues. Is this project

strictly medical knowledge, or tools also? Either way, I will put it here, and wait for feedback! Snellen chart and also: Medical thermometer

Twillisjr (talk) 20:33, 21 November 2016 (UTC)

> The Snellen chart is already part of WPMED so is in the app. Articles lead needs to be brought to a good standard before it is included into this list. **Doc James** (talk · contribs · email) 13:33, 22 November 2016 (UTC)

Welcome to the "Offline Medical Encyclopedia" by [[Wikipedia]]. This is a complete collection of all health care, sanitation, anatomy, and medication related topics from Wikipedia in an offline format. Like Wikipedia all content is open access, meaning that it is free to download, reuse, share, and build upon.

We are working to develop these apps in a number of languages, including English, Persian, Chinese, and Hindi. There are ongoing [[Wikipedia:WikiProject_Medicine/Translation_task_force|efforts to increase access to medical information in all languages]] in collaboration with [[Translators Without Borders]] among others. If you like this app and are interested in helping us make it better please join [[Wikipedia:WikiProject Medicine]] or contact us directly.

Please keep in mind that this is volunteer generated content. While we try our best to make it as accurate as possible it is not perfect. Thus we request that you use common sense.

## From today's featured article

IWGP Intercontinental Championship belt

**Wrestle Kingdom 9** was a professional wrestling event at the Tokyo Dome on January 4, 2015, produced by the New Japan Pro Wrestling (NJPW) promotion. The first event on the 2015 NJPW schedule, it featured ten professional wrestling matches and one pre-show match, six of which were for championships. In the double main event, Shinsuke Nakamura successfully defended the IWGP Intercontinental Championship *(belt pictured)* against Kota Ibushi, and Hiroshi Tanahashi successfully defended the IWGP Heavyweight Championship against Kazuchika Okada. The appearance of Pro Wrestling Noah wrestlers led to a storyline in which NJPW's Suzuki-gun group began wrestling at Noah events. Wrestle Kingdom 9 was attended by 36,000 people and was broadcast as a pay-per-view event with English commentary in the United States and Canada. Critics issued universally positive reviews; *Paste* magazine said it presented "some of the most passionate and poignant performance art today". Readers of the *Wrestling Observer Newsletter* voted Wrestle Kingdom 9 the Best Major Wrestling Show of 2015, and named its Ibushi–Nakamura match as the 2015 Pro Wrestling Match of the Year. **Feral pigeons** (*Columba livia domestica*) are birds derived from domestic pigeons that have returned to the wild. Originally bred from the wild rock dove, which naturally inhabits sea cliffs and mountains, these pigeons use the ledges of buildings as a substitute for cliffs. They have become adapted to urban life, preying on insects and scavenging. They are abundant in towns and cities throughout much of the world.

## Explore Wikipedia's Contents

There are two ways to look things up in Wikipedia: by searching or by browsing.

- If you know the name of an article for which you are looking, simply type it into Wikipedia's search box.
- If you would like to look around the encyclopedia to see what is on it, use Wikipedia's **Contents** pages. Lists and indices are examples of contents for a published work, and Wikipedia has many of each, including a complete alphabetical index and indices by category.
- Links to all of Wikipedia's main contents pages are presented below, and they in turn link to the more specific pages.

## Curated article collections

### Overview articles

Overview articles summarize in prose a broad topic like biology, and also have illustrations and links to subtopics like cell biology, biographies like Carl Linnaeus, and other related articles like Human Genome Project.

- Portal:Contents/Overviews lists overview articles from covered areas of knowledge in a single page.

### Outline pages

Outline pages have trees of article links in an outline format. They show how important subtopics relate to each other, and can be useful as a more condensed, non-prose alternative to overview articles.

- Portal:Contents/Outlines is a comprehensive list of "Outline of __" pages, organized by subject
- Outline of academic disciplines covers subjects studied in college or university, and links directly to prose overview articles

### Third-party classification systems

Various third-party classification systems have been mapped to Wikipedia articles, which can be accessed from these pages:

- List of Dewey Decimal classes
- Library of Congress Classification
- Wikipedia:Outline of Roget's Thesaurus

## Vital articles

*Main page: Wikipedia:Vital articles*

Vital articles are lists of subjects for which Wikipedia should have corresponding high-quality articles. They serve as centralized watchlists to track the status of Wikipedia's most important articles.

- Vital articles level 1 – 10 most important articles
- Vital articles level 2 – 100 most important articles
- Vital articles level 3 – 1,000 most important articles
- Vital articles level 4 – 10,000 most important articles

# Reference collections

Wikipedia has several types of pages which provide content in a non-prose form, for reference purposes.

## List pages

List pages enumerate items of a particular type, such as the List of sovereign states or List of South Africans. Wikipedia has "lists of lists" when there are too many items to fit on a single page, when the items can sorted in different ways, or as a way of navigating lists on a topic (for example Lists of countries and territories or Lists of people). There are several ways to find lists:

- Portal:Contents/Lists – A limited single-page collection of lists and lists of lists
- List of lists of lists – A broad single-page collection of lists of lists
- Category:Lists – Browse lists comprehensively via the multi-page Wikipedia category system

## Timelines

Timelines list events chronologically, sometimes including links to articles with more detail. There are several ways to find timelines:

- List of timelines has a long single-page collection
- Category:Timelines has a comprehensive multi-page collection via the Wikipedia category system

Of particular interest may be:

- List of centuries
- List of decades
- List of historical anniversaries—e.g. events on January 1 of any year
- 2017—major events this year
- Portal:Current events—featured current events and related project activities
- Deaths in 2017—lists notable people who died this year
- Category:Graphical timelines—graphical timelines in the category and subcategories, arranged alphabetically

## Glossaries

Glossaries are lists of terms with definitions. Wikipedia includes hundreds of alphabetical glossaries; they can be found two ways:

- Portal:Contents/Glossaries – A single-page list of glossaries
- Category:Wikipedia glossaries – Browse glossaries comprehensively via the Wikipedia category system

## Bibliographies

Bibliographies list sources on a given topic, for verification or further reading outside Wikipedia:

- Category:Wikipedia bibliographies has a complete multi-page listing

### Category:Discographies

Discographies catalog the sound recordings of individual artists or groups.

- Category:Discographies has a complete multi-page listing

## Special format collections

### Portals

Portals include featured articles, images, news, categories, excerpts of key articles, links to related portals, and to-do lists for editors. There are two ways to find portals:

- Portal:Contents/Portals – A single-page list of portals
- Category:Portals – Browse portals comprehensively via the Wikipedia category system

### Wikipedia books

Wikipedia books are collections of Wikipedia articles that can be viewed, downloaded, or printed into a book. They provide a roadmap for a course of study in a particular subject.

- Category:Wikipedia books (community books)—an alphabetical list of the books
- Category:Wikipedia books—a list of the books, categorized by topic

### Spoken articles

Growing collections of Wikipedia articles are starting to become available as spoken word recordings as well.

- Category:Spoken articles—an organized list of all spoken articles
- Wikipedia:Spoken articles—some general information about the spoken article technology

## Collections of articles

### Category system

Wikipedia's collection of category pages is a classified index system. It is automatically generated from category tags at the bottoms of articles and most other pages. Nearly all of the articles available so far on the website can be found through these subject indexes.

If you are simply looking to browse articles by topic, there are three top-level pages to choose from:

- Category:Main topic classifications—probably what you are looking for: Arts, History, Technology, etc.
- Category:Fundamental categories—organizes articles into "abstract" ontological categories in a way that every article can reasonably be expected to be classified within it
- Portal:Contents/Categories—a hand-crafted list of first- and second-level topic categories

For biographies, see Category:People.

Category:Contents is technically at the top of the category hierarchy, but contains many categories useful to editors but not readers. Special:Categories lists every category alphabetically.

### Alphabetical lists of articles

Wikipedia's alphabetical article indexes

- Special:Allpages lists all of the current pages in Wikipedia.
- Portal:Contents/A–Z index provides an easy way to skip to a particular part of the alphabet in the list of all articles.

- Lists of alphabetical indexes
  - Category:Wikipedia indexes—alphabetical list of topic indexes
  - Portal:Contents/Indices—indexes sorted by topic area

As their name suggests, bee-eaters predominantly eat flying insects, especially bees and wasps, which are caught in the air by flights from an open perch.

*This* **Signpost** *"Featured content" report covers material promoted from 13 November to 17 December. Text may be adapted from the respective articles and lists; see their page histories for attribution.*

## Featured articles

Twenty-three featured articles were promoted.

- *Aries* (*nominated by Magiciandude*) is the ninth studio album by Mexican recording artist Luis Miguel. It was released by WEA Latina in 1993. After attaining commercial success in 1991 with his previous album, *Romance*, Miguel decided to return to a style similar to his earlier work, featuring pop ballads and dance numbers with R&B influences. The record was produced by Miguel, who was assisted by Kiko Cibrian, Rudy Pérez, David Foster, and Juan Luis Guerra. It peaked at number one on the US *Billboard* Latin Pop Albums, where it stayed for 19 weeks. Internationally, the album was certified triple platinum in Mexico, and was certified diamond in Argentina. *Aries* sold over two million copies worldwide through 2000. Upon its release, the album received mixed reviews from music critics; they were divided on the dance tunes and ballads, although Miguel's vocals and the album's arrangements garnered positive reactions. Miguel received several accolades,

Lewis Hamilton gestures to his home crowd following his fifth win of the 2015 Formula One season at Silverstone.

including a Grammy Award for Best Latin Pop Album.

- **Northampton War Memorial** *(nominated by HJ Mitchell)* is a First World War memorial on Wood Hill in the centre of Northampton, the county town of Northamptonshire. Designed by architect Sir Edwin Lutyens, it is a Stone of Remembrance flanked by twin obelisks draped with painted stone flags standing in a small garden in what was once part of the churchyard of All Saints' Church. Today it is a Grade I listed building.
- The **2015 Formula One season** *(nominated by Tvx1)* was the 66th season of the Formula One World Championship, a motor racing championship for Formula One cars, recognised by the sport's governing body, the Fédération Internationale de l'Automobile, as the highest class of competition for open-wheel racing cars. Twenty-two drivers representing ten teams contested nineteen Grands Prix, starting in Australia and ending in Abu Dhabi as they competed for the World Drivers' and World Constructors' championships. Lewis Hamilton secured his third Drivers' Championship with three races left in the season. The runner-up was his teammate Nico Rosberg, with Ferrari's Sebastian Vettel third. Mercedes clinched the 2015 Constructors' title at the Russian Grand Prix, ahead of Ferrari and Williams, and ended the season with a record 703 points.
- *Giganotosaurus* *(nominated by FunkMonk)* is a genus of theropod dinosaur that lived in what is now Argentina, during the early Cenomanian age of the Late Cretaceous period, approximately 99.6 to 97 million years ago. The holotype specimen was discovered in the Candeleros Formation of Patagonia in 1993, and is almost 70% complete. The animal was named *G. carolinii* in 1995; the genus name translates as "giant southern lizard" and the specific name honours the discoverer, Rubén D. Carolini. A dentary bone, a tooth and some tracks, discovered before the holotype, were later assigned to this animal. The genus attracted much interest and became part of a scientific debate about the maximum sizes of theropod dinosaurs.
- **First Tennessee Park** *(nominated by NatureBoyMD)* is a minor league baseball park in downtown Nashville, Tennessee. The home of the Triple-A Nashville Sounds of the Pacific Coast League, it opened in 2015, and can seat up to 10,000 people. It replaced the Sounds' former home, Herschel Greer Stadium, where

the team played from its founding in 1978 until 2014. The design of the park incorporates Nashville's musical and baseball heritage and the use of imagery inspired by country music, Sulphur Dell, and Nashville's former baseball players and teams. The ballpark's wide concourse wraps entirely around the stadium and provides views of the field from every location. The greenway section connects with two other greenways in the city.

- *Turbinellus floccosus* *(nominated by Casliber)* is a cantharelloid mushroom of the family Gomphaceae native to Asia and North America. The orange-capped vase- or trumpet-shaped fruiting bodies may reach 30 cm (12 in) high and 30 cm (12 in) wide. The lower surface, the hymenium, is covered in wrinkles and ridges, and is pale buff or yellowish to whitish. *T. floccosus* forms symbiotic relationships with various types of conifer, growing in coniferous woodlands. Though mild-tasting, they generally cause gastrointestinal symptoms of nausea, vomiting and diarrhea when consumed.
- *Crucifix* *(nominated by Ceoil and Kafka Liz)* is a wooden crucifix, painted in distemper, attributed to the Florentine painter and mosaicist Cimabue. The work was commissioned by the Franciscan friars of Santa Croce and is built from a complex arrangement of five main and eight ancillary timber boards. It is one the first Italian artworks to break from the late medieval Byzantine style and is renowned for its technical innovations and humanistic iconography. The work was in the Basilica di Santa Croce, Florence, since the late thirteenth century, and

at the Museo dell'Opera Santa Croce since restoration following the flooding of Arno in 1966. It remains in poor condition despite conservation efforts.

- *Night of January 16th* *(nominated by RL0919)* is a theatrical play by Russian-American author Ayn Rand, inspired by the death of the "Match King", Ivar Kreuger. Set in a courtroom during a murder trial, an unusual feature of the play is that members of the audience are chosen to play the jury. The court hears the case of Karen Andre, a former secretary and lover of businessman Bjorn Faulkner, of whose murder she is accused. The play does not directly portray the events leading to Faulkner's death; instead the jury must rely on character testimony to decide whether Andre is guilty. The play's ending depends on the verdict. Rand's intention was to dramatize a conflict between individualism and conformity, with the jury's verdict revealing which viewpoint they preferred.
- **SMS** *Mecklenburg* *(nominated by Parsecboy)* was the fifth ship of the *Wittelsbach* class of pre-dreadnought battleships of the German Imperial Navy. Laid down in 1900 at the AG Vulcan shipyard in Stettin, she was finished in 1903. *Mecklenburg* was armed with a main battery of four 24 cm (9.4 in) guns and had a top speed of 18 kn (33 km/h; 21 mph). It spent the early period of her career in the I Squadron of the German fleet, participating in the peacetime routine of training cruises and exercises. After World War I began in 1914, the ship was mobilized with her sisters as the IV Battle Squadron. She saw limited duty in the Baltic Sea against Russian naval forces, and as a guard ship in the North Sea. The German High Command withdrew the ship from active service in 1916 due to a threat from submarines and naval mines, together with severe shortages in personnel. For the remainder of her career, *Mecklenburg* served as a prison ship and as a barracks ship based in Kiel. She was stricken from the navy list in 1920 and sold for scrapping the following year.
- **State Route 76** *(nominated by Rschen7754)* is a 52.63 mi (84.70 km) long state highway in the U.S. state of California. It is a much used east–west route in the North County region of San Diego County. A route along the corridor has existed since the early 20th century, as has the

bridge over the San Luis Rey River near Bonsall. The route was added to the state highway system in 1933, and was officially designated by the California State Legislature as SR 76 in the 1964 state highway renumbering.

- *Super Mario Galaxy* *(nominated by Jaguar)* is a platform video game developed and published by Nintendo for the Wii worldwide in 2007. It is the third 3D game in the *Super Mario* series and the eighth main instalment overall. The game was re-released as a Nintendo Selects title in 2011, and as a download via the Wii U's eShop in 2015. The story revolves around the protagonist, Mario, who is on a quest to rescue Princess Peach whilst simultaneously saving the universe from Bowser. The levels in the game consist of galaxies filled with minor planets and worlds, with different variations of gravity, the central element of gameplay. It was a critical and commercial success, hailed as one of the greatest video games of all time. Critics praised the game's graphics, gravity mechanics, and setting.
- **Ike Altgens** *(nominated by ATS)* (1919–1995) was an American photojournalist, photo editor, and field reporter for the Associated Press (AP) based in Dallas, Texas, who became known for his photographic work during the assassination of President John F. Kennedy. He was 19 when he began his AP career, which was interrupted by military service during World War II. When his service time ended, Altgens returned to Dallas and got married, then went back to work for the local AP bureau and eventually earned a position as a senior editor. Altgens appeared briefly as a film actor and model during his 40-year career with the AP, which ended in 1979. He spent his later years working in display advertising, and answering letters and other requests made by assassination researchers. Altgens and his wife died in 1995 at about the same time in their Dallas home.
- *After the Deluge* *(nominated by Iridescent)* is a Symbolist oil painting by English artist George Frederic Watts, first exhibited as *The Sun* in an incomplete form in 1886 and completed in 1891. It shows a scene from the story of Noah's Flood, in which after 40 days of rain Noah opens the window of his Ark to see that the rain has stopped. Watts felt that modern society was in decline owing to a lack of moral values, and he often painted works on the topic of the Flood and its cleansing of the unworthy from the world. The painting takes the form of a stylised seascape, dominated by a bright sunburst breaking through clouds. Although this was a theme Watts had depicted previously in *The Genius of Greek Poetry* in 1878, *After the Deluge* took a radically different approach. With this painting he intended to evoke a monotheistic God in the act of creation, but avoid depicting the Creator directly.
- **Bradley Cooper** *(nominated by FrB.TG)* (born 1975) is an American actor and producer. His career began with a guest role in the television series *Sex and the City* in 1999 and his film debut came two years later in *Wet Hot American Summer*. He first gained recognition as Will Tippin in the spy-action television show *Alias* (2001–2006), and achieved minor success with a supporting part in the comedy film *Wedding Crashers* (2005). His breakthrough role came in 2009 with *The Hangover*, a commercially successful comedy which spawned two sequels in 2011 and 2013. In 2011, Cooper was named International Man of the Year by *GQ* and Sexiest Man Alive by *People*. He is one of the highest-paid actors in the world, and has been nominated for several accolades, including four Academy Awards, two British Academy Film Awards and two Golden Globe Awards. *Time* magazine named him one of the 100 most influential people in the world in 2015.
- *The Pale Emperor* *(nominated by Homeostasis07)* is the ninth studio album by American rock band Marilyn Manson. It was released in 2015, through Marilyn Manson's Hell, etc. label, and was distributed in the US by Loma Vista Recordings and internationally by Cooking Vinyl. The album was

released in standard and deluxe editions on CD and 2×LP vinyl, and as a limited edition box set. The standard version of the album contains ten tracks; the deluxe edition includes three acoustic versions as bonus tracks. The album was released to generally positive reviews from music critics. Several writers referred to it as the band's best album in over a decade, and multiple publications ranked it as one of the best albums of 2015. It was also a commercial success, debuting at number eight on the *Billboard* 200 with the band's highest opening week sales since *Eat Me, Drink Me* in 2007. It topped *Billboard*'s Hard Rock Albums chart, as well as the national albums chart in Switzerland, and peaked within the top ten in fifteen other countries.

- *Seri Rambai (nominated by Singora)* is a 17th-century Dutch cannon displayed at Fort Cornwallis in George Town. It is the largest bronze gun in Malaysia, a fertility symbol and the subject of legends and prophecy.
- **Gottlob Berger** *(nominated by Peacemaker67)* (1896–1975) was a senior German Nazi official who held the rank of *SS-Obergruppenführer und General der Waffen-SS*, and was the chief of the SS Main Office responsible for *Schutzstaffel* recruiting during World War II. He had a key role in the Reich Ministry for the Occupied Eastern Territories from mid-1942. In this role he proposed a plan to kidnap and enslave 50,000 Eastern European children between the ages of 10 and 14, under the codename Heuaktion, a plan that was subsequently carried out. He surrendered to U.S. troops near Berchtesgaden, and was promptly arrested. He was tried and convicted in the Ministries Trial of the U.S. Nuremberg Military Tribunals for war crimes, and was sentenced to 25 years imprisonment. His sentence was soon reduced to 10 years, and he was released after serving six and a half years.
- **Dick Cresswell** *(nominated by Ian Rose)* (1920–2006) was an officer and pilot in the Royal Australian Air Force (RAAF). He held command of No. 77 (Fighter) Squadron twice during World War II, and again during the Korean War. Cresswell was credited with being the first RAAF pilot to shoot down an enemy aircraft at night over Australian soil, the only man to serve as commanding officer of an RAAF squadron on three occasions during wartime, and the first officer to lead a jet-equipped Australian squadron in combat. His performance in Korea earned him both the Commonwealth and the US Distinguished Flying Crosses.
- The **Montreal Laboratory** *(nominated by Hawkeye7)* was established by the National Research Council of Canada during World War II to undertake nuclear research in collaboration with the United Kingdom, and to absorb some of the scientists and work of the Tube Alloys nuclear project in Britain. It became part of the Manhattan Project, and designed and built some of the world's first nuclear reactors.
- The **bee-eaters** *(nominated by Sabine's Sunbird and Jimfbleak)* are a group of near-passerine birds in the family Meropidae containing three genera and 27 species. Most species are found in Africa and Asia, with a few in southern Europe, Australia, and New Guinea. They are characterised by richly coloured plumage, slender bodies, and usually elongated central tail feathers. All have long down-turned bills and medium to long wings, which may be pointed or round. Male and female plumages are usually similar.
- The **Tahiti rail** *(nominated by FunkMonk)* is an extinct species of rail that lived on Tahiti. It was first recorded during James Cook's second voyage around the world (1772–1775), on which it was illustrated by Georg Forster and described by Johann Reinhold Forster. The Tahiti rail was 9 in (23 cm) long, and its colouration was unusual for a rail. The Tahiti rail was supposedly flightless, and nested on the ground. It is said to have been seen in open areas, marshes, and in coconut plantations.
- *Love, Inc. (nominated by Aoba47)* is an American television sitcom, created by Andrew Secunda, which originally aired for one season on United Paramount Network. The show revolves around five matchmakers working at a dating agency. Despite being set in New York, filming took place at Paramount Studios in Hollywood, Los Angeles and other locations in California. It was canceled following UPN's merger with the WB to launch the CW in 2006. Critical response to *Love, Inc.* was mixed: some critics praised its multi-ethnic cast, while others felt that the storylines and characters were unoriginal and Philipps' portrayal of her character as unsympathetic.
- The **Alabama Centennial half dollar** *(nominated by Wehwalt)* was a commemorative fifty-cent coin struck by the United States Bureau of the Mint in 1921 as a belated acknowledgement of the 100th anniversary of Alabama's admission to the Union in 1819. The coin was created by Laura Gardin Fraser, who became the first woman designer of a coin. To boost sales, a symbol, 2X2 (recognizing Alabama as the 22nd state) was included in the design for a minority of the coins; these are generally more expensive today.

- Ipswich Town F.C. is an English association football club founded in 1878. In 2007, the club created a

**hall of fame** *(nominated by The Rambling Man)* into which a number of personnel associated with the club are inducted every year. The inaugural members, Ray Crawford, Mick Mills, Ted Phillips and John Wark, were selected in 2007 by a ballot of former Ipswich players. As of 2016, forty-six people have been inducted into the hall of fame.

- The **Masters Tournament Par-3 contest** *(nominated by The Rambling Man)* is a golf competition which precedes the Masters Tournament at Augusta National Golf Club in Augusta, Georgia. The first Par-3 contest was held in 1960, and was won by three-time Masters champion Sam Snead. The contest takes place in a single round on a nine-hole, par-27 course in the northeast corner of Augusta National Grounds, which was designed in 1958 by George Cobb and club founder Clifford Roberts. Traditionally the golfers playing in the contest have invited family members onto the course to caddy for them, sometimes allowing them to play shots on their behalf. Numerous holes in one have been made during the history of the tournament, including nine in the 2016 tournament. No winner of the Par-3 contest has gone on to win the Masters in the same year.
- Ravichandran Ashwin (born 1986) is a Test, One Day International and Twenty20 International cricketer who represents the India national cricket team. As of December 2016, **Ashwin has taken 24 five-wicket hauls in international cricket** *(nominated by Vensatry)*; he ranks joint 13th in the all-time list, and joint third among his countrymen. He is one of only 45 bowlers who have taken 15 or more five-wicket hauls at international level in their cricketing careers.
- Michael Fassbender (born 1977) is a German-Irish actor. **His filmography** *(nominated by Cowlibob)* includes thirty-two films, seven television films and thirty-six television episodes. He also voiced Logan in the 2010 video game *Fable III*.
- A One Day International (ODI) is a 50 over cricket match between two representative teams, each having ODI status, as determined by the International Cricket Council (ICC). As of November 2016, **50 players have represented the Kenyan national team in ODIs** *(nominated by Yellow Dingo)*, since its debut in 1996. Thomas Odoyo and Steve Tikolo have played the most ODIs for Kenya with 131 each. Tikolo has scored the most runs with 3369 for the team, while Odoyo has taken the most wickets with 141.
- Shannen Doherty (born 1971) is an American actress, producer, author, and television director. **She has appeared in numerous television programs and motion pictures.** *(nominated by Aoba47)* She has appeared in sixteen films (with currently four of them being in post-production), in forty-eight television films and numerous television episodes (being a series regular on seven television shows).
- Rajinikanth (born 1950) is an Indian actor who predominantly works in Tamil cinema. He began his **film career** *(nominated by Kailash29792 and Vensatry)* by playing antagonistic and supporting roles before graduating to a lead actor. After starring in numerous commercially successful films throughout the 1980s and 1990s, he has continued to hold a matinée idol status in the popular culture of Tamil Nadu. Writing for Slate, Grady Hendrix called him the "biggest movie star you've probably never heard of." Rajinikanth has also worked in other Indian film industries such as Bollywood, Telugu, Kannada, Malayalam and Bengali. As of 2016, he has appeared in over 150 films.
- Maryland is a state located in the Southern United States. According to the 2010 United States Census, Maryland is the 19th most populous state with 5,773,785 inhabitants but the 9th smallest by land area spanning 9,707.24 sq mi (25,141.6 $km^2$) of land. Maryland is divided into 23 counties and contains **157 incorporated municipalities** *(nominated by Mattximus)* consisting of cities, towns, or villages. Incorporated municipalities cover only 4.4% of the state's land mass but are home to 26.2% of its population.
- Cardiff City F.C., a professional association football club based in Cardiff, Wales, was founded in 1899. As of the end of the 2015–16 season, the club had spent 11 seasons in the top tier of English football, 47 in the second, 22 in the third and 5 in the fourth. **This list** *(nominated by Kosack)* details their achievements in first-team competitions, and records their top goalscorer, for each completed season since their first appearance in the English football pyramid as members of the Southern Football League in 1910–11. Due to the unavailability of complete statistics, seasons prior to 1910 in the amateur Welsh leagues are not included.
- Essex is a county in the east of England. It has an area of 1,420 sq mi (3,700 $km^2$), with a coastline of 400 mi (640 km), and a population of 1,393,600 according to the 2011 census. As of August 2016 there are **forty-nine Local Nature Reserves (LNRs) in Essex** *(nominated by Dudley Miles)*. Nine are also Sites of Special Scientific Interest, three are also Scheduled Monuments and four are managed by the Essex Wildlife Trust. LNRs are designated by local authorities under the National Parks and Access to the Countryside Act 1949. The local authority must have a legal control over the site, by owning or leasing it or having an agreement with the owner. LNRs are sites which have a special local interest either biologically or geologically, and local authorities have a duty to care for them. They can apply local bye-laws to manage and protect LNRs.

This page provides **assistance** with the most common questions about Wikipedia.

To start, click on what you need assistance with below, or search all the help pages using the search box to the right. You may also browse the **Help menu** or the **Help directory**.

## **Read** or **find** an article

The **Readers' FAQ** and our **about page** contain the most commonly sought information about Wikipedia.

For simple searches, there is a search box at the top of every page. Type what you are looking for in the box. Partial matches will appear in a dropdown list. Select any page in the list to go to that page. Or, select the magnifying glass "Go" button, or press Enter, to go to a full search result. For advanced searches, see **Help:Searching**.

There are other ways to browse and explore Wikipedia articles; many can be found at **Portal:Contents**. Also see our **disclaimer** for cautions about Wikipedia's limitations.

## **Edit** an article

Contributing is easy: see **how to edit a page**. For a quick summary on participating, see **contributing to Wikipedia**. For a listing of introductions and tutorials by topic, see **getting started**. Or play **the Wikipedia Adventure** to learn to edit in an hour. The **Cheatsheet** can remind you of basic wiki markup.

**Be bold** in improving articles! When adding facts, please **provide references** so others may verify them. If you are affiliated with the article subject, please see our **conflict of interest guideline**.

If you feel someone is bullying you or if you don't understand why your edits are being reverted, you can ask for help at the **Help desk** or at the **Teahouse**. Volunteers will respond as soon as possible.

If you're looking for places you can help out, the **community portal** is the place to go. You can practice editing and experiment in a **sandbox**.

## **Report a problem** with an article

**If there is a problem with an article about yourself, a family member, a friend or a colleague, please read Wikipedia:Biographies of living persons/Help and, if necessary, add a discussion to the biographies of living persons noticeboard.**

If you spot a problem with an article, *you* can fix it directly, by clicking on the "Edit" link at the beginning of that page. **See the "edit an article" section of this page for more information.**

If you don't feel ready to fix the article yourself, please post a message on the article's **talk page**. This will bring the matter to the attention of others who work on that article. There is a "Talk" link at the beginning of *every* article page.

Alternatively you can **contact us**. If it's an article about you or your organization, see **Contact us – Subjects**.

## **Create a new article** or **upload media**

Check **Your first article** to see if your topic is appropriate, then the **Article wizard** will walk you through creating the article.

Once you have created an article, see **Writing better articles** for guidance on how to improve it and what to include (like reference **citations**).

For contributing images, audio or video files, see the **Introduction to uploading images**. Then the **Upload wizard** will guide you through that process.

### How to make your watchlist easier to read

If you use Firefox, there is a JavaScript you can install called **Watchlist sorter**.

This script sorts your watchlist by namespace, and adds spaces within each entry. This makes the watchlist much easier to read.

To install the script, copy/paste it to your your common.js page. This will install the script across all your skins.

Note: After saving, you have to bypass Firefox's cache

to see the changes. To do this, hold down the Shift key while clicking Reload (or press Ctrl + Shift + R). Or, you may have to **purge** the Wikipedia server cache.

Wikipedia (/ˌwɪkɪˈpiːdi.ə/ or /ˌwɪkiˈpiːdi.ə/ *WIK-i-PEE-dee-ə*) is a multilingual, web-based, free-content encyclopedia project supported by the Wikimedia Foundation and based on a model of openly editable content. The name "Wikipedia" is a portmanteau of the words *wiki* (a technology for creating collaborative websites, from the Hawaiian word *wiki*, meaning "quick") and *encyclopedia*. Wikipedia's articles provide links designed to guide the user to related pages with additional information.

Wikipedia is written collaboratively by largely anonymous volunteers who write without pay. Anyone with Internet access can write and make changes to Wikipedia articles, except in limited cases where editing is restricted to prevent disruption or vandalism. Users can contribute anonymously, under a pseudonym, or, if they choose to, with their real identity.

The fundamental principles by which Wikipedia operates are the five pillars. The Wikipedia community has developed many policies and guidelines to improve the encyclopedia; however, it is not a formal requirement to be familiar with them before contributing.

Since its creation in 2001, Wikipedia has grown rapidly into one of the largest reference websites, attracting 374 million unique visitors monthly as of September 2015.[1] There are about 70,000 active contributors working on more than 41,000,000 articles in 294 languages. As of today, there are 5,323,769 articles in English. Every day, hundreds of thousands of visitors from around the world collectively make tens of thousands of edits and create thousands of new articles to augment the knowledge held by the Wikipedia encyclopedia. (See the statistics page for more information.)

People of all ages, cultures and backgrounds can add or edit article prose, references, images and other media here. What is contributed is more important than the expertise or qualifications of the contributor.

What will remain depends upon whether the content is free of copyright restrictions and contentious material about living people, and whether it fits within Wikipedia's policies, including being verifiable against a published reliable source, thereby excluding editors' opinions and beliefs and unreviewed research. Contributions cannot damage Wikipedia because the software allows easy reversal of mistakes and many experienced editors are watching to help ensure that edits are cumulative improvements. Begin by simply clicking the *Edit* link at the top of any editable page!

Wikipedia is a live collaboration differing from paper-based reference sources in important ways. Unlike printed encyclopedias, Wikipedia is continually created and updated, with articles on historic events appearing within minutes, rather than months or years. Because everybody can help improve it, Wikipedia has become more comprehensive than any other encyclopedia. In addition to quantity, its contributors work on improving quality as well. Wikipedia is a work-in-progress, with articles in various stages of completion. As articles develop, they tend to become more comprehensive and balanced. Quality also improves over time as misinformation and other errors are removed or repaired. However, because anyone can click "edit" at any time and add stuff in, any article may contain undetected misinformation, errors, or vandalism. Awareness of this helps the reader to obtain valid information, avoid recently added misinformation (see *Wikipedia:Researching with Wikipedia*), and fix the article.

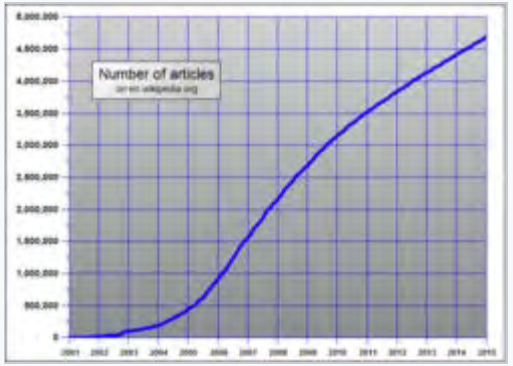
## Wikipedia history

*For more details on this topic, see History of Wikipedia.*

Wikipedia was founded as an offshoot of Nupedia, a now-abandoned project to produce a free encyclopedia, begun by the online media company Bomis. Nupedia had an elaborate system of peer review and required highly qualified contributors, but the writing of articles was slow. During 2000, Jimmy Wales (founder of Nupedia and co-founder of Bomis), and Larry Sanger, whom Wales had employed to work on the encyclopedia project, discussed ways of supplementing Nupedia with a more open, complementary project. Multiple sources suggested that a wiki might allow members of the public to contribute material, and Nupedia's first wiki went online on January 10, 2001.



The English edition of Wikipedia has grown to 5,323,769 articles, equivalent to over 2,000 print volumes of the *Encyclopædia Britannica*. Including all language editions, Wikipedia has over 38 million articles, equivalent to over 15,000 print volumes.

There was considerable resistance on the part of Nupedia's editors and reviewers to the idea of associating Nupedia with a website in the wiki format, so the new project was given the name "Wikipedia" and launched on its own domain, wikipedia.com, on January 15 (now called "Wikipedia Day" by some users). The bandwidth and server (in San Diego) were donated by Wales. Other current and past Bomis employees who have worked on the project include Tim Shell, one of the cofounders of Bomis and its current CEO, and programmer Jason Richey.

In May 2001, a large number of non-English Wikipedias were launched—in Catalan, Chinese, Dutch, Esperanto, French, German, Hebrew, Italian, Japanese, Portuguese, Russian, Spanish, and Swedish. These were soon joined by Arabic and Hungarian. In September,[2] Polish was added, and further commitment to the multilingual provision of Wikipedia was made. At the end of the year, Afrikaans, Norwegian, and Serbo-Croatian versions were announced.

The domain was eventually changed to the present wikipedia.org when the not-for-profit Wikimedia Foundation was launched, in 2003, as its new parent organization, with the ".org" top-level domain denoting its non-commercial nature. Today, there are Wikipedias in over 250 languages.

Anyone with Web access can edit Wikipedia, and this openness encourages inclusion of a tremendous amount of content. About 70,000 editors—from expert scholars to casual readers—regularly edit Wikipedia, and these experienced editors often help to create a consistent style throughout the encyclopedia, following our Manual of Style.

Several mechanisms are in place to help Wikipedia members carry out the important work of crafting a high-quality resource while maintaining civility. Editors are able to watch pages and technically skilled persons can write editing programs to keep track of or rectify bad edits. Where there are disagreements on how to display facts, editors often work together to compile an article that fairly represents current expert opinion on the subject.

Although the Wikimedia Foundation owns the site, it is largely uninvolved in writing and daily operations.

## Trademarks and copyrights

*Main pages: Wikipedia:Copyrights and wmf:Trademark policy*

"Wikipedia" is a registered trademark of the not-for-profit Wikimedia Foundation, which has created a family of free-content projects that are built by user contributions.

Most of Wikipedia's text and many of its images are dual-licensed under the Creative Commons Attribution-Sharealike 3.0 Unported License (CC-BY-SA) and the GNU Free Documentation License (GFDL) (unversioned, with no invariant sections, front-cover texts, or back-cover texts). Some text has been imported only under CC-BY-SA and CC-BY-SA-compatible license and cannot be reused under GFDL; such text is identified either on the page footer, in the page history or on the discussion page of the article that utilizes the text. Every image has a description page that indicates the license under which it is released or, if it is non-free, the rationale under which it is used.

Contributions remain the property of their creators, while the CC-BY-SA and GFDL licenses ensure the content is freely distributable and reproducible. (See content disclaimer for more information.)

## Credits

Text on Wikipedia is a collaborative work, and the efforts of individual contributors to a page are recorded in that page's history, which is publicly viewable. Information on the authorship of images and other media, such as sound files, can be found by clicking on the image itself or the nearby information icon to display the file page, which includes the author and source, where appropriate, along with other information.

## Exploring Wikipedia

*Main page: Portal:Contents*

Many visitors come to Wikipedia to acquire knowledge, while others come to share knowledge. At this very instant, dozens of articles are being improved, and new articles are also being created. Changes can be viewed at the Recent changes page and a random page at random articles. Over 4,500 articles have been designated by the Wikipedia community as featured articles, exemplifying the best articles in the encyclopedia. Another 22,000 articles are designated as good articles. Some information on Wikipedia is organized into lists; the best of these are designated as featured lists. Wikipedia also has portals, which organize content around topic areas; our best portals are selected as featured portals. Articles can be found using the search box on the top-right side of the screen.

Wikipedia is available in languages other than English. Wikipedia has more than two hundred and eighty languages, including a Simple English version, and related projects include a dictionary, quotations, books, manuals, and scientific reference sources, and a news service (see sister projects). All of these are maintained, updated, and managed by separate communities, and often include information and articles that can be hard to find through other common sources.

## Basic navigation in Wikipedia

*Main page: Help:Navigation*

Wikipedia articles are all linked, or cross-referenced. When highlighted text like this is seen, it means there is a link to some relevant article or Wikipedia page with further in-depth information. Holding the mouse over the link will often show to where the link will lead. There are other links towards the ends of most articles, for other articles of interest, relevant external websites and pages, reference material, and organized categories of knowledge which can be searched and traversed in a loose hierarchy for more information. Some articles may also have links to dictionary definitions, audio-book readings, quotations, the same article in other languages, and further information available on our sister projects. Additional links can be easily made if a relevant link is missing—this is one simple way to contribute.

## Using Wikipedia as a research tool

*Main pages: Wikipedia:Researching with Wikipedia and Wikipedia:Citing Wikipedia*

As wiki documents, articles are never considered complete and may be continually edited and improved. Over time, this generally results in an upward trend of quality and a growing consensus over a neutral representation of information.

Users should be aware that not all articles are of encyclopedic quality from the start: they may contain false or debatable information. Indeed, many articles start their lives as displaying a single viewpoint; and, after a long process of discussion, debate, and argument, they gradually take on a neutral point of view reached through consensus. Others may, for a while, become caught up in a heavily unbalanced viewpoint which can take some time—months or years perhaps—to achieve better balanced coverage of their subject. In part, this is because editors often contribute content in which they have a particular interest and do not attempt to make each article that they edit comprehensive. However, eventually, additional editors expand and contribute to articles and strive to achieve balance and comprehensive coverage. In addition, Wikipedia operates a number of internal resolution processes that can assist when editors disagree on content and approach. Usually, editors eventually reach a consensus on ways to improve the article.

The *ideal* Wikipedia article is well written, balanced, neutral, and encyclopedic, containing comprehensive, notable, verifiable knowledge. An increasing number of articles reach this standard over time, and many already have. Our best articles are called Featured Articles (and display a small star in the upper right corner of the article), and our second best tier of articles are designated Good Articles. However, this is a process and can take months or years to be achieved through the concerted effort of editors. Some articles contain statements which have not yet been fully cited. Others will later be augmented with new sections. Some information will be considered by later contributors to be insufficiently founded and, therefore, may be removed.

While the overall trend is toward improvement, it is important to use Wikipedia carefully if it is intended to be used as a research source, since individual articles will, by their nature, vary in quality and maturity. Guidelines and information pages are available to help users and researchers do this effectively, as is an article that summarizes third-party studies and assessments of the reliability of Wikipedia.

## Wikipedia vs paper encyclopedias

*Main page: Wikipedia is not paper (on Wikimedia Meta-Wiki).*

Wikipedia has advantages over traditional paper encyclopedias. First, is that it is not limited in space: it can keep growing as fast as people add to it.

Second, there are no qualifications required to be able to author its articles. Therefore, it has a very large pool of contributors: the whole world. This, and the first advantage mentioned above, have enabled Wikipedia to become the most comprehensive encyclopedia on Earth.

Third, a paper encyclopedia remains static (stays the same) and falls out of date until the next edition. But Wikipedia is dynamic: you don't have to wait for the next edition to come out (there are no editions), as Wikipedia is published on-line as it is written on-line. Articles are made available as is, regardless of what stage of development they are in. *You* can update Wikipedia at any instant, and people do so continually around the clock, thereby helping each other to keep abreast of the most recent events everywhere and of the latest facts in every subject.

Fourth, Wikipedia has a very low "publishing" cost for adding or expanding entries, as it is on-line, with no

need to buy paper or ink for distribution. This has allowed it to be made available for free, making it more accessible to everyone. This has enabled Wikipedia to be independently developed and published in many different languages at the same time, by people literate in each language. Of the 280+ different language Wikipedias, 132 of them have 10,000 or more articles.

Fifth, Wikipedia has a low environmental impact in some respects, since it never needs to be printed, although computers have their own environmental cost.

Sixth, Wikipedia is extra-linear (more than linear). Instead of in-line explanations, Wikipedia incorporates hypertext in the form of wikilinks. Throughout its content is a robust network of links, providing another dimension of knowledge accessibility. The encyclopedia also has correlates to tables of contents and indexes, with each entry in them hyperlinked to an article on the topic specified.

Seventh, each Wikipedia article provides an introduction summarizing the more extensive detail of its contents.

Eighth, being open to anyone to edit, articles on Wikipedia are subject to additions that are erroneous or written poorly. It is a community effort, with most people who are involved helping to improve the work, fixing problems they encounter along the way. See more about Wikipedia's strengths and weaknesses, below...

## Strengths, weaknesses, and article quality in Wikipedia

*Main pages: Wikipedia:Why Wikipedia is so great and Wikipedia:Why Wikipedia is not so great*
*See also: Reliability of Wikipedia and Wikipedia:Researching with Wikipedia*

Wikipedia's greatest strengths, weaknesses, and differences all arise because it is open to anyone, it has a large contributor base, and its articles are written by consensus, according to editorial guidelines and policies.

- Wikipedia is **open to a large contributor base**, drawing a large number of editors from diverse backgrounds. This allows Wikipedia to significantly reduce regional and cultural bias found in many other publications, and makes it very difficult for any group to censor and impose bias. A large, diverse editor base also provides access and breadth on subject matter that is otherwise inaccessible or little documented. A large number of editors contributing at any moment also means that Wikipedia can produce encyclopedic articles and resources covering newsworthy events within hours or days of their occurrence. It also means that like any publication, Wikipedia may reflect the cultural, age, socio-economic, and other biases of its contributors. There is no systematic process to make sure that "obviously important" topics are written about, so Wikipedia may contain unexpected oversights and omissions. While *most* articles may be altered by anyone, in practice editing will be performed by a certain demographic (younger rather than older, male rather than female, rich enough to afford a computer rather than poor, et cetera) and may, therefore, show some bias. Some topics may not be covered well, while others may be covered in great depth.
- Allowing **anyone to edit** Wikipedia means that it is more easily vandalized or susceptible to unchecked information, which requires removal. See Wikipedia:Administrator intervention against vandalism. While blatant vandalism is usually easily spotted and rapidly corrected, Wikipedia is more subject to subtle viewpoint promotion than a typical reference work. However, bias that would be unchallenged in a traditional reference work is likely to be ultimately challenged or considered on Wikipedia. While Wikipedia articles generally attain a good standard after editing, it is important to note that fledgling articles and those monitored less well may be susceptible to vandalism and insertion of false information. Wikipedia's radical openness also means that any given article may be, at any given moment, in a bad state, such as in the middle of a large edit, or a controversial rewrite. Many contributors do not yet comply fully with key policies, or may add information without citable sources. Wikipedia's open approach tremendously increases the chances that any particular factual error or misleading statement will be relatively promptly corrected. Numerous editors at any given time are monitoring recent changes and edits to articles on their watchlists.
- Wikipedia is **written by open and transparent consensus**—an approach that has its pros and cons. Censorship or imposing "official" points of view is extremely difficult to achieve and usually fails after a time. Eventually for most articles, all notable views become fairly described and a neutral point of view reached. In reality, the process of reaching consensus may be long and drawn-out, with articles fluid or

changeable for a long time while they find their "neutral approach" that all sides can agree on. Reaching neutrality is occasionally made harder by extreme-viewpoint contributors. Wikipedia operates a full editorial dispute resolution process, one that allows time for discussion and resolution in depth, but one that also permits disagreements to last for months before poor-quality or biased edits are removed. A common conclusion is that Wikipedia is a valuable resource and provides a good reference point on its subjects.

- That said, articles and subject areas sometimes suffer from significant omissions, and while misinformation and vandalism are usually corrected quickly, this does not always happen. (See for example this incident in which a person inserted a fake biography linking a prominent journalist to the Kennedy assassinations and Soviet Russia as a joke on a co-worker which went undetected for four months, saying afterwards he "didn't know Wikipedia was used as a serious reference tool".)
- Wikipedia is **written largely by amateurs**. Those with expert credentials are given no additional weight. Wikipedia is also not subject to any peer review for scientific, medical or engineering articles. One advantage to having amateurs write in Wikipedia is that they have more free time on their hands so that they can make rapid changes in response to current events. The wider the general public interest in a topic, the more likely it is to attract contributions from non-specialists.

The MediaWiki software that runs Wikipedia retains a history of all edits and changes, thus information added to Wikipedia never "vanishes" irreversibly. Discussion pages are an important resource on contentious topics. Therefore, serious researchers can often find a wide range of vigorously or thoughtfully advocated viewpoints not present in the consensus article. As with any source, information should be checked. A 2005 editorial by a BBC technology writer comments that these debates are probably symptomatic of cultural changes that are happening across all sources of information (including search engines and the media), and may lead to "a better sense of how to evaluate information sources".[3]

## Disclaimers

*Main page: Wikipedia:General disclaimer*

Wikipedia disclaimers apply to all pages on Wikipedia. However, the consensus in Wikipedia is to put all disclaimers only as links and at the end of each article. Proposals to have a warning box at the beginning have been rejected. Some do not like the way it looks or that it calls attention to possible errors in Wikipedia.

Wikipedia, in common with many websites, has a disclaimer that, at times, has led to commentators citing these in order to support a view that Wikipedia is unreliable. A selection of similar disclaimers from places which are often regarded as reliable (including sources such as Encyclopædia Britannica, Associated Press, and the Oxford English Dictionary) can be read and compared at Wikipedia:Non-Wikipedia disclaimers.

# Contributing to Wikipedia

*Main page: Wikipedia:Contributing to Wikipedia*
*See also: Wikipedia:Your first article and Guide to fixing vandalism*

Anyone can contribute to Wikipedia by clicking on the *Edit* tab in an article. Before beginning to contribute, however, read some handy helping tools such as the tutorial and the policies and guidelines, as well as our welcome page. Creating an account offers many benefits. It is important to realize that in contributing to Wikipedia, users are expected to be civil and neutral, respecting all points of view, and only add verifiable and factual information rather than personal views and opinions. "The five pillars of Wikipedia" cover this approach and are recommended reading before editing. (Vandals are reported via the Administrator Notice Board and may be

Most articles start as stubs, but after many contributions, they can become featured articles. Once the contributor has decided a topic of interest, they may want to request that the article be written (or they could research the issue and write it themselves). Wikipedia has on-going projects, focused on specific topic areas or tasks, which help coordinate editing.

The ease of editing Wikipedia results in many people editing. That makes the updating of the encyclopedia very quick, almost as fast as news websites.

## Editing Wikipedia pages

*Main pages: Help:Editing and Help:Wiki markup*

Wikipedia uses a simple yet powerful page layout to allow editors to concentrate on adding material rather than page design. Page aspects facilitated include:

- sections and subsections—which follow a page's lead section/introduction and (if specific conditions are met) a table of contents,
- references,
- images,
- tables,
- indentations
- lists,
- links,
- ISBNs,
- maths,
- formatting elements and most world alphabets and common symbols, Most of which have simple formats that are deliberately very easy and intuitive.

Normally editing is chosen by clicking the `Edit` tab at the top of a Wikipedia page (or on a section-edit link). This will take you to a new page with a text box containing the editable text of the page you were viewing. In this box, you can type in the text that you want to add, using wiki markup to format the text and add other elements like images and tables. You should then press the `Show preview` button to review your contributions for any errors. When you have finished editing, you should write a short edit summary in the small field below the edit-box describing your changes before you press the `Save page` button. This will help others to understand the intention of your edit. To avoid accidentally leaving edit summaries blank, you can select "Prompt me when entering a blank edit summary" on the `Editing` tab of your personal preferences.

Page editing is accessed through tabs that are found along the top edge of the page. These are:

- *Article.* Shows the main Wikipedia article.
- *Talk.* Shows a user discussion about the article's topic and possible revisions, controversies, etc.
- *Edit.* This tab allows users to edit the article. Depending on the page's susceptibility to vandalism, according to its visibility or the degree of controversy surrounding the topic, this tab may not be shown for all users. (For example, any user who is not an administrator will not be able to edit the Main Page.)

Wikipedia has robust version and reversion controls. This means that poor-quality edits or vandalism can quickly and easily be reversed or brought up to an appropriate standard by any other editor, so inexperienced editors cannot accidentally do permanent harm if they make a mistake in their editing. As there are many more editors intent on improving articles than not, error-ridden articles are usually corrected promptly.

## Wikipedia content criteria

*Main pages: Wikipedia:Wikipedia in brief and Wikipedia:Core content policies*

Wikipedia content is intended to be factual, notable, verifiable with cited external sources, and neutrally presented.

The appropriate policies and guidelines for these are found at:

1. Wikipedia:What Wikipedia is not, which summarizes what belongs in Wikipedia and what does not;
2. Wikipedia:Neutral point of view, which describes Wikipedia's mandatory core approach to neutral, unbiased article-writing;
3. Wikipedia:No original research, which prohibits the use of Wikipedia to publish personal views and original research of editors and defines Wikipedia's role as an encyclopedia of existing *recognized* knowledge;
4. Wikipedia:Verifiability, which explains that it must be possible for readers to verify all content against credible external sources (following the guidance in the Wikipedia:Risk disclaimer that is linked-to at the end of every article);
5. Wikipedia:Reliable sources, which explains what factors determine whether a source is acceptable;
6. Wikipedia:Citing sources, which describes the manner of citing sources so that readers can verify content for themselves;
7. And Wikipedia:Manual of Style, which offers a style guide—in general editors tend to acquire knowledge of appropriate writing styles and detailed formatting over time.

## Editorial administration, oversight, and management

*Main pages: Wikipedia:Administration and Wikipedia:Editorial oversight and control*

The Wikipedia community is largely self-organising, so that anyone may build a reputation as a competent editor and become involved in any role s/he may choose, subject to peer approval. Individuals often will choose to become involved in specialised tasks, such as reviewing articles at others' request, watching current edits for vandalism, watching newly created articles for quality control purposes, or similar roles. Editors who believe they can serve the community better by taking on additional administrative responsibility may ask their peers for agreement to undertake such responsibilities. This structure enforces meritocracy and communal standards of editorship and conduct. At

present a minimum approval of 75–80% from the community is required to take on these additional tools and responsibilities. This standard tends to ensure a high level of experience, trust, and familiarity across a broad front of aspects within Wikipedia.

does Wikipedia work even though anyone can edit it?

A variety of software-assisted systems and automated programs help editors and administrators to watch for problematic edits and editors. Theoretically all editors and users are treated equally with no "power structure". There is, however, a hierarchy of permissions and positions, some of which are listed hereafter:

1. *Anyone* can edit most of the articles here. Some articles are protected because of vandalism or edit-warring, and can only be edited by certain editors.
2. Anyone with an account that has been registered for four days or longer and has made at least ten edits becomes *autoconfirmed*, and gains the technical ability to do three things that non-autoconfirmed editors cannot:
   - Move articles.
   - Edit semi-protected articles.
   - Vote in certain elections (minimum edit count to receive suffrage varies depending on the election).
3. Many editors with accounts obtain access to certain tools that make editing easier and faster. Few editors learn about most of those tools, but one common privilege granted to editors in good standing is "rollback", which is the ability to undo edits more easily.
4. Administrators ("admins" or "sysops") have been approved by the community, and have access to some significant administrative tools. They can delete articles, block accounts or IP addresses, and edit fully protected articles.
5. Bureaucrats are chosen in a process similar to that for selecting administrators. There are not very many bureaucrats. They have the technical ability to add or remove admin rights and approve or revoke "bot" privileges.
6. The Arbitration Committee is analogous to Wikipedia's supreme court. They deal with disputes that remain unresolved after other attempts at dispute resolution have failed. Members of this Committee are elected by the community and tend to be selected from among the pool of experienced admins.
7. Stewards hold the top echelon of community permissions. Stewards can do a few technical things, and one almost never hears much about them since they normally only act when a local admin or bureaucrat is not available, and hence almost never on the English Wikipedia. There are very few stewards.
8. Jimmy Wales, the founder of Wikipedia, has several special roles and privileges. In most instances, however, he does not expect to be treated differently than any other editor or administrator.

## Handling disputes and abuse

*Main pages: Wikipedia:Vandalism, Wikipedia:Dispute resolution, Wikipedia:Consensus, Wikipedia:Sock puppetry, and Wikipedia:Conflict of interest*

Wikipedia has a rich set of methods to handle most abuses that commonly arise. These methods are well-tested and should be relied upon.

- Intentional *vandalism* can be reported and corrected by anyone.
- Unresolved *disputes* between editors, whether based upon behavior, editorial approach, or validity of content, can be addressed through the talk page of an article, through requesting comments from other editors or through Wikipedia's comprehensive dispute resolution process.
- *Abuse of user accounts*, such as the creation of "Internet sock puppets" or solicitation of friends and other parties to enforce a non-neutral viewpoint or inappropriate consensus within a discussion, or to disrupt other Wikipedia processes in an annoying manner, are addressed through the sock puppet policy.

In addition, new users may initially find that their votes are given less weight by editors in some informal polls in order to prevent abuse of single-purpose accounts.

## Editorial quality review

As well as systems to catch and control substandard and vandalistic edits, Wikipedia also has a full style and content manual and a variety of positive systems for continual article review and improvement. Examples of the processes include peer review, good article assessment, and the featured article process, a rigorous review of articles that are intended to meet the highest standards and showcase Wikipedia's capability to produce high-quality work.

In addition, specific types of article or fields often have their own specialized and comprehensive projects, assessment processes (such as biographical article assessment), and expert reviewers within specific subjects. Nominated articles are also frequently the subject of specific focus on the neutral point of view noticeboard or in WikiProject Cleanup.

# Technical attributes

Wikipedia uses MediaWiki software, the open-source program used not only on Wikimedia projects but also on many other third-party websites. The hardware supporting the Wikimedia projects is based on several hundred servers in various hosting centers around the world. Full descriptions of these servers and their roles are available on this Meta-Wiki page. For technical information about Wikipedia, check Technical FAQ. Wikipedia publishes various types of metadata; and, across its pages, are many thousands of microformats.

# Feedback and questions

Wikipedia is run as a communal effort. It is a community project whose result is an encyclopedia. Feedback about content should, in the first instance, be raised on the discussion pages of those articles. Be bold and edit the pages to add information or correct mistakes.

## Frequently asked questions (FAQ)

*Main page: Wikipedia:FAQ*

- FAQ index
- Category:Wikipedia FAQ

## Static help

The Help:Contents may be accessed by clicking *help* displayed under the ► *Interaction* tab at the top left of all pages.

- Help:Menu—is a menu-style page that will direct you to the right place to find information.
- Help:Directory—is a descriptive listing of all Wikipedia's informative, instructional and consultation pages.

## Giving feedback

There is an established escalation-and-dispute process within Wikipedia, as well as pages designed for questions, feedback, suggestions, and comments. For a full listing of the services and assistance that can be requested on Wikipedia, see Wikipedia:Request directory.

- Talk pages—the associated discussion page for discussion of an article or policy's contents (usually the first place to go)
- Wikipedia:Vandalism—a facility for reporting vandalism (but fix vandalism as well as report it)
- Dispute resolution—the procedure for handling disputes that remain unresolved within an article's talk space
- Village pump—the Wikipedia discussion area, part of the Community portal
- Wikipedia:Contact us

See also:

- Bug tracker—a facility for reporting problems with the Wikipedia website or the MediaWiki software that runs it

- Village pump: proposals page—a place for making non-policy suggestions
- Wikipedia:Help desk—Wikipedia's general help desk, if other pages have not answered the query

### Research help and similar questions

Facilities to help users researching specific topics can be found at:

- Wikipedia:Requested articles—to suggest or request articles for the future.
- Wikipedia:Reference desk—to ask for help with any questions, or in finding specific facts.
- Wikipedia:Researching with Wikipedia—for information on using Wikipedia as a research tool.

Because of the nature of Wikipedia, it is encouraged that people looking for information should try to find it themselves in the first instance. If, however, information is found to be missing from Wikipedia, be bold and add it so others can gain.

### Community discussion

For a listing of ongoing discussions and current requests, see the dashboard. For specific discussion not related to article content or editor conduct, see the Village pump, which covers such subjects as milestone announcements, policy and technical discussion, and information on other specialized portals such as the help, reference and peer review desks. The Community portal is a centralized place to find things to do, collaborations, and general editing help information, and find out what is happening. *The Signpost*, a community-edited newspaper, has recent news regarding Wikipedia, its sister projects, and the Wikimedia Foundation.

### Contacting individual Wikipedia editors

To contact individual contributors, leave a message on their talk page. Standard places to ask policy and project-related questions are the Village pump, online, and the Wikipedia mailing lists, over e-mail. Reach other Wikipedians via IRC and e-mail.

In addition, the Wikimedia Foundation **Meta-Wiki** is a site for coordinating the various Wikipedia projects and sister projects (and abstract discussions of policy and direction). Also available are places for submitting bug reports and feature requests.

For a full list of contact options, see **Wikipedia:Contact us**.

## Other languages

This Wikipedia is written in English. Started in 2001, it currently contains 5,323,769 articles. Many other Wikipedias are available; some of the largest are listed below.

## How to make your watchlist easier to read

If you use Firefox, there is a JavaScript you can install called **Watchlist sorter**.

This script sorts your watchlist by namespace, and adds spaces within each entry. This makes the watchlist much easier to read.

To install the script, copy/paste it to your your common.js page. This will install the script across all your skins.

Note: After saving, you have to bypass Firefox's cache to see the changes. To do this, hold down the Shift key while clicking Reload (or press Ctrl + Shift + R). Or, you may have to **purge** the Wikipedia server cache.

# Wikipedia:WikiProject Medicine/Open Textbook of Medicine

From Wikipedia, the free encyclopedia

Welcome to the **Offline Medical Encyclopedia** by Wikipedia. This is a complete collection of all health care, sanitation, anatomy, and medication related topics from Wikipedia in an offline format. Like Wikipedia all content is open access, meaning that it is free to download, reuse, share, and build upon.

We are working to develop these apps in a number of languages, including English, Persian, Chinese, and Hindi. There are ongoing efforts to increase access to medical information in all languages in collaboration with Translators Without Borders among others. If you like this app and are interested in helping us make it better please join Wikipedia:WikiProject Medicine or contact us directly.

Please keep in mind that this is volunteer generated content. While we try our best to make it as accurate as possible it is not perfect. Thus we request that you use common sense.

# Book creator

With the *book creator* you can create a book containing wiki pages of your choice. You can export the book in different formats (for example PDF or ODF) or order a printed copy.

*See Help:Books for more information.*

## Using the book creator

After the *book creator* has been enabled, the box as seen below is shown above each wiki page.

The book creator interface

*Add this page to your book*
: Adds the currently viewed article (page) to your book.

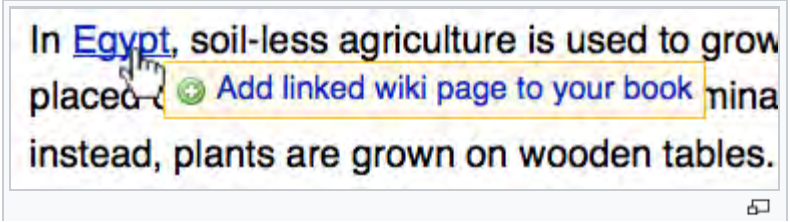
*Show book*
: Opens a new page which will show a list of all articles (pages) that you added to your book. On that page, you can **change the order** of the articles in your book and **structure** them using chapters. Further, you can **download** the books as a PDF or ODF, or order a **printed book**.

*Suggest pages*
: This tool analyzes the current set of pages in your book and **suggests** articles that might be also relevant to the overall topic of your book. This tool allows to create books **quickly**.

*Disable*
: This will **disable** the *Book creator* and **delete** your book (unless you saved it first).

### Adding pages without visiting them

A quick way to add pages is to simply hover on a linked article. If you wait about one second, a small box will pop up with the message "Add linked wiki page to your book". Click on this link, and the linked article will be added to your book.



Hovering your mouse over links is a convenient way to add pages to your book

## Adding whole categories

If you are viewing a category page, you can add all the pages in that category at once. The *Add this page to your book* link will have changed into *Add this category to your book*. Click on this new link, and all the articles in that category will be added to your book. Relevant categories may be found at the very bottom of Wikipedia articles. Categories can also be added by hovering category links.

# Benign paroxysmal positional vertigo

From Wikipedia, the free encyclopedia

**Benign paroxysmal positional vertigo** (**BPPV**) is a disorder arising from problems in the inner ear.[1] Symptoms are repeated brief periods of vertigo with movement, that is, of a spinning sensation caused by changes in the position of the head.[2] This can occur with turning in bed or changing position. Each episode of vertigo typically lasts less than one minute.[1] Nausea is commonly associated.[3] BPPV is one of the most common causes of vertigo.[2][4]

BPPV can result from a head injury or simply occur among those who are older. A specific cause is often not found. The underlying mechanism involves a small calcified otolith moving around loose in the inner ear. It is a type of balance disorder along with labyrinthitis and Ménière's disease.[1] Diagnosis is typically made when the Dix-Hallpike maneuver results in nystagmus (a specific movement pattern of the eyes) and other possible causes have been ruled out. In typical cases medical imaging is not needed.[2]

BPPV is often treated with a number of simple movements such as the Epley maneuver or Brandt-Daroff exercises.[1][5] Medications may be used to help with nausea.[3] There is tentative evidence that betahistine may help with the vertigo but its use is not generally needed.[2][6] BPPV is not a serious condition. Typically it resolves in one to two weeks. It however may recur in some people.[3]

The first medical description of the condition occurred in 1921 by Robert Barany.[7] About 2.4% of people are affected at some point in time.[2] Among those who live until their 80s, 10% have been affected.[4] BPPV affects females twice as often as males.[3] Onset is typically in the person's 50s to 70s.[4]

## Signs and symptoms [edit]

- Symptoms
  - Vomiting is common, depending on the strength of the vertigo itself and the causes for this illness.
  - Nausea is often associated.
  - Paroxysmal — Sudden onset of episodes with a short duration: lasts only seconds to minutes.
  - Positional in onset: Can only be induced by a change in position.
  - Pre-syncope (feeling faint) or syncope (fainting) is unusual but possible.
  - Rotatory (torsional) nystagmus, where the top of the eye rotates towards the affected ear in a beating or twitching fashion, which has a latency and can be fatigued (the vertigo should lessen with deliberate repetition of the provoking maneuver). Nystagmus should only last for 30 seconds to one minute.
  - Visual disturbance: It may be difficult to read or see during an attack due to associated nystagmus.
  - Vertigo — Spinning dizziness, which must have a rotational component.

Many patients will report a history of vertigo as a result of fast head movements. Many patients are also capable of describing the exact head movements that provoke their vertigo. Purely horizontal nystagmus and symptoms of vertigo lasting more than one minute can also indicate BPPV occurring in the horizontal semicircular canal.

Patients do not experience other neurological deficits such as numbness or weakness, and if these symptoms are present, a more serious etiology, such as posterior circulation stroke or ischemia, must be considered.

The spinning sensation experienced from BPPV is usually triggered by movement of the head, will have a sudden onset, and can last anywhere from a few seconds to several minutes. The most common movements patients report triggering a spinning sensation are tilting their heads upwards in order to look at something, and rolling over in bed.[8]

## Cause [edit]

Within the labyrinth of the inner ear lie collections of calcium crystals known as otoconia or otoliths. In patients with BPPV, the otoconia are dislodged from their usual position within the utricle, and migrate over time into one of the semicircular canals (the posterior canal is most commonly affected due to its anatomical position). When the head is reoriented relative to gravity, the gravity-dependent movement of the heavier otoconial debris (colloquially "ear rocks") within the affected semicircular canal causes abnormal (pathological) endolymph fluid displacement and a resultant sensation of vertigo. This more common condition is known as canalithiasis.

In rare cases, the crystals themselves can adhere to a semicircular canal cupula, rendering it heavier than the surrounding endolymph. Upon reorientation of the head relative to gravity, the cupula is weighted down by the dense particles, thereby inducing an immediate and sustained excitation of semicircular canal afferent nerves. This condition is termed cupulolithiasis.

There is evidence in the dental literature that malleting of an osteotome during closed sinus floor elevation, otherwise known as *osteotome sinus elevation* or *lift*, transmits percussive and vibratory forces capable of detaching otoliths from their normal location and thereby leading to the symptoms of BPPV.[9][10]

It can be triggered by any action which stimulates the posterior semi-circular canal, including:

- Looking up or down
- Post-head injury
- Sudden head movement
- Rolling over in bed

Tilting the head

BPPV may be made worse by any number of modifiers which may vary between individuals:

- Changes in barometric pressure — patients may feel increased symptoms up to two days before rain or snow
- Lack of sleep (required amounts of sleep may vary widely)
- Stress

An episode of BPPV may be triggered by dehydration, such as that caused by diarrhea. For this reason, it commonly occurs in post-operative patients who have diarrhea induced by post-operative antibiotics.

BPPV is one of the most common vestibular disorders in patients presenting with dizziness; migraine is implicated in idiopathic cases. Proposed mechanisms linking the two are genetic factors and vascular damage to the labyrinth.[11]

Although BPPV can occur at any age, it is most often seen in people over the age of 60.[12] Besides aging, there are no major risk factors known for developing BPPV, although previous episodes of trauma to the head, or inner ear infections known as labyrinthitis, may predispose individuals to future development of BPPV.[8]

## Mechanism [edit]

The inside of the ear is composed of an organ called the vestibular labyrinth. The vestibular labyrinth includes semicircular canals, which contain fluids and fine hairlike sensors which act as a monitor to the rotations of the head. An important structure in the inner ear includes the otolith organs which contain crystals that are sensitive to gravity. These crystals are responsible for sensitivity to head positions, and can also be dislocated, causing them to lodge inside one of the semicircular canals, which causes dizziness.

## Diagnosis [edit]

The condition is diagnosed by the patient's history, and by performing the Dix-Hallpike maneuver and/or the roll test.[13][14]

The Dix-Hallpike test is a common test performed by examiners to determine whether the posterior semicircular canal is involved.[14] It involves a reorientation of the head to align the posterior semicircular canal (at its entrance to the ampulla) with the direction of gravity. This test will reproduce vertigo and nystagmus characteristic of posterior canal BPPV.[13]

When performing the Dix-Hallpike test, patients are lowered quickly to a supine position, with the neck extended by the clinician performing the maneuver. For some patients, this maneuver may not be indicated, and a modification may be needed that also targets the posterior semicircular canal. Such patients include those who are too anxious about eliciting the uncomfortable symptoms of vertigo, and those who may not have the range of motion necessary to comfortably be in a supine position. The modification involves the patient moving from a seated position to side-lying *without* their head extending off the examination table, such as with Dix-Hallpike. The head is rotated 45 degrees away from the side being tested, and the eyes are examined for nystagmus. A positive test is indicated by patient report of a reproduction of vertigo and clinician observation of nystagmus. Both the Dix-Hallpike and the side-lying testing position have yielded similar results, and as such the side-lying position can be used if the Dix-Hallpike cannot be performed easily.[15]

The roll test can determine whether the horizontal semicircular canal is involved.[13] The roll test requires the patient to be in a supine position with their head in 30° of cervical flexion. Then the examiner quickly rotates the head 90° to the left side, and checks for vertigo and nystagmus. This is followed by gently bringing the head back to the starting position. The examiner then quickly rotates the head 90° to the right side, and checks again for vertigo and nystagmus.[13] In this roll test, the patient may experience vertigo and nystagmus on both sides, but rotating towards the affected side will trigger a more intense vertigo. Similarly, when the head is rotated towards the affected side, the nystagmus will beat towards the ground

and be more intense.[14]

As mentioned above, both the Dix-Hallpike and roll test provoke the signs and symptoms in subjects suffering from archetypal BPPV. The signs and symptoms patients with BPPV experience are typically a short-lived vertigo, and observed nystagmus. In some patients, though rarely, the vertigo can persist for years. Assessment of BPPV is best done by a medical health professional skilled in management of dizziness disorders, commonly a physiotherapist, audiologist or other physician.

The nystagmus associated with BPPV has several important characteristics which differentiate it from other types of nystagmus.

- Latency of onset: there is a 5-10 second delay prior to onset of nystagmus.
- Nystagmus lasts for 5–120 seconds.
- Positional: the nystagmus occurs only in certain positions.
- Repeated stimulation, including via Dix-Hallpike maneuvers, cause the nystagmus to fatigue or disappear temporarily.
- Rotatory/Torsional component is present, or (in the case of lateral canal involvement) the nystagmus beats in either a geotropic (towards the ground) or ageotropic (away from the ground) fashion.
- Visual fixation suppresses nystagmus due to BPPV.

Although rare, CNS disorders can sometimes present as BPPV. A practitioner should be aware that if a patient whose symptoms are consistent with BPPV, but does not show improvement or resolution after undergoing different particle repositioning maneuvers — detailed in the Treatment section below — need to have a detailed neurological assessment and imaging performed to help identify the pathological condition.[2]

### Differential diagnosis [edit]

Vertigo, a distinct process sometimes confused with the broader term, dizziness, accounts for about six million clinic visits in the United States every year; between 17 and 42% of these patients are eventually diagnosed with BPPV.[2] Other causes of vertigo include:

- Motion sickness/motion intolerance: a disjunction between visual stimulation, vestibular stimulation, and/or proprioception
- Visual exposure to nearby moving objects (examples of optokinetic stimuli include passing cars and falling snow)
- Other diseases: (labyrinthitis, Ménière's disease, and migraine,[16] etc.)

## Treatment [edit]

### Repositioning maneuvers [edit]

A number of maneuvers have been found to be effective including: the Epley maneuver, the Semont maneuver, and to a lesser degree Brandt-Daroff exercises.[5] Both the Epley and the Semont maneuver are equally effective.[5]

### Epley maneuver [edit]

*Main article: Epley maneuver*

The Epley maneuver employs gravity to move the calcium crystal build-up that causes the condition.[17] This maneuver can be performed during a clinic visit by health professionals, or taught to patients to practice at home, or both.[18] Postural restriction after the Epley maneuver increases its effect somewhat.[19]

When practiced at home, the Epley maneuver is more effective than the Semont maneuver. The most effective repositioning treatment for posterior canal BPPV is the therapist-performed Epley combined with home-practiced Epley maneuvers.[20] Devices like the DizzyFIX can help users conduct the Epley maneuver

at home, and are available for the treatment of BPPV.[21]

The Epley maneuver does not address the actual presence of the particles (otoconia); rather it changes their location. The maneuver aims to move these particles from some locations in the inner ear which cause symptoms such as vertigo, and reposition them to where they do not cause these problems.

## Semont maneuver [edit]

*Main article: Semont maneuver*

The Semont maneuver has a cure rate of 90.3%.[22] It is performed as follows:

1. The patient is seated on a treatment table with their legs hanging off the side of the table. The therapist then turns the patient's head towards the unaffected side 45 degrees.
2. The therapist then quickly tilts the patient so they are lying on the affected side. The head position is maintained, so their head is turned up 45 degrees. This position is maintained for 3 minutes. The purpose is to allow the debris to move to the apex of the ear canal.
3. The patient is then quickly moved so they are lying on the unaffected side with their head in the same position (now facing downwards 45 degrees). This position is also held for 3 minutes. The purpose of this position is to allow the debris to move toward the exit of the ear canal.
4. Finally, the patient is slowly brought back to an upright seated position. The debris should then fall into the utricle of the canal and the symptoms of vertigo should decrease or end completely.

Some patients will only need one treatment, but others may need multiple treatments, depending on the severity of their BPPV. In the Semont maneuver, as with the Epley maneuver, patients themselves are able to achieve canalith repositioning.[18]

## Brandt-Daroff exercises [edit]

The Brandt-Daroff exercises may be prescribed by the clinician as a home treatment method, usually in conjunction with particle-repositioning maneuvers or in lieu of the particle-repositioning maneuver. The exercise is a form of habituation exercise, designed to allow the patient to become accustomed to the position which causes the vertigo symptoms. The Brandt-Daroff exercises are performed in a similar fashion to the Semont maneuver; however, as the patient rolls onto the unaffected side, the head is rotated toward the affected side.[23] The exercise is typically performed 3 times a day with 5-10 repetitions each time, until symptoms of vertigo have resolved for at least 2 days.[13]

## Roll maneuver [edit]

For the lateral (horizontal) canal, a separate maneuver has been used for productive results. It is unusual for the lateral canal to respond to the canalith repositioning procedure used for the posterior canal BPPV. Treatment is therefore geared towards moving the canalith from the lateral canal into the vestibule.[24] The roll maneuver or its variations are used, and involve rolling the patient 360 degrees in a series of steps to reposition the particles.[2] This maneuver is generally performed by a trained clinician who begins seated at the head of the examination table with the patient supine[25] There are four stages, each a minute apart, and at the third position the horizontal canal is oriented in a vertical position with the patient's neck flexed and on forearm and elbows.[25] When all four stages are completed, the head roll test is repeated, and if negative, treatment ceases.[25]

## Medications [edit]

Medical treatment with anti-vertigo medications may be considered in acute, severe exacerbation of BPPV, but in most cases are not indicated. These primarily include drugs of the anti-histamine and anti-cholinergic class, such as meclizine and hyoscine butylbromide (scopolamine) respectively. The medical management of vestibular syndromes has become increasingly popular over the last decade, and numerous novel drug therapies (including existing drugs with new indications) have emerged for the treatment of vertigo/dizziness syndromes. These drugs vary considerably in their mechanisms of action, with many of

them being receptor- or ion channel-specific. Among them are betahistine or dexamethasone/gentamicin for the treatment of Ménière's disease, carbamazepine/oxcarbazepine for the treatment of paroxysmal dysarthria and ataxia in multiple sclerosis, metoprolol/topiramate or valproic acid/tricyclic antidepressant for the treatment of vestibular migraine, and 4-aminopyridine for the treatment of episodic ataxia type 2 and both downbeat and upbeat nystagmus.[26] These drug therapies offer symptomatic treatment, and do not affect the disease process or resolution rate. Medications may be used to suppress symptoms during the positioning maneuvers if the patient's symptoms are severe and intolerable. More dose-specific studies are required, however, in order to determine the most effective drug(s) for both acute symptom relief and long-term remission of the condition.[26]

### Surgery [edit]

Surgical treatments, such as a semi-circular canal occlusion, do exist for BPPV, but carry the same risk as any neurosurgical procedure. Surgery is reserved as a last resort option for severe and persistent cases which fail vestibular rehabilitation (including particle repositioning and habituation therapy).

**Hearing loss**, also known as **hearing impairment**, is a partial or total inability to hear.[2] A **deaf** person has little to no hearing.[3] Hearing loss may occur in one or both ears.[3] In children hearing problems can affect the ability to learn language and in adults it can cause work related difficulties.[4] In some people, particularly older people, hearing loss can result in loneliness.[3] Hearing loss can be temporary or permanent.

Hearing loss may be caused by a number of factors, including: genetics, ageing, exposure to noise, some infections, birth complications, trauma to the ear, and certain medications or toxins. A common condition that results in hearing loss is chronic ear infections. Certain infections during pregnancy such as syphilis and rubella may also cause hearing loss. Hearing loss is diagnosed when hearing testing finds that a person is unable to hear 25 decibels in at least one ear.[3] Testing for poor hearing is recommended for all newborns.[4] Hearing loss can be categorised as mild, moderate, moderate-severe, severe, or profound.[3] There are three main types of hearing loss, conductive hearing loss, sensorineural hearing loss, and mixed hearing loss.[5]

Half of hearing loss is preventable. This includes by immunization, proper care around pregnancy, avoiding loud noise, and avoiding certain medications.[3] The World Health Organization recommends that young people limit the use of personal audio players to an hour a day in an effort to limit exposure to noise.[6] Early identification and support are particularly important in children. For many hearing aids, sign language, cochlear implants and subtitles are useful. Lip reading is another useful skill some develop. Access to hearing aids, however, is limited in many areas of the world.[5]

As of 2013 hearing loss affects about 1.1 billion people to some degree.[7] It causes disability in 5% (360 to 538 million) and moderate to severe disability in 124 million people.[3][8][9] Of those with moderate to severe disability 108 million live in low and middle income countries.[8] Of those with hearing loss it began in 65 million during childhood.[10] Those who use sign language and are members of Deaf culture see themselves as having a difference rather than an illness.[11] Most members of

Deaf culture oppose attempts to cure deafness[12][13][14] and some within this community view cochlear implants with concern as they have the potential to eliminate their culture.[15] The term hearing impairment is often viewed negatively as it emphasises what people cannot do.[11]

## Definition [edit]

- Hearing loss exists when there is diminished sensitivity to the sounds normally heard.[10] The terms hearing impaired or hard of hearing are usually reserved for people who have relative insensitivity to sound in the speech frequencies. The severity of a hearing loss is categorized according to the increase

in volume above the usual level necessary before the listener can detect it.

- Deafness is defined as a degree of loss such that a person is unable to understand speech even in the presence of amplification.[10] In profound deafness, even the loudest sounds produced by an audiometer (an instrument used to measure hearing by producing pure tone sounds through a range of frequencies) may not be detected. In total deafness, no sounds at all, regardless of amplification or method of production, are heard.
- Speech perception - Another aspect of hearing involves the perceived clarity of a word rather than the amplitude of sound made by the word. In humans, that aspect is usually measured by tests of speech perception. These tests measure one's ability to understand speech, not to merely detect sound. There are very rare types of hearing loss which affect speech perception alone.[*clarification needed*][16]

Use of the terms "hearing impaired," "deaf-mute," or "deaf and dumb" to describe deaf and hard of hearing people is discouraged by advocacy organizations as they are offensive to many deaf and hard of hearing people.[17]

## Hearing standards [edit]

*See also: Absolute threshold of hearing and Hearing range*
*Further information: Equal-loudness contour and A-weighting*

Human hearing extends in frequency from 20-20,000 Hz, and in amplitude from 0 dB to 130 dB or more. 0 dB does not represent absence of sound, but rather the softest sound an average unimpaired human ear can hear; some people can hear down to -5 or even -10 dB. 130 dB represents the threshold of pain. But the ear doesn't hear all frequencies equally well; hearing sensitivity peaks around 3000 Hz. There are many qualities of human hearing besides frequency range and amplitude that can't easily be measured quantitatively. But for many practical purposes, normative hearing is defined by a frequency versus amplitude graph, or audiogram, charting sensitivity thresholds of hearing at defined frequencies. Because of the cumulative impact of age and exposure to noise and other acoustic insults, 'typical' hearing may not be normative.[18][19]

## Signs and symptoms [edit]

- difficulty using the telephone
- loss of directionality of sound
- difficulty understanding speech, especially of women and children
- difficulty in speech discrimination against background noise (cocktail party effect)
- sounds or speech becoming dull, muffled or attenuated
- need for increased volume on television, radio, music and other audio sources

Hearing loss is sensory, but may have accompanying symptoms:

- pain or pressure in the ears
- a blocked feeling

There may also be accompanying secondary symptoms:

- hyperacusis, heightened sensitivity to certain volumes and frequencies of sound, sometimes resulting from "recruitment"
- tinnitus, ringing, buzzing, hissing or other sounds in the ear when no external sound is present
- vertigo and disequilibrium
- tympanophonia, abnormal hearing of one's own voice and respiratory sounds, usually as a result of a patulous eustachian tube or dehiscent superior semicircular canals
- disturbances of facial movement (indicating possible tumour or stroke)

## Causes [edit]

Hearing loss has multiple causes, including ageing, genetics, perinatal problems and acquired causes like noise and disease. For some kinds of hearing loss the cause may be classified as of unknown cause.

## Age [edit]

There is a progressive loss of ability to hear high frequencies with aging known as presbycusis. For men, this can start as early as 25 and women at 30. Although genetically variable it is a normal concomitant of ageing and is distinct from hearing losses caused by noise exposure, toxins or disease agents.[20] Common conditions that can increase the risk of hearing loss in elderly people are high blood pressure, diabetes or the use of certain medications harmful to the ear.[21] While everyone loses hearing with age, the amount and type of hearing loss is variable.[22]

## Noise [edit]

*Main article: Noise-induced hearing loss*

The examples and perspective in this section **may not represent a worldwide view of the subject**. You may improve this article, discuss the issue on the talk page, or create a new article, as appropriate. *(December 2015) (Learn how and when to remove this template message)*

Noise exposure is the cause of approximately half of all cases of hearing loss, causing some degree of problems in 5% of the population globally.[23] The National Institute for Occupational Safety and Health (NIOSH) recognizes that the majority of hearing loss is not due to age, but due to noise exposure. By correcting for age in assessing hearing, one tends to overestimate the hearing loss due to noise for some and underestimate it for others.[24]

Hearing loss due to noise may be temporary, called a 'temporary threshold shift', a reduced sensitivity to sound over a wide frequency range resulting from exposure to a brief but very loud noise like a gunshot, firecracker, jet engine, jackhammer, etc. or to exposure to loud sound over a few hours such as during a pop concert or nightclub session.[25] Recovery of hearing is usually within 24 hours, but may take up to a week.[26] Both constant exposure to loud sounds (85 dB(A) or above) and one-time exposure to extremely loud sounds (120 dB(A) or above) may cause permanent hearing loss.[27]

Noise-induced hearing loss (NIHL) typically manifests as elevated hearing thresholds (i.e. less sensitivity or muting) between 3000 and 6000 Hz, centered at 4000 Hz. As noise damage progresses, damage spreads to affect lower and higher frequencies. On an audiogram, the resulting configuration has a distinctive notch, called a 'noise' notch. As aging and other effects contribute to higher frequency loss (6–8 kHz on an audiogram), this notch may be obscured and entirely disappear.

Various governmental, industry and standards organizations set noise standards.[28]

The U.S. Environmental Protection Agency has identified the level of 70 dB(A) (40% louder to twice as loud as normal conversation; typical level of TV, radio, stereo; city street noise) for 24 hour exposure as the level necessary to protect the public from hearing loss and other disruptive effects from noise, such as sleep disturbance, stress-related problems, learning detriment, etc.[29] Noise levels are typically in the 65 to 75 dB (A) range for those living near airports of freeways and may result in hearing damage if sufficient time is spent outdoors.[30]

Louder sounds cause damage in a shorter period of time. Estimation of a "safe" duration of exposure is possible using an *exchange rate* of 3 dB. As 3 dB represents a doubling of intensity of sound, duration of exposure must be cut in half to maintain the same energy dose. For workplace noise regulation, the "safe" daily exposure amount at 85 dB A, known as an exposure action value, is 8 hours, while the "safe" exposure at 91 dB(A) is only 2 hours.[31] Different standards use exposure action values between 80dBA and 90dBA. Note that for some people, sound may be damaging at even lower levels than 85 dB A. Exposures to other ototoxins (such as pesticides, some medications including chemotherapy agents, solvents, etc.) can lead to greater susceptibility to noise damage, as well as causing its own damage. This is called a *synergistic* interaction. Since noise damage is cumulative over long periods of time, persons who are exposed to non-workplace noise, like recreational activities or environmental noise, may have compounding damage from all sources.

Some national and international organizations and agencies use an exchange rate of 4 dB or 5 dB.[32] While these exchange rates may indicate a wider zone of comfort or safety, they can significantly underestimate the damage caused by loud noise. For example, at 100 dB (nightclub music level), a 3 dB exchange rate would limit exposure to 15 minutes; the 5 dB exchange rate allows an hour.

Many people are unaware of the presence of environmental sound at damaging levels, or of the level at which sound becomes harmful. Common sources of damaging noise levels include car stereos, children's toys, motor vehicles, crowds, lawn and maintenance equipment, power tools, gun use, musical instruments, and even hair dryers. Noise damage is cumulative; all sources of damage must be considered to assess risk. If one is exposed to loud sound (including music) at high levels or for extended durations (85 dB A or greater), then hearing loss will occur. Sound intensity (sound energy, or propensity to cause damage to the ears) increases dramatically with proximity according to an inverse square law: halving the distance to the sound quadruples the sound intensity.

In the USA, 12.5% of children aged 6–19 years have permanent hearing damage from excessive noise exposure.[33] The World Health Organization estimates that half of those between 12 and 35 are at risk from using personal audio devices that are too loud.[6]

Hearing loss due to noise has been described as primarily a condition of modern society.[34] In preindustrial times, humans had far less exposure to loud sounds. Studies of primitive peoples indicate that much of what has been attributed to age-related hearing loss may be long term cumulative damage from all sources, especially noise. People living in preindustrial societies have considerably less hearing loss than similar populations living in modern society. Among primitive people who have migrated into modern society, hearing loss is proportional to the number of years spent in modern society.[35][36][37] Military service in World War II, the Korean War, and the Vietnam War, has likely also caused hearing loss in large numbers of men from those generations, though proving that hearing loss was a direct result of military service is problematic without entry and exit audiograms.[38]

Hearing loss in adolescents may be caused by loud noise from toys, music by headphones, and concerts or events.[39]

## Genetic [edit]

Hearing loss can be inherited. Around 75–80% of all these cases are inherited by recessive genes, 20–25% are inherited by dominant genes, 1–2% are inherited by X-linked patterns, and fewer than 1% are inherited by mitochondrial inheritance.[40]

When looking at the genetics of deafness, there are 2 different forms, syndromic and nonsyndromic. Syndromic deafness occurs when there are other signs or medical problems aside from deafness in an individual. This accounts for around 30% of deaf individuals who are deaf from a genetic standpoint.[40] Nonsyndromic deafness occurs when there are no other signs or medical problems associated with an individual other than deafness. From a genetic standpoint, this accounts for the other 70% of cases, and represents the majority of hereditary hearing loss.[40] Syndromic cases occur with diseases such as Usher syndrome, Stickler syndrome, Waardenburg syndrome, Alport's syndrome, and neurofibromatosis type 2. These are diseases that have deafness as one of the symptoms or as a common feature associated with it. Many of the genetic mutations giving rise to syndromic deafness have been identified. In nonsyndromic cases, where deafness is the only finding, it is more difficult to identify the genetic mutation although some have been discovered.

- Recent gene mapping has identified several nonsyndromic dominant (DFNA#) and recessive (DFNB#) forms of deafness. The first gene mapped for non-syndromic deafness, DFNA1, involves a splice site mutation in the formin related homolog diaphanous 1 (DIAPH1). A single base change in a large Costa Rican family was identified as causative in a rare form of low frequency onset progressive hearing loss with autosomal dominant inheritance exhibiting variable age of onset and complete penetrance by age 30.[41] The most common type of congenital hearing loss in developed countries is DFNB1, also known as connexin 26 deafness or GJB2-related deafness.
- The most common dominant syndromic forms of hearing loss include Stickler syndrome and Waardenburg syndrome.

- The most common recessive syndromic forms of hearing loss are Pendred syndrome and Usher syndrome.
- The congenital defect microtia, deformed or unformed outer ear, can be associated with partial or complete conductive deafness, depending upon the severity of the deformity and whether the middle ear is also affected. It can also be associated with abnormalities of the inner ear giving rise to an additional sensorineural component to the hearing loss (mixed deafness).
- Mutations in PTPRQ are a cause of autosomal-recessive nonsyndromic hearing loss.[42]

## Perinatal problems [edit]

- Fetal alcohol spectrum disorders are reported to cause hearing loss in up to 64% of infants born to alcoholic mothers, from the ototoxic effect on the developing fetus plus malnutrition during pregnancy from the excess alcohol intake.
- Premature birth can be associated with sensorineural hearing loss because of an increased risk of hypoxia, hyperbilirubinaemia, ototoxic medication and infection as well as noise exposure in the neonatal units. The risk of hearing loss is greatest for those weighing less than 1500 g at birth.

## Disorders [edit]

- strokes - Depending on what blood vessels are affected by the stroke, one of the symptoms can be deafness.
- multiple sclerosis can have an effect on hearing as well. Multiple sclerosis, or MS, is an autoimmune disease where the immune system attacks the myelin sheath, a covering that protects the nerves. If the auditory nerve becomes damaged, the affected person will become completely deaf in one or both ears. There is no cure for MS.
- perilymph fistula - a microtear in either the round or oval window (membranes separating the middle and inner ear) of the cochlea causing perilymph to leak into the middle ear. This usually occurs as a consequence of trauma, including barotrauma, and can give rise to vertigo as well as hearing loss.
- viral - viral infections of the ear can cause sensorineural hearing loss usually as the consequence of a labyrinthitis. The patient may be generally unwell at the time.
  - Measles may cause auditory nerve damage but usually gives rise to a chronic middle ear problem giving rise to a mixed hearing loss.
  - Mumps (Epidemic parotitis) may result in profound sensorineural hearing loss (90 dB or more), unilateral (one ear) or bilateral (both ears).
  - congenital rubella (also called German measles) syndrome, can cause deafness in newborns
  - several varieties of herpes viruses that cause other diseases can also infect the ear, and can result in hearing loss: congenital infection with cytomegalovirus is responsible for deafness in newborn children and also progressive sensorineural hearing loss in childhood; herpes simplex type 1, oral herpes associated with cold sores; Epstein Barr virus that causes mononucleosis; varicella zoster oticus that causes facial paralysis (Ramsay Hunt syndrome)[43]
  - People with HIV/AIDS may develop hearing problems due to medications they take for the disease, the HIV virus, or due to an increased rate of other infections.[44]
  - West Nile virus, which can cause a variety of neurological disorders, can also cause hearing loss by attacking the auditory nerve
- Meningitis may damage the auditory nerve or the cochlea.
- Syphilis is commonly transmitted from pregnant women to their fetuses, and about a third of infected children will eventually become deaf.
- inherited
  - People with Down syndrome are more likely to have hearing loss.[45] This is usually due to middle ear effusions in childhood but towards the end of the second decade they may develop a high frequency sensorineural hearing loss which can get progressively worse with time.
  - Charcot–Marie–Tooth disease variant 1E (CMT1E) is noted for demyelinating in addition to deafness.[46]
  - Autoimmune disease is recognized as a cause for cochlear damage. Although rare, it is possible for autoimmune processes to target the cochlea specifically as a first presentation. Granulomatosis with

polyangiitis is one of the autoimmune conditions that may precipitate hearing loss. Cogan's syndrome commonly presents with hearing loss.
- Otosclerosis is a condition that can cause fixation of the stapes (or stirrup) in the middle ear preventing its movement and causing a conductive hearing loss.
- Vestibular schwannoma, erroneously known as Acoustic neuromas, and other types of brain tumors can cause hearing loss by infringement of the tumor on the vestibulocochlear nerve
- Congenital problems
  - Superior semicircular canal dehiscence, a gap in the bone cover above the inner ear, can lead to low-frequency conductive hearing loss, autophony and vertigo.
- recurring ear infections or concommitant secondary infections (such as bacterial infection subsequent to viral infection) can result in hearing loss

## Medications [edit]

Some medications may reversibly affect hearing. These medications are considered ototoxic. This includes loop diuretics such as furosemide and bumetanide, non-steroidal anti-inflammatory drugs (NSAIDs) both over-the-counter (aspirin, ibuprofen, naproxen) as well as prescription (celecoxib, diclofenac, etc.), paracetamol, quinine, and macrolide antibiotics. The link between NSAIDs and hearing loss tends to be greater in women, especially those who take ibuprofen six or more times a week.[47] Others may cause permanent hearing loss.[48] The most important group is the aminoglycosides (main member gentamicin) and platinum based chemotherapeutics such as cisplatin and carboplatin.[*medical citation needed*]

On October 18, 2007, the U.S. Food and Drug Administration (FDA) announced that a warning about possible sudden hearing loss would be added to drug labels of PDE5 inhibitors, which are used for erectile dysfunction.[49]

## Chemicals [edit]

*Main article: Ototoxicity*

In addition to medications, hearing loss can also result from specific chemicals: metals, such as lead; solvents, such as toluene (found in crude oil, gasoline[50] and automobile exhaust,[50] for example); and asphyxiants.[51] Combined with noise, these ototoxic chemicals have an additive effect on a person's hearing loss.[51]

Hearing loss due to chemicals starts in the high frequency range and is irreversible. It damages the cochlea with lesions and degrades central portions of the auditory system.[51] For some ototoxic chemical exposures, particularly styrene,[52] the risk of hearing loss can be higher than being exposed to noise alone.

- Solvents
  - toluene, styrene, xylene, *n*-hexane, ethyl benzene, white spirits/Stoddard, carbon disulfide, jet fuel, perchloroethylene, trichloroethylene, *p*-xylene[53]
- Asphyxiants
  - carbon monoxide, hydrogen cyanide
- Heavy metals
  - lead, mercury, cadmium, arsenic, tin-hydrocarbon compounds (trimethyltin)
- Pesticides and herbicides - The evidence is weak regarding association between herbicides and hearing loss; hearing loss in such circumstances may be due to concommitant exposure to insecticides.
  - paraquat, organophosphates

## Physical trauma [edit]

There can be damage either to the ear itself or to the brain centers that process the aural information conveyed by the ears. People who sustain head injury are especially vulnerable to hearing loss or tinnitus, either temporary or permanent.[54][55]

# Pathophysiology [edit]

From a neurobiological perspective, there are three reasons that could cause a person to have hearing loss: either there is something wrong with the mechanical portion of the process, meaning the conductive portions of the ear (external and middle ear), or there is something wrong with the sensory portion of the process (inner ear or cochlea and related structures) or there is something wrong with the neural portion of the process, meaning the nerves or brain.

The process of understanding how sound travels to the brain is imperative in understanding how and why disease can cause a person to develop hearing loss. The process is as follows: sound waves are transmitted to the outer ear, sound waves are conducted down to ear canal, bringing the sound waves to the eardrum which they cause to vibrate, these vibrations are now passed through the 3 tiny ear bones in the middle ear, which transfer the vibrations to the fluid in the inner ear, the fluid moves the hair cells, the movement of the hair cells cause the vibrations to be converted into nerve impulses, the nerve impulses are taken to the brain by the auditory nerve,[56] the auditory nerve takes the impulses to the medulla oblongata, the brainstem send the impulses to the midbrain, which finally goes to the auditory cortex of the temporal lobe to be interpreted as sound.[57]

This process is complex and involves several steps that depend on the previous step in order for the vibrations or nerve impulses to be passed on. This is why if anything goes wrong at either the mechanical or neural portion of the process, it could result in sound not being processed by the brain, hence, leading to hearing loss.

Lesions to the auditory association cortex produced by physical trauma can result in deafness and other problems in auditory perception. The place where the lesion occurs on the auditory cortex plays an important role in what type of hearing deficit will occur in a person. A study conducted by Clarke et al. (2000) tested three subjects for the ability to identify a produced environmental sound, the source of the sound, and whether or not the source is moving. All three subjects had trauma to different parts of the auditory cortex, and each patient demonstrated a different set of auditory deficits, suggesting that different parts of the auditory cortex controlled different parts of the hearing process.[58] This means, lesion one part of auditory cortex and it could result in one or two deficits.[*clarification needed*] It would take larger lesions at the right parts to produce deafness.

# Diagnosis [edit]

Identification of a hearing loss is usually conducted by a general practitioner medical doctor, otolaryngologist, certified and licensed audiologist, school or industrial audiometrist, or other audiology technician. Diagnosis of the cause of a hearing loss is carried out by a specialist physician (audiovestibular physician) or otorhinolaryngologist

## Case history [edit]

A case history (usually a written form, with questionnaire) can provide valuable information about the context of the hearing loss, and indicate what kind of diagnostic procedures to employ. Case history will include such items as:

- major concern
- birth and pregnancy information
- medical history
- development history
- family history
- workplace environment
- home environment

## Examination [edit]

- otoscopy, visual examination of the outer ear, ear canal, eardrum, and middle ear (through the translucent eardrum) using an optical instrument inserted into the ear canal called an otoscope
- tympanometry
- differential testing - the Weber, Rinne, Bing and Schwabach tests are simple manual tests of auditory function conducted with a low frequency (usually 512 Hz) tuning fork that can provide a quick indication of type of hearing loss: unilateral/bilateral, conductive, or other

## Laboratory testing [edit]

In case of infection or inflammation, blood or other body fluids may be submitted for laboratory analysis.

## Hearing tests [edit]

*See also: Audiometry, Pure tone audiometry, Auditory brainstem response, and Otoacoustic emissions*

Hearing loss is generally measured by playing generated or recorded sounds, and determining whether the person can hear them. Hearing sensitivity varies according to the frequency of sounds. To take this into account, hearing sensitivity can be measured for a range of frequencies and plotted on an audiogram.

Another method for quantifying hearing loss is a speech-in-noise test. As the name implies, a speech-in-noise test gives an indication of how well one can understand speech in a noisy environment. A person with a hearing loss will often be less able to understand speech, especially in noisy conditions. This is especially true for people who have a sensorineural loss – which is by far the most common type of hearing loss. As such, speech-in-noise tests can provide valuable information about a person's hearing ability, and can be used to detect the presence of a sensorineural hearing loss. A recently developed digit-triple speech-in-noise test may be a more efficient screening test.[59]

Otoacoustic emissions test is an objective hearing test that may be administered to toddlers and children too young to cooperate in a conventional hearing test. The test is also useful in older children and adults.

Auditory brainstem response testing is an electrophysiological test used to test for hearing deficits caused by pathology within the ear, the cochlear nerve and also within the brainstem. This test can be used to identify delay in the conduction of neural impulses due to tumours or inflammation but can also be an objective test of hearing thresholds. Other electophysiological tests, such as cortical evoked responses, can look at the hearing pathway up to the level of the auditory cortex.

## Scans [edit]

MRI and CT scans can be useful to identify the pathology of many causes of hearing loss. They are only needed in selected cases.

## Classification [edit]

Hearing loss is categorized by type, severity, and configuration. Furthermore, a hearing loss may exist in only one ear (unilateral) or in both ears (bilateral). Hearing loss can be temporary or permanent, sudden or progressive.

## Severity [edit]

The severity of a hearing loss is ranked according to the additional intensity above a nominal threshold that a sound must be before being detected by an individual; it is measured in decibels of hearing loss, or dB HL. Hearing loss may be ranked as slight, mild, moderate, moderately severe, severe or profound as defined below:[*medical citation needed*]

- Slight: between 16 and 25 dB HL
- Mild:
  - for adults: between 26 and 40 dB HL

    - for children: between 20 and 40 dB HL[10]
- Moderate: between 41 and 54 dB HL[10]
- Moderately severe: between 55 and 70 dB HL[10]
- Severe: between 71 and 90 dB HL[10]
- Profound: 91 dB HL or greater[10]
- Totally deaf: Have no hearing at all. This is called *anacusis*.

Hearing loss may affect one or both ears. If both ears are affected, then one ear may be more affected than the other. Thus it is possible, for example, to have normal hearing in one ear and none at all in the other, or to have mild hearing loss in one ear and moderate hearing loss in the other.

For certain legal purposes such as insurance claims, hearing loss is described in terms of percentages. Given that hearing loss can vary by frequency and that audiograms are plotted with a logarithmic scale, the idea of a percentage of hearing loss is somewhat arbitrary, but where decibels of loss are converted via a legally recognized formula, it is possible to calculate a standardized "percentage of hearing loss", which is suitable for legal purposes only.

## Type [edit]

There are four main types of hearing loss, conductive hearing loss, sensorineural hearing loss, central deafness and combinations of conductive and sensorienural hearing losses which is called mixed hearing loss.[10] An additional problem which is increasingly recognised is auditory processing disorder which is not a hearing loss as such but a difficulty perceiving sound.

- Conductive hearing loss

Conductive hearing loss is present when the sound is not reaching the inner ear, the cochlea. This can be due to external ear canal malformation, dysfunction of the eardrum or malfunction of the bones of the middle ear. The ear drum may show defects from small to total resulting in hearing loss of different degree. Scar tissue after ear infections may also make the ear drum dysfunction as well as when it is retracted and adherent to the medial part of the middle ear.

Dysfunction of the three small bones of the middle ear – malleus, incus, and stapes – may cause conductive hearing loss. The mobility of the ossicles may be impaired for different reasons and disruption of the ossicular chain due to trauma, infection or ankylosis may also cause hearing loss.

- Sensorineural hearing loss

Sensorineural hearing loss is one caused by dysfunction of the inner ear, the cochlea or the nerve that transmits the impulses from the cochlea to the hearing centre in the brain. The most common reason for sensorineural hearing loss is damage to the hair cells in the cochlea. Depending on the definition it could be estimated that more than 50% of the population over the age of 70 has impaired hearing.[60]

- Central deafness

Damage to the brain can lead to a central deafness. The peripheral ear and the auditory nerve may function well but the central connections are damaged by tumour, trauma or other disease and the patient is unable to hear.

- Mixed hearing loss

Mixed hearing loss is a combination of conductive and sensorineural hearing loss. Chronic ear infection (a fairly common diagnosis) can cause a defective ear drum or middle-ear ossicle damages, or both. In addition to the conductive loss, a sensory component may be present.

- Central auditory processing disorder

This is not an actual hearing loss but gives rise to significant difficulties in hearing. One kind of auditory processing disorder is King-Kopetzky syndrome, which is characterized by an inability to process out background noise in noisy environments despite normal performance on traditional hearing tests.

## Configuration [edit]

The shape of an audiogram shows the relative configuration of the hearing loss, such as a Carhart notch for otosclerosis, 'noise' notch for noise-induced damage, high frequency rolloff for presbycusis, or a flat audiogram for conductive hearing loss. In conjunction with speech audiometry, it may indicate central auditory processing disorder, or the presence of a schwannoma or other tumor. There are four general configurations of hearing loss:

1. Flat: thresholds essentially equal across test frequencies.

2. Sloping: lower (better) thresholds in low-frequency regions and higher (poorer) thresholds in high-frequency regions.

3. Rising: higher (poorer) thresholds in low-frequency regions and lower (better) thresholds in higher-frequency regions.

4. Trough-shaped ("cookie-bite" or "U" shaped): greatest hearing loss in the mid-frequency range, with lower (better) thresholds in low- and high-frequency regions.

### Unilateral and bilateral [edit]

People with unilateral hearing loss or single-sided deafness (SSD) have difficulty in:

- hearing conversation on their impaired side
- localizing sound
- understanding speech in the presence of background noise.

In quiet conditions, speech discrimination is approximately the same for normal hearing and those with unilateral deafness; however, in noisy environments speech discrimination varies individually and ranges from mild to severe.

One reason for the hearing problems these patients often experience is due to the head shadow effect. Newborn children with no hearing on one side but one normal ear could still have problems.[61] Speech development could be delayed and difficulties to concentrate in school are common. More children with unilateral hearing loss have to repeat classes than their peers. Taking part in social activities could be a problem. Early aiding is therefore of utmost importance.[62][63]

## Prevention [edit]

It is estimated that half of cases of hearing loss are preventable.[64] A number of preventative strategies are effective including: immunisation against rubella to prevent congenital rubella syndrome, immunization against *H. influenza* and *S. pneumoniae* to reduce cases of meningitis, and avoiding or protecting against excessive noise exposure.[10] The World Health Organization also recommends immunization against measles, mumps, and meningitis, efforts to prevent premature birth, and avoidance of certain medication as prevention.[65]

The use of antioxidants is being studied for the prevention of noise-induced hearing loss.[66]

### Hearing protectors [edit]

Education regarding noise exposure increases the use of hearing protectors.[67]

### Workplace noise regulation [edit]

Noise is widely recognized as an occupational hazard. In the United States, the National Institute for Occupational Safety and Health (NIOSH) and the Occupational Safety and Health Administration (OSHA) work together to provide standards and enforcement on workplace noise levels.[68][69] The hierarchy of hazard controls demonstrates the different levels of controls to reduce or eliminate exposure to noise and prevent hearing loss, including engineering controls and personal protective equipment (PPE).[70] Other programs and initiative have been created to prevent hearing loss in the workplace. For example, the Safe-in-Sound Award was created to recognize organizations with successful noise control implementations.[71]

Additionally, the Buy Quiet program was created to encourage employers to purchase quieter machinery and tools.[72] By purchasing less noisy power tools like those found on the NIOSH Power Tools Database and limiting exposure to ototoxic chemicals, great strides can be made in preventing hearing loss.[73]

Companies can also provide personal hearing protector devices tailored to both the worker and type of employment. Some hearing protectors universally block out all noise, and some allow for certain noises to be heard. Workers are more likely to wear hearing protector devices when they are properly fitted.[74]

Better enforcement of laws can decrease levels of noise at work.[75]

### Screening [edit]

The United States Preventive Services Task Force recommends screening for all newborns.[4]

The American Academy of Pediatrics advises that children should have their hearing tested several times throughout their schooling:[33]

- When they enter school
- At ages 6, 8, and 10
- At least once during middle school
- At least once during high school

There is not enough evidence to determine the utility of screening in adults over 50 years old who do not have any symptoms.[76]

## Treatment [edit]

Treatment depends on the specific cause if known as well as the extent, type and configuration of the hearing loss. Most hearing loss, that resulting from age and noise, is progressive and irreversible, and there are currently no approved or recommended treatments; management is by hearing aid. A few specific kinds of hearing loss are amenable to surgical treatment. In other cases, treatment is addressed to underlying pathologies, but any hearing loss incurred may be permanent.

There are a number of devices that can improve hearing in those who are deaf or hard of hearing or allow people with these conditions to manage better in their lives.

### Hearing aids [edit]

Hearing aids are devices that work to improve the hearing and speech comprehension of those with hearing loss.[77] It works by magnifying the sound vibrations in the ear so that one can understand what is being said around them.[77] The use of this technological device may or may not have an effect on one's sociability. Some people feel as if they cannot live without one because they say it is the only thing that keeps them engaged with the public. Others dislike hearing aids very much because they feel wearing them is embarrassing or weird. Due to their low-esteem, they avoid hearing aid usage altogether and would rather remain quiet and to themselves in a social environment.[78]

### Assistive devices [edit]

Many deaf and hard of hearing individuals use assistive devices in their daily lives:

- Individuals can communicate by telephone using telephone typewriters (TTY). Other common names are textphone, minicom and telecommunications device for the deaf (TDD). These devices look like typewriters or word processors and transmit typed text over regular telephone lines. This allows communication through visual messaging. TTYs can transmit messages to individuals who don't have TTY by using the National Relay service which is an operator that acts as a messenger to each caller.[79] For mobile phones, software apps are available to provide TDD/textphone functionality on some carriers/models to provide 2-way communications.
- There are several new telecommunications relay service technologies including IP Relay and captioned

telephone technologies. A deaf or hard of hearing person can communicate over the phone with a hearing person via a human translator. Phone captioning is a service in which a hearing person's speech is captioned by a third party, enabling a deaf or hard of hearing person to conduct a conversation with a hearing person over the phone.[80] Wireless, Internet and mobile phone/SMS text messaging are beginning to take over the role of the TDD.
- Real-time text technologies, involving streaming text that is continuously transmitted as it is typed or otherwise composed. This allows conversational use of text. Software programs are now available that automatically generate a closed-captioning of conversations. Examples include discussions in conference rooms, teleconference calls, classroom lectures, and/or religious services.
- Instant messaging software.
- Videophones and similar video technologies can be used for distance communication using sign language. Video conferencing technologies permit signed conversations as well as permitting a sign language–English interpreter to voice and sign conversations between a deaf or hard of hearing person and that person's hearing party, negating the use of a TTY device or computer keyboard.
- Video relay service and video remote interpreting (VRI) services also use a third-party telecommunication service to allow a deaf or hard-of-hearing person to communicate quickly and conveniently with a hearing person, through a sign language interpreter.
- Hearing dogs are a specific type of assistance dog specifically selected and trained to assist the deaf and hard of hearing by alerting their handler to important sounds, such as doorbells, smoke alarms, ringing telephones, or alarm clocks.
- The advent of the Internet's World Wide Web and closed captioning has given the deaf and hard of hearing unprecedented access to information. Electronic mail and online chat have reduced the need for deaf and hard-of-hearing people to use a third-party Telecommunications Relay Service to communicate with the hearing and other deaf people.
- A person with hearing loss cannot always hear the phone or distinguish their own ringtone from another. A signalling transmitter can be attached to a phone that will cause a light or a vibration device to activate. Transmitters can also be used to activate visuals cues to represent fire alarms.[79]
- Individuals with hearing loss require phones with amplifiers that have a higher power of amplification when compared to a regular phone. The Hearing Aid Telephone Interconnect System is a hands free amplification system which allows people to amplify sound when using telephones, cell phones, computer and pay phones by way of the attachment of a portable unit.[79]

## Wireless hearing aids [edit]

A wireless device has two main components: a transmitter and a receiver. The transmitter broadcasts the captured sound, and the receiver detects the broadcast audio and enables the incoming audio stream to be connected to accommodations such as hearing aids or captioning systems.

Three types of wireless systems are commonly used: FM, audio induction loop, and InfraRed. Each system has advantages and benefits for particular uses. FM systems can be battery operated or plugged into an electrical outlet. FM system produce an analog audio signal, meaning they have extremely high fidelity. Many FM systems are very small in size, allowing them to be used in mobile situations. The audio induction loop permits the listener with hearing loss to be free of wearing a receiver provided that the listener has a hearing aid or cochlear implant processor with an accessory called a "telecoil". If the listener does not have a telecoil, then he or she must carry a receiver with an earpiece. As with FM systems, the infrared (IR) system also requires a receiver to be worn or carried by the listener. An advantage of IR wireless systems is that people in adjoining rooms cannot listen in on conversations, making it useful for situations where privacy and confidentiality are required. Another way to achieve confidentiality is to use a hardwired amplifier, which contains or is connected to a microphone and transmits no signal beyond the earpiece plugged directly into it.[81]

## Surgical [edit]

There is no treatment surgical or otherwise for hearing lost due to the most common causes (age, noise and genetic defects). For a few specific conditions, surgical intervention can provide a remedy:

Illustration of a cochlear implant

- surgical correction of superior canal dehiscence
- myringotomy, surgical insertion of drainage ventilation tubes in the tympanic membrane. Such placement is usually temporary until the underlying pathology (infection or other inflammation) can be resolved.
- radiotherapy or surgical excision of vestibular schwannoma or acoustic neuroma, though, in most cases, it is unlikely that hearing will be preserved
- Stapedectomy and stapedotomy for otosclerosis - replacement or reshaping of the stapes bone of the middle ear can restore hearing in cases of conductive hearing loss

Surgical and implantable hearing aids are an alternative to conventional external hearing aids. If the ear is dry and not infected, an air conduction aid could be tried; if the ear is draining, a direct bone condition hearing aid is often the best solution. If the conductive part of the hearing loss is more than 30–35 dB, an air conduction device could have problems overcoming this gap. A bone-anchored hearing aid could, in this situation, be a good option. The active bone conduction hearing implant Bonebridge is also an option. This implant is invisible under the intact skin and therefore minimises the risk of skin irritations.[63]

Cochlear implants improve outcomes in people with hearing loss in either one or both ears.[82] They work by artificial stimulation of the cochlear nerve by providing an electric impulse substitution for the firing of hair cells. They are expensive, and require programming along with extensive training for effectiveness.

Cochlear implants as well as bone conduction implants can help with single sided deafness. Middle ear implants or bone conduction implants can help with conductive hearing loss.[63]

People with cochlear implants are at a higher risk for bacterial meningitis. Thus, meningitis vaccination is recommended.[83] People who have hearing loss, especially those who develop a hearing problem in childhood or old age, may need support and technical adaptations as part of the rehabilitation process. Recent research shows variations in efficacy but some studies[84] show that if implanted at a very young age, some profoundly impaired children can acquire effective hearing and speech, particularly if supported by appropriate rehabilitation.

## Classroom [edit]

For a classroom setting, children with hearing loss often benefit from direct instruction and communication. One option for students is to attend a school for the Deaf, where they will have access to the language, communication, and education. Another option is to have the child attend a mainstream program, with special accommodation such as providing favorable seating for the child. Having the student sit as close to the teacher as possible improves the student's ability to hear the teacher's voice and to more easily read the teacher's lips. When lecturing, teachers can help the student by facing them and by limiting unnecessary noise in the classroom. In particular, the teacher can avoid talking when their back is turned to the classroom, such as while writing on a whiteboard.

Some other approaches for classroom accommodations include pairing deaf or hard of hearing students with hearing students. This allows the deaf or hard of hearing student to ask the hearing student questions about concepts that they have not understood. The use of CART (Communication Access Real Time) systems, where an individual types a captioning of what the teacher is saying, is also beneficial.[85] The student views this captioning on their computer. Automated captioning systems are also becoming a popular option.[86] In an automated system, software, instead of a person, is used to generate the captioning. Unlike CART systems, automated systems generally do not require an Internet connection and thus they can be used anywhere and anytime. Another advantage of automated systems over CART is that they are much lower in cost. However, automated systems are generally designed to only transcribe what

the teacher is saying and to not transcribe what other students say. An automated system works best for situations where just the teacher is speaking, whereas a CART system will be preferred for situations where there is a lot of classroom discussion.

For those students who are completely deaf, one of the most common interventions is having the child communicate with others through an interpreter using sign language.[87]

## Epidemiology [edit]

Globally hearing loss affects about 10% of the population to some degree.[23] It caused moderate to severe disability in 124.2 million people as of 2004 (107.9 million of whom are in low and middle income countries).[8] Of these 65 million acquired the condition during childhood.[10] At birth ~3 per 1000 in developed countries and more than 6 per 1000 in developing countries have hearing problems.[10]

Hearing loss increases with age. In those between 20 and 35 rates of hearing loss are 3% while in those 44 to 55 it is 11% and in those 65 to 85 it is 43%.[4]

## History [edit]

*See also: History of deaf education in the United States*

Abbé Charles-Michel de l'Épée opened the first school for the deaf in Paris at the deaf school. The American Thomas Gallaudet witnessed a demonstration of deaf teaching skills from Épée's successor Abbé Sicard and two of the school's deaf faculty members, Laurent Clerc and Jean Massieu; accompanied by Clerc, he returned to the United States, where in 1817 they founded American School for the Deaf in Hartford, Connecticut. American Sign Language (ASL) started to evolve from primarily French Sign Language (LSF), and other outside influences.[88]

## Society and culture [edit]

*See also: Deaf culture*

### After language [edit]

*Main article: Post-lingual deafness*

*Post-lingual deafness* is hearing loss that is sustained after the acquisition of language, which can occur due to disease, trauma, or as a side-effect of a medicine. Typically, hearing loss is gradual and often detected by family and friends of affected individuals long before the patients themselves will acknowledge the disability.[*citation needed*] Post-lingual deafness is far more common than pre-lingual deafness. Those who lose their hearing later in life, such as in late adolescence or adulthood, face their own challenges, living with the adaptations that allow them to live independently.

### Before language [edit]

*Main article: Prelingual deafness*

*Prelingual deafness* is hearing loss that is sustained before the acquisition of language, which can occur due to a congenital condition or through hearing loss in early infancy. Prelingual deafness impairs an individual's ability to acquire a *spoken* language. Children born into signing families rarely have delays in language

development, but most prelingual hearing loss is acquired via either disease or trauma rather than genetically inherited, so families with deaf children nearly always lack previous experience with sign language. Cochlear implants allow prelingually deaf children to acquire an oral language with remarkable success if implantation is performed within the first 2–4 years.[89]

Jack Gannon, a professor at Gallaudet University, said this about Deaf culture. "Deaf culture is a set of learned behaviors and perceptions that shape the values and norms of deaf people based on their shared or common experiences." Some doctors believe that being deaf makes a person more social. Bill Vicar, from ASL University, shared his experiences as a deaf person, "[deaf people] tend to congregate around the kitchen table rather than the living room sofa… our good-byes take nearly forever, and our hellos often consist of serious hugs. When two of us meet for the first time we tend to exchange detailed biographies."[90] Deaf culture is not about contemplating what deaf people cannot do and how to fix their problems, an approach known as the "pathological view of the deaf."[91] Instead deaf people celebrate what they can do. There is a strong sense of unity between deaf people as they share their experiences of suffering through a similar struggle. This celebration creates a unity between even deaf strangers. Bill Vicars expresses the power of this bond when stating, "if given the chance to become hearing most [deaf people] would choose to remain deaf."[92]

## Views of treatments [edit]

There has been considerable controversy within the culturally deaf community over cochlear implants. For the most part, there is little objection to those who lost their hearing later in life, or culturally deaf adults choosing to be fitted with a cochlear implant.[15]

Many in the deaf community strongly object to a deaf child being fitted with a cochlear implant (often on the advice of an audiologist); new parents may not have sufficient information on raising deaf children and placed in an oral-only program that emphasizes the ability to speak and listen over other forms of communication such as sign language or total communication. Many Deaf people view cochlear implants and other hearing devices as confusing to one's identity. A Deaf person will never be a hearing person and therefore would be trying to fit into a way of living that is not their own. Other concerns include loss of Deaf culture and identity and limitations on hearing restoration.[15]

The U.S. National Association of the Deaf has a statement on its website regarding cochlear implants.[93] The NAD asserts that the choice to implant is up to the individual (or the parents), yet strongly advocates a fully informed decision in all aspects of a cochlear implant. Much of the negative reaction to cochlear implants stems from the medical viewpoint that deafness is a condition that needs to be "cured," while the Deaf community instead regards deafness a defining cultural characteristic.

Many other assistive devices are more acceptable to the Deaf community, including but not limited to, hearing aids, closed captioning, email and the Internet, text telephones, and video relay services.

## Sign language [edit]

*Main article: Sign language*

Sign languages convey meaning through manual communication and body language instead of acoustically conveyed sound patterns. This involves the simultaneous combination of hand shapes, orientation and movement of the hands, arms or body, and facial expressions to express a speaker's thoughts. "Sign languages are based on the idea that vision is the most useful tool a deaf person has to communicate and receive information".[94]

Those who are deaf (by either state or federal standards) have access to a free and appropriate public education. If a child does qualify as being deaf or hard of hearing and receives an individualized education plan, the IEP team must consider, "the child's language and communication needs. The IEP must include opportunities for direct communication with peers and professionals. It must also include the student's academic level, and finally must include the students full range of needs"[95][96]

In part, the Department of Education defines deafness as "... a hearing impairment that is so severe that the child is impaired in processing linguistic information through hearing, with or without amplification ...." Hearing impairment is defined as "... an impairment in hearing, whether permanent or fluctuating, that adversely affects a child's educational performance but that is not included under the definition of deafness ...."[97]

It is commonly misunderstood that least restrictive environment means mainstreaming or inclusion. Sometimes the resources available at the public schools do not match up to the resources at a residential school for the deaf. Many hearing parents choose to have their deaf child educated in the general education classroom as much as possible because they are told that mainstreaming is the least restrictive environment, which is not always the case. However, there are parents that live in Deaf communities who feel that the general education classroom is not the least restrictive environment for their child. These parents feel that placing their child in a residential school where all children are deaf may be more appropriate for their child because the staff tend to be more aware of the needs and struggles of deaf children. Another reason that these parents feel a residential school may be more appropriate is because in a general education classroom, the student will not be able to communicate with their classmates due to the language barrier.[*citation needed*]

Alexander Graham Bell with teachers and students of the Scott Circle School for deaf children, Washington, D.C., 1883

In a residential school where all the children use the same communication system (whether it is a school using ASL, Total Communication or Oralism), students will be able to interact normally with other students, without having to worry about being criticized. An argument supporting inclusion, on the other hand, exposes the student to people who are not just like them, preparing them for adult life. Through interacting, children with hearing disabilities can expose themselves to other cultures which in the future may be beneficial for them when it comes to finding jobs and living on their own in a society where their disability may put them in the minority. These are some reasons why a person may or may not want to put their child in an inclusion classroom.[96]

- Driving: Myth: Deaf people are not permitted to drive. Fact: Deaf people may use special devices to alert them to sirens or other noises, or panoramic mirrors to enable improved visibility.[98] Many countries allow deaf people to drive, although at least 26 countries do not allow deaf citizens to hold a driver's license.[98]
- Lip reading: Myth: Most deaf people are able to understand others by reading lips. Fact: Only about 30% of spoken English is visible on the lips.[99][100] Lip reading requires not only good lighting, but also a good understanding of the oral language in question, and may also depend on contextual knowledge about what is being said.[99]
- Inheritance: Myth: Deafness is passed down from parent to child. Fact: Fewer than 5% of deaf children in the United States have a deaf parent.[101]

## Communication barriers [edit]

> This section **may stray from the topic of the article**. Please help improve this section or discuss this issue on the talk page. *(December 2014)*

The most predominant forms of communication barriers originate from one's own personal self and they are directly the result of the hearing loss condition. These barriers are associated specifically with speech and language. In terms of speech, hearing loss has an effect on speech sound production, for example distortion caused by the omission of various letters from words. The pitch of their voice may sound too high or low and their volume may be louder or quieter than is intended. Resonance of voice is also affected, as it can be hypernasal or denasal. Prosody, which represents the patterns of stress and rhythm in the voice, will often become irregular. As a result of such changes to speech, the receiver during a conversation is likely to deem the communicator's speech unintelligible. The placement of improper stresses on syllables makes it more difficult for the receiver to clearly perceive and hear the intended words. Three major problems in terms of language are present for those with hearing loss. First, there are problems with language formation, where individuals may overuse nouns and verbs and they may improperly place words within a sentence. Second, the actual content of the language is troubling, for example the interpretation of synonyms and antonyms. This results in a limited vocabulary. The third major problem is associated with Pragmatics, which includes the inability of individuals to recognize that a message has been delivered to them, therefore resulting in inappropriate questions being asked. All of these speech and language barriers make it difficult for those with hearing loss to control their own speech and understand what others have to say, therefore making it quite hard to hold a conversation altogether.[102]

## Family [edit]

The communication limitations between people who are deaf and their hearing family members can often cause difficulties in family relationships, and affect the strength of relationships among individual family members. It was found that most people who are deaf have hearing parents, which means that the channel that the child and parents communicate through can be very different, often affecting their relationship in a negative way. If a parent communicates best verbally, and their child communicates best using sign language, this could result in ineffective communication between parents and children. Ineffective communication can potentially lead to fights caused by misunderstanding, less willingness to talk about life events and issues, and an overall weaker relationship. Even if individuals in the family made an effort to learn deaf communication techniques such as sign language, a deaf family member often will feel excluded from casual banter; such as the exchange of daily events and news at the dinner table. It is often difficult for people who are deaf to follow these conversations due to the fast paced and overlapping nature of these exchanges. This can cause a deaf individual to become frustrated and take part in less family conversations. This can potentially result in weaker relationships between the hearing individual and their immediate family members. This communication barrier can have a particularly negative effect on relationships with extended family members as well. Communication between a deaf individual and their extended family members can be very difficult due to the gap in verbal and non-verbal communication.

This can cause the individuals to feel frustrated and unwilling to put effort into communicating effectively. The lack of effort put into communicating can result in anger, miscommunication, and unwillingness to build a strong relationship.[103]

## Community [edit]

People who have hearing loss can often experience many difficulties as a result of communication barriers among them and other hearing individuals in the community. Some major areas that can be impacted by this are involvement in extracurricular activities and social relationships. For young people, extracurricular activities are vehicles for physical, emotional, social, and intellectual development. However, it is often the case that communication barriers between people who are deaf and their hearing peers and coaches/club advisors limit them from getting involved. These communication barriers make it difficult for someone with a hearing loss to understand directions, take advice, collaborate, and form bonding relationships with other team or club members. As a result, extracurricular activities such as sports teams, clubs, and volunteering are often not as enjoyable and beneficial for individuals who have hearing loss, and they may engage in them less often. A lack of community involvement through extracurricular activities may also limit the individual's social network. In general, it can be difficult for someone who is deaf to develop and maintain friendships with their hearing peers due to the communication gap that they experience. They can often miss the jokes, informal banter, and "messing around" that is associated with the formation of many friendships among young people. Conversations between people who are deaf and their hearing peers can often be limited and short due to their differences in communication methods and lack of knowledge on how to overcome these differences. Deaf individuals can often experience rejection by hearing peers who are not willing to make an effort to find their way around communication difficulties. Patience and motivation to overcome such communication barriers is required by both the deaf or hard of hearing and hearing individuals in order to establish and maintain good friendships.[103]

Many people tend to forget about the difficulties that deaf children encounter, as they view the deaf child differently from a deaf adult. Deaf children grow up being unable to fully communicate with their parents, siblings and other family members. Examples include being unable to tell their family what they have learned, what they did, asking for help, or even simply being unable to interact in daily conversation. Deaf children have to learn sign language and to read lips at a young age, however they cannot communicate with others using it unless the others are educated in sign language as well. Children who are deaf or hard of hearing are faced with many complications while growing up, for example some children have to wear hearing aids and others require assistance from sign language (ASL) interpreters. The interpreters help them to communicate with other individuals until they develop the skills they need to efficiently communicate on their own. Although growing up for deaf children may entitle more difficulties than for other children, there are many support groups that allow deaf children to interact with other children. This is where they develop friendships. There are also classes for young children to learn sign language in an environment that has other children in their same situation and around their same age. These groups and classes can be very beneficial in providing the child with the proper knowledge and not to mention the societal interactions that they need in order to live a healthy, young, playful and carefree life that any child deserves.

There are three typical adjustment patterns adopted by adults with hearing loss. The first one is to remain withdrawn into your own self. This provides a sense of safety and familiarity which can be a comforting way to lead your life. The second is to act "as if" one does not even have hearing loss. A positive attitude will help people to live a life with no barriers and thus, engage in optimal interaction. The final and third pattern is for the person to accept their hearing loss as a part of them without undervaluing oneself. This means understanding that one is forced to live life with this disability, however it is not the only thing that constitutes life's meaning. Furthermore, many feel as if their inability to hear others during conversation is their fault. It's important that these individuals learn how to become more assertive individuals who do not lack fear when it comes to asking someone to repeat something or to speak a little louder. Although there is much fatigue and frustration that is produced from one's inability to hear, it is important to learn from personal experiences in order to improve on one's communication skills. In essence, these patterns will help adults with hearing loss deal with the communication barriers that are present.[78]

## Workplace [edit]

In most instances, people who are deaf find themselves working with hearing colleagues, where they can often be cut off from the communication going on around them. Interpreters can be provided for meetings and workshops, however are seldom provided for everyday work interactions. Communication of important information needed for jobs typically comes in the form of written or verbal summaries, which do not convey subtle meanings such as tone of voice, side conversations during group discussions, and body language. This can result in confusion and misunderstanding for the worker who is deaf, therefore making it harder to do their job effectively. Additionally, deaf workers can be unintentionally left out of professional networks, informal gatherings, and casual conversations among their collogues. Information about informal rules and organizational culture in the workplace is often communicated though these types of interactions, which puts the worker who is deaf at a professional and personal disadvantage. This could sever their job performance due to lack of access to information and therefore, reduce their opportunity to form relationships with their co-workers. Additionally, these communication barriers can all affect a deaf person's career development. Since being able to effectively communicate with one's co-workers and other people relevant to one's job is essential to managerial positions, people with hearing loss can often be denied such opportunities.[103]

To avoid these situations in the workplace, individuals can take full-time or part-time sign language courses. In this way, they can become better able to communicate with the deaf and hard of hearing. Such courses teach the American Sign Language (ASL) language as most North Americans use this particular language to communicate. It is a visual language made up of specific gestures (signs), hand shapes, and facial expressions that contain their own unique grammatical rules and sentence structures [104] By completing sign language courses, it ensures that deaf individuals feel a part of the workplace and have the ability to communicate with their co-workers and employer in the manner as other hearing employees do.

## Health care [edit]

Not only can communication barriers between deaf and hearing people affect family relationships, work, and school, but they can also have a very significant effect on a deaf individual's health care. As a result of poor communication between the health care professional and the deaf or hard of hearing patient, many patients report that they are not properly informed about their disease and prognosis. [105] This lack of or poor communication could also lead to other issues such as misdiagnosis, poor assessments, mistreatment, and even possibly harm to patients. Poor communication in this setting is often the result of health care providers having the misconception that all people who are deaf or hard of hearing have the same type of hearing loss, and require the same type of communication methods. In reality, there are many different types and range of hearing loss, and in order to communicate effectively a health care provider needs to understand that each individual with hearing loss has unique needs. This affects how individuals have been educated to communicate, as some communication methods work better depending on an individual's severity of hearing loss. For example, assuming every deaf or hard of hearing patient knows American Sign Language would be incorrect because there are different types of sign language, each varying in signs and meanings. A patient could have been educated to use cued speech which is entirely different from ASL.[105] Therefore, in order to communicate effectively, a health care provider needs to understand that each individual has unique needs when communicating.

Although there are specific laws and rules to govern communication between health care professionals and people who are deaf, they are not always followed due to the health care professional's insufficient knowledge of communication techniques. This lack of knowledge can lead them to make assumptions about communicating with someone who is deaf, which can in turn cause them to use an unsuitable form of communication. Acts in countries such as the Americans with Disabilities Act (ADA) state that all health care providers are required to provide reasonable communication accommodations when caring for patients who are deaf. These accommodations could include qualified sign language interpreters, CDIs, and technology such as Internet interpretation services. A qualified sign language interpreter will enhance communication between a deaf individual and a health care professional by interpreting not only a health professional's verbal communication, but also their non-verbal such as expressions, perceptions, and body language. A Certified Deaf Interpreter (CDI) is a sign language interpreter who is also a member of the Deaf community.[106] They accompany a sign language interpreter and are useful for communication with deaf individuals who also have language or cognitive deficits. A CDI will transform what the health care professional communicates into basic, simple language. This method takes much longer, however it can

also be more effective than other techniques. Internet interpretation services are convenient and less costly, but can potentially pose significant risks. They involve the use of a sign language interpreter over a video device rather than directly in the room. This can often be an inaccurate form of communication because the interpreter may not be licensed, is often unfamiliar with the patient and their signs, and can lack knowledge of medical terminology.[107]

Aside from utilizing interpreters, healthcare professionals can improve their communication with deaf or hard of hearing patients by educating themselves on common misconceptions and proper practices depending on the patient's needs. For example, a common misconception is that exaggerating words and speaking loudly will help the patient understand more clearly. However, many individuals with hearing loss depend on lip-reading to identify words. Exaggerated pronunciation and a raised voice can distort the lips, making it even more difficult to understand. Another common mistake health care professionals make are the use of single words rather than full sentences. Although language should be kept simple and short, keeping context is important because certain homophonous words are difficult to distinguish by lip-reading. Health care professionals can further improve their own communication with their patients by eliminating any background noise and positioning themselves in a way where their face is clearly visible to the patient, and suitably lit. The healthcare professional should know how to use body language and facial expressions to properly communicate different feelings.[105]

# Research [edit]

## Stem cell transplant and gene therapy [edit]

A 2005 study achieved successful regrowth of cochlea cells in guinea pigs.[108] However, the regrowth of cochlear hair cells does not imply the restoration of hearing sensitivity, as the sensory cells may or may not make connections with neurons that carry the signals from hair cells to the brain. A 2008 study has shown that gene therapy targeting Atoh1 can cause hair cell growth and attract neuronal processes in embryonic mice. Some hope that a similar treatment will one day ameliorate hearing loss in humans.[109]

Recent research, reported in 2012 achieved growth of cochlear nerve cells resulting in hearing improvements in gerbils,[110] using stem cells. Also reported in 2013 was regrowth of hair cells in deaf adult mice using a drug intervention resulting in hearing improvement.[111] The Hearing Health Foundation in the US has embarked on a project called the Hearing Restoration Project.[112] Also Action on Hearing Loss in the UK is also aiming to restore hearing.[113]

Researchers reported in 2015 that genetically deaf mice which were treated with TMC1 gene therapy recovered some of their hearing.[114][115]

## Audition [edit]

Besides research studies seeking to improve hearing, such as the ones listed above, research studies on the deaf have also been carried out in order to understand more about audition. Pijil and Shwarz (2005) conducted their study on the deaf who lost their hearing later in life and, hence, used cochlear implants to hear. They discovered further evidence for rate coding of pitch, a system that codes for information for frequencies by the rate that neurons fire in the auditory system, especially for lower frequencies as they are coded by the frequencies that neurons fire from the basilar membrane in a synchronous manner. Their results showed that the subjects could identify different pitches that were proportional to the frequency stimulated by a single electrode. The lower frequencies were detected when the basilar membrane was stimulated, providing even further evidence for rate coding.[58]

# Mandibular fracture

From Wikipedia, the free encyclopedia

*"Broken jaw" redirects here. For other uses, see Broken jaw (disambiguation).*

**Mandibular fracture**, also known as **fracture of the jaw**, is a break through the mandibular bone. In about 60% of cases the break occurs in two places. It may result in a decreased ability to fully open the mouth. Often the teeth will not feel properly aligned or there may be bleeding of the gums.[1] Mandibular fractures occur most commonly among males in their 30s.[2]

Mandibular fractures are typically the result of trauma. This can include a fall onto the chin or a hit from the side.[1] Rarely they may be due to osteonecrosis or tumors in the bone.[2] The most common area of fracture is at the condyle (36%), body (21%), angle (20%) and symphysis (14%). While a diagnosis can occasionally be made with plain X-ray, modern CT scans are more accurate.[1]

Immediate surgery is not necessarily required. Occasionally people may go home and follow up for surgery in the next few days.[1] A number of surgical techniques may be used including maxillomandibular fixation and open reduction internal fixation (ORIF).[3][2] People are often put on antibiotics such as penicillin for a brief period of time.[4][2] The evidence to support this practice; however, is poor.[5]

## General [edit]

By far, the two most common symptoms described are pain and the feeling that teeth no longer correctly meet (traumatic malocclusion, or disocclusion). The teeth are very sensitive to pressure (proprioception), so even a small change in the location of the teeth will generate this sensation. People will also be very sensitive to touching the area of the jaw that is broken, or in the case of condylar fracture the area just in front of the tragus of the ear.

Other symptoms may include loose teeth (teeth on either side of the fracture will feel loose because the fracture is mobile), numbness (because the inferior alveolar nerve runs along the jaw and can be compressed by a fracture) and trismus (difficulty opening the mouth).

Outside the mouth, signs of swelling, bruising and deformity can all be seen. Condylar fractures are deep, so it is rare to see significant swelling although, the trauma can cause fracture of the bone on the anterior aspect of the external auditory meatus so bruising or bleeding can sometimes be seen in the ear canal. Mouth opening can be diminished (less than 3 cm). There can be numbness or altered sensation (anesthesia/paraesthesia in the chin and lower lip (the distribution of the mental nerve).

Intraorally, if the fracture occurs in the tooth bearing area, a step may seen between the teeth on either side of the fracture or a space can be seen (often mistaken for a lost tooth) and bleeding from the gingiva in the area. There can be an open bite where the lower teeth, no longer meet the upper teeth. In the case of a unilateral condylar fracture the back teeth on the side of the fracture will meet and the open bite will get progressively greater towards the other side of the mouth.

Sometimes bruising will develop in the floor of the mouth (sublingual eccymosis) and the fracture can be moved by moving either side of the fracture segment up and down. For fractures that occur in the non-tooth bearing area (condyle, ramus, and sometimes the angle) an open bite is an important clinical feature since little else, other than swelling, may be apparent.[6]:page number needed

## Condylar [edit]

This type of fractured mandible can involve one condyle (unilateral) or both (bilateral). Unilateral condylar fracture may cause restricted and painful jaw movement. There may be swelling over the temporomandibular joint region and bleeding from the ear because of lacerations to the external auditory meatus. The hematoma may spread downwards and backwards behind the ear, which may be confused with Battle's sign (a sign of a base of skull fracture), although this is an uncommon finding so if present, intra-cranial injury must be ruled out. If the bones fracture and overlie each other there may be shortening of the height of the ramus. This results in gagging of the teeth on the fractured side (the teeth meet too soon on the fractured side, and not on the non fractured side, i.e. "open bite" that becomes progressively worse to the unaffected side). When the mouth is opened, there may be deviation of the mandible towards the fractured side. Bilateral condylar fractures may cause the above signs and symptoms, but on both sides.[7] Malocclusion and restricted jaw movement are usually more severe.[7] Bilateral body or parasymphysis fractures are sometimes termed "flail mandible", and can cause involuntary posterior movement of the tongue with subsequent obstruction of the upper airway.[8] Displacement of the condyle through the roof of glenoid fossa and into the middle cranial fossa is rare.[9] Bilateral condylar fractures combined with a symphyseal fracture is sometimes termed a guardsman's fracture. The name comes from this injury occurring in soldiers who faint on parade grounds and strike the floor with their chin.[*citation needed*]

# Diagnosis [edit]

## Plain film radiography [edit]

Traditionally, plain films of the mandible would be exposed but had lower sensitivity and specificity owing to overlap of structures. Views included AP (for parasymphsis), lateral oblique (body, ramus, angle,

Nondisplaced fracture of the mandible

coronoid process) and Towne's (condyle) views. Condylar fractures can be especially difficult to identify, depending on the direction of condylar displacement or dislocation so multiple views of it are usually examined with two views at perpendicular angles.[10]

## Panoramic radiography [edit]

Panoramic radiographs are tomograms where the mandible is in the focal trough and show a flat image of the mandible. Because the curve of the mandible appears in a 2-dimensional image, fractures are easier to spot leading to an accuracy similar to CT except in the condyle region. In addition, broken, missing or malaligned teeth can often be appreciated on a panoramic image which is frequently lost in plain films. Medial/lateral displacement of the fracture segments and especially the condyle are difficult to gauge so the view is sometimes augmented with plain film radiography or computed tomography for more complex mandible fractures.

## Computed tomography [edit]

Computed tomography is the most sensitive and specific of the imaging techniques. The facial bones can be visualized as slices through the skeletal in either the axial, coronal or sagittal planes. Images can be reconstructed into a 3-dimensional view, to give a better sense of the displacement of various fragments. 3D reconstruction, however, can mask smaller fractures owing to volume averaging, scatter artifact and surrounding structures simply blocking the view of underlying areas.

Research has shown that panoramic radiography is similar to computed tomography in its diagnostic accuracy for mandible fractures and both are more accurate than plain film radiograph.[11] The indications to use CT for mandible fracture vary by region, but it does not seem to add to diagnosis or treatment planning except for comminuted or avulsive type fractures,[12] although, there is better clinician agreement on the location and absence of fractures with CT compared to panoramic radiography.[13]

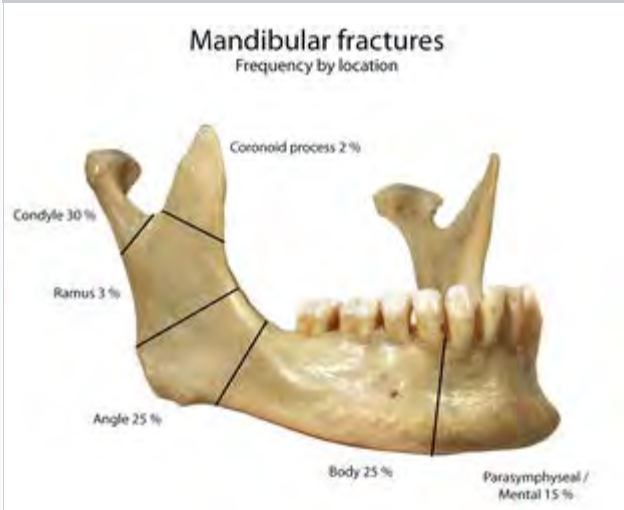
## Classification [edit]

There are various classification systems of mandibular fractures in use.

## Location [edit]

This is the most useful classification, because both the signs and symptoms, and also the treatment are dependent upon the location of the fracture.[7] The mandible is usually divided into the following zones for the purpose of describing the location of a fracture (see diagram): condylar, coronoid process, ramus, angle of mandible, body (molar and premolar areas), parasymphysis and symphysis.[7]



The most frequent locations of a mandibular fracture.

### Alveolar [edit]

This type of fracture involves the alveolus, also termed the alveolar process of the mandible.

### Condylar [edit]

Condylar fractures are classified by location compared to the capsule of ligaments that hold the temporomandibular joint (intracapsular or extracapsular), dislocation (whether or not the condylar head has come out of the socket (glenoid fossa) as the muscles (lateral pterygoid) tend to pull the condyle anterior and medial) and neck of the condyle fractures. E.g. extracapsular, non-displaced, neck fracture. Pediatric condylar fractures have special protocols for management.[14]

### Coronoid [edit]

Because the coronoid process of the mandible lies deep to many structures, including the zygomatic complex (ZMC), it is rare to be broken in isolation. It usually occurs with other mandibular fractures or with fracture of the zygomatic complex or arch. Isolated fractures of the coronoid process should be viewed with suspicion and fracture of the ZMC should be ruled out.[15]

### Ramus [edit]

Ramus fractures are said to involve a region inferiorly bounded by an oblique line extending from the lower third molar (wisdom tooth) region to the posteroinferior attachment of the masseter muscle, and which could not be better classified as either condylar or coronoid fractures.[*medical citation needed*]

### Angle [edit]

The angle of the mandible refers to the angle created by the arrangement of the body of the mandible and

the ramus. Angle fractures are defined as those that involve a triangular region bounded by the anterior border of masseter muscle and an oblique line extending from the lower third molar (wisdom tooth) region to the posteroinferior attachment of the masseter muscle.[*medical citation needed*]

### Body [edit]

Fractures of the mandibular body are defined as those that involve a region bounded anteriorly by the parasymphysis (defined as a vertical line just distal to the canine tooth) and posteriorly by the anterior border of the masseter muscle.[*medical citation needed*]

### Parasymphysis [edit]

Parasymphyseal fractures are defined as mandibular fractures that involve a region bounded bilaterally by vertical lines just distal to the canine tooth.[*medical citation needed*]

### Symphysis [edit]

Symphyseal fractures are a linear fractures that run in the midline of the mandible (the symphysis).[*medical citation needed*]

## Fracture type [edit]

Mandibular fractures are also classified according to categories that describe the condition of the bone fragments at the fracture site and also the presence of communication with the external environment.[16]

### Greenstick [edit]

Greenstick fractures are incomplete fractures of flexible bone, and for this reason typically occur only in children. This type of fracture generally has limited mobility.[16]

### Simple [edit]

A simple fracture describes a complete transection of the bone with minimal fragmentation at the fracture site.[16]

### Comminuted [edit]

The opposite of a simple fracture is a comminuted fracture, where the bone has been shattered into fragments, or there are secondary fractures along the main fracture lines. High velocity injuries (e.g. those caused by bullets, improvised explosive devices, etc...) will frequently cause comminuted fractures.[16][17]

### Compound [edit]

A compound fracture is one that communicates with the external environment. In the case of mandibular fractures, communication may occur through the skin of the face or with the oral cavity. Mandibular fractures that involve the tooth-bearing portion of the jaw are by definition compound fractures,[16] because there is at least a communication via the periodontal ligament with the oral cavity and with more displaced fractures there may be frank tearing of the gingival and alveolar mucosa.

## Involvement of teeth [edit]

When a fracture occurs in the tooth bearing portion of the mandible, whether or not it is dentate or edentulous will affect treatment. Wiring of the teeth helps stabilize the fracture (either during placement of osteosynthesis or as a treatment by itself), so the lack of teeth will guide treatment. When an edentulous mandible (no teeth) is less than 1 cm in height (as measured on panoramic radiograph or CT scan) addition risks apply because the blood flow from the marrow (endosseous) is minimal and the healing bone must rely on blood supply from the periosteum surrounding the bone.[18][*needs update*] If a fracture occurs in a child with mixed dentition different treatment protocols are needed.[19]

Other fractures of the body, are classified as open or closed. Because fractures that involve the teeth, by definition, communicate with the mouth this distinction is largely lost in mandible fractures. Condylar, ramus, and coronoid process fractures are generally closed whereas angle, body and parasymphsis fractures are generally open.

### Displacement [edit]

The degree to which the segments are separated. The larger the separation, the more difficult it is to bring them back together (approximate the segments)

multiple mandible fractures of a patient in the right condyle (extracapsular/neck/not dislocated), right body (vertically unfavourable) and left coronoid process

### Favourability [edit]

For angle and posterior body fractures, when the angle of the fracture line is angled back (more posterior at the top of the jaw and more anterior at the bottom of the jaw) the muscles tend to bring the fracture segments together. This is called favorable. When the angle of the fractures is pointing to the front, it is unfavorable.[20][*non-primary source needed*]

### Age of the fracture [edit]

While mandible fractures have similar complication rates whether treated immediately or days later, older fractures are believed to have higher non-union and infection rates although the data on this makes it difficult to draw firm conclusions.[21]

## Treatment [edit]

Like all fractures, consideration has to be given to other illnesses that might jeopardize the patient, then to reduction and fixation of the fracture itself. Except in avulsive type injuries, or those where there might be airway compromise, a several day delay in the treatment of mandible fractures seems to have little impact on the outcome or complication rates.

### General considerations [edit]

Since mandible fractures are usually the result of blunt force trauma to the head and face, other injuries need to be considered before the mandible fracture. First and foremost is compromise of the airway. While rare, bilateral mandible fractures that are unstable can cause the tongue to fall back and block the airway. Fractures such as a symphyseal or bilateral parasymphyseal may lead to mobility of the central portion of the mandible where genioglossus attaches, and allow the tongue to fall backwards and block the airway.[7] In larger fractures, or those from high velocity injuries, soft tissue swelling can block the airway.

In addition to the potential for airway compromise, the force delivered to break the jaw can be great enough to either fracture the cervical spine or cause intra-cranial injury (head injury). It is common for both to be assessed with facial fractures.

Finally, vascular injury can result (with particular attention to the internal carotid and jugular) from high velocity injuries or severely displaced mandible fractures.

Loss of consciousness combined with aspiration of tooth fragments, blood and possibly dentures mean that the airway may be threatened.[7]

### Reduction [edit]

Reduction refers to approximating the ends of the bones edges that are broken. This is done with either an open technique, where an incision is made, the fracture is found and is physically manipulated into place, or closed technique where no incision is made.

The mouth is unique, in that the teeth are well secured to the bone ends but come through epithelium

(mucosa). A leg or wrist, for instance, has no such structure to help with a closed reduction. In addition, when the fracture happens to be in a tooth bearing area of the jaws, aligning the teeth well usually results in alignment of the fracture segments.

To align the teeth, circumdental wiring is often used where wire strands (typically 24 gauge or 26 gauge) are wrapped around each tooth then attached to a stainless steel arch bar. When the maxillary (top) and mandibular (bottom) teeth are aligned together, this brings the fracture segments into place. Higher tech solutions are also available, to help reduce the segments with arch bars using bonding technology.[22]

## Fixation [edit]

Simple fractures are usually treated with closed reduction and indirect skeletal fixation, more commonly referred to as maxillo-mandibular fixation (MMF). The closed reduction is explained above. The indirect skeletal fixation is accomplished by placing an arch bar, secured to the teeth on the maxillary and mandibular dentition, then securing the top and bottom arch bars with wire loops.

Many alternatives exist to secure the maxillary and mandibular dentition including resin bonded arch bars, Ivy loops (small eyelets of wires), orthodontic bands and MMF bone screws where titanium screws with holes in the head of them are screwed into the basal bone of the jaws then secured with wire.

Closed reduction with direct skeletal fixation follows the same premise as MMF except that wires are passed through the skin and around the bottom jaw in the mandibule and through the piriform rim or zygomatic buttresses of the maxilla then joined together to secure the jaws. The option is sometimes used when a patient is edentulous (has no teeth) and rigid internal fixation cannot be used.

Open reduction with direct skeletal fixation allows the bones to be directly mandibulated through an incision so that the fractured ends meet, then they can be secured together either rigidly (with screws or plates and screws) or non-rigidly (with transosseous wires). There are a multitude of various plate and screw combinations including compression plates, non-compression plates, lag-screws, mini-plates and biodegradable plates.

External fixation, which can be used with either open or closed reduction uses a pin system, where long screws are passed through the skin and into either side of a fracture segment (typically 2 pins per side) then secured in place using an external fixator. This is a more common approach when the bone is heavily comminuted (shattered into small pieces, for instance in a bullet wound) and when the bone is infected (osteomyelitis).

Regardless of the method of fixation, the bone need to remain relatively stable for a period of 3–6 weeks. On average, the bone gains 80% of its strength by 3 weeks and 90% of it by 4 weeks. There is great variation depending on the severity of injury and health of the wound and patient.

## Special considerations [edit]

### Condyle [edit]

The best treatment for condylar fractures is controversial.[23] There are two main options, namely closed reduction or open reduction and fixation. Closed reduction may involve intermaxillary fixation, where the jaws are splinted together in the correct position for a period of weeks. Open reduction involves surgical exposure of the fracture site, which can be carried out via incisions within the mouth or incisions outside the mouth over the area of the condyle. Open reduction is sometimes combined with use of an endoscope to aid visualization of fracture site. Although closed reduction carries a risk of the bone healing out of position, with consequent alteration of the bite or the creation of facial asymmetry, it does not risk temporary damage to the facial nerve or result in any facial scar that accompanies open reduction. A systematic review was unable to find sufficient evidence of the superiority of one method over another in the management of condylar fractures.[23] Paediatric condylar fractures are especially problematic, owing to the remaining growth potential and possibility of ankylosis of the joint. Early mobilization is often recommended as in the Walker protocol.[24][25]

### Edentulous mandible [edit]

A broken jaw that has no teeth in it faces two additional issues. First, the lack of teeth makes reduction and fixation using MMF difficult. Instead of placing circumdental wires around the teeth, existing dentures can be left in (or Gunning splints, a type of temporary denture) and the mandible fixated to the maxilla using skeletal fixation (circummandibular and circumzygomatic wires) or using MMF bone screws. More commonly, open reduction and rigid internal fixation is placed.

When the width of the mandible is less than 1 cm, the jaw loses its endosteal blood supply. Instead, the blood supply comes largely from the periosteum. Open reduction (which normally strips the periosteum during the dissection) can lead to avascular necrosis. In these cases, oral surgeons sometimes opt for external fixation, closed reduction, supraperiosteal dissection or other techniques to maintain the periosteal blood flow.[26]

### High velocity injuries [edit]

In high velocity injuries, the soft tissue can be severely damaged far from the bullet wound itself due to hydrostatic shock. Because of this the airway must be carefully managed and vessels well examined. Because the jaw can be highly comminuted, MMF and rigid internal fixation can be difficult. Instead, external fixation is often used[27],.[28]

### Pathologic fracture [edit]

Fractures where large cysts or tumours are in the area (and weaken the jaw), where there is an area of osteomyelitis or where osteonecrosis exist cause special challenges to fixation and healing. Cysts and tumours can limit effective bone to bone contact and osteomyelitis or osteonecrosis compromise blood supply to the bone. In all of the situations, healing will be delayed and sometimes, resection is the only alternative to treatment.[29]

## Prognosis [edit]

The healing time for a routine mandible fractures is 4–6 weeks whether MMF or rigid internal fixation (RIF) is used. For comparable fractures, patients who received MMF will lose more weight and take longer to regain mouth opening, whereas, those who receive RIF have higher infection rates.

The most common long-term complications are loss of sensation in the mandibular nerve, malocclusion and loss of teeth in the line of fracture. The more complicated the fracture (infection, comminution, displacement) the higher the risk of fracture.[30]

Condylar fractures have higher rates of malocclusion which in turn are dependent on the degree of displacement and/or dislocation. When the fracture is intracapsular there is a higher rate of late-term osteoarthritis and the potential for ankylosis although the later is a rare complication as long as mobilization is early.[23] Pediatric condylar fractures have higher rates of ankylosis and the potential for growth disturbance.[19],[31]

Rarely, mandibular fracture can lead to Frey's syndrome.[32]

## Epidemiology [edit]

Mandible fracture causes vary by the time period and the region studied. In North America, blunt force trauma (a punch) is the leading cause of mandible fracture[33] whereas in India, motor vehicle collisions are now a leading cause.[34] On battle grounds, it is more likely to be high velocity injuries (bullets and shrapnel).[35] Prior to the routine use of seat belts, airbags and modern safety measures, motor vehicle collisions where a leading cause of facial trauma. The relationship to blunt force trauma explains why 80% of all mandible fractures occur in males. Mandibular fracture is a rare complication of third molar removal, and may occur during the procedure or afterwards.[36] With respect to trauma patients, roughly 10% have some sort of facial fracture, the majority of which come from motor vehicle collisions. When the person is unrestrained in a car, the risk of fracture rises 50% and when an unhelmeted motorcyclist the risk rises 4-fold.[37]

## History [edit]

Management of mandible fractures has been mentioned as early as 1700 B.C. in the Edwin Smith Papyrus and later by Hippocrates in 460 B.C., "Displaced but incomplete fractures of the mandible where continuity of the bone is preserved should be reduced by pressing the lingual surface with the fingers...". Open reduction was described as early as 1869.[38] Since the late 19th century, modern techniques including MMF (see above) have been described with titanium based rigid internal fixation becoming commonplace since the 1970s and biodegradable plates and screws being available since the 1980s.

# Nasal polyp

From Wikipedia, the free encyclopedia

**Nasal polyps** (**NP**) are [non-cancerous](#) growths within the [nose or sinuses](#).[1] Symptoms include trouble breathing through the nose, [loss of smell](#), decreased taste, [post nasal drip](#), and a [runny nose](#). The growths are [sac-like](#), movable, and nontender. They typically occur in both nostrils in those who are affected. Face pain may occasionally occur.[1] Complications may include [sinusitis](#).[2]

The exact cause is unclear. They occur more commonly among people who have [allergies](#), [cystic fibrosis](#), [aspirin sensitivity](#), or certain infections. They are overgrowths of the [mucous membranes](#). Diagnosis may occur by looking up the nose and a [CT scan](#) may be used to help plan treatment.[1]

Treatment is typically with [steroids](#), often in the form of a nasal spray. If this is not effective [surgery](#) may be considered. The condition may recur following surgery. [Antihistamines](#) may help with symptoms but do not change the underlying disease. [Antibiotics](#) are not required unless complications occur. About 4% of people currently have nasal polyps while up to 40% of people develop them at some point in their life. They most often occur after the age of 20 and are more frequent in males than females.[1]

## Signs and symptoms [edit]

Nasal polyps are usually classified into *antrochoanal* polyps and *ethmoidal* polyps. Antrochoanal polyps arise from the [maxillary sinuses](#) and are the much less common;[3] ethmoidal polyps arise from the [ethmoidal sinuses](#).[4]

Symptoms of polyps include [nasal congestion](#), [sinusitis](#), [anosmia](#) (loss of smell), and secondary [infection](#) leading to [headache](#). They may be removed by surgery, but are found to recur in about 70% of cases. Sinus surgery requires a great amount of precision as this involves risk of damage to [orbit](#) matter.[5]

## Causes [edit]

The pathogenesis of nasal polyps is unknown. Nasal polyps are most commonly thought to be caused by allergy and rarely by cystic fibrosis although a significant number are associated with non-allergic adult asthma or no respiratory or allergic trigger that can be demonstrated. Nasal mucosa, particularly in the region of middle meatus becomes oedematous due to collection of extracellular fluid causing polypoidal change. Polyps which are sessile in the beginning become pedunculated due to gravity and excessive sneezing.[6]

Micrograph of a sinonasal papilloma (H&E stain), which may have serious consequences and should be distinguished from nasal polyps

In early stages, surface of nasal polyp is covered by ciliated columnar epithelium, but later it undergoes metaplastic change to squamous type on atmospheric irritation. Submucosa shows large intercellular spaces filled with serous fluid.[7]

There are various diseases associated with polyp formation:[8]

1. Chronic rhinosinusitis
2. Asthma
3. Aspirin-induced asthma, or aspirin-exacerbated respiratory disease (AERD)
4. Cystic fibrosis
5. Allergic fungal sinusitis
6. Kartagener's syndrome
7. Young's syndrome
8. Eosinophilic granulomatosis with polyangiitis
9. Nasal mastocytosis

Exposure to some forms of chromium can cause nasal polyps and associated diseases.[*citation needed*] Chronic rhinosinusitis is a common chronic medical condition that can be classified into two groups presenting either with nasal polyposis or without.[9] Chronic rhinosinusitis with nasal polyposis can be divided into eosinophilic chronic rhinosinusitis, which include allergic fungal rhinosinusitis and aspirin-exacerbated respiratory disease, or nasal polyps associated with neutrophilic inflammation, which is primarily characterized by cystic fibrosis.[10]

## Diagnosis [edit]

There are two criteria (major and minor) that must be met. The former in the form of facial pressure, nasal blockage, decreased smell and the latter in the form of fever, headache, cough and dental pain.[9]

### Types [edit]

There are two major types of nasal polyp.[*citation needed*]

1. Antrochoanal
    a. Single, Unilateral
    b. Can originate from maxillary sinus
    c. Usually found in children
2. Ethmoidal
    a. Bilateral
    b. Usually found in adults

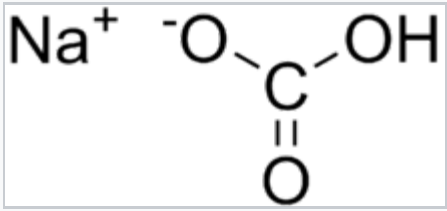
Nasal polyps consist of hyperplastic oedematous connective tissue with some seromucous glands and inflammatory cells (mostly neutrophils and eosinophils) with respiratory epithelium, sometimes with metaplastic squamous epithelium on the surface.Nasal polyps should be distinguished from nasal papillomas, which are benign epithelial tumors and have more serious consequences.[*citation needed*]

## Treatment [edit]



Sodium bicarbonate

Nasal polyps are most often treated with steroids or topical, but can also be treated with surgical methods.[11] Before and after surgery, sinus rinses with sterile warm water mixed with a small amount of salts (sodium chloride and sodium bicarbonate) can be helpful to clear the sinuses.[12]

The removal of nasal polyps via surgery lasts approximately 45 minutes to 1 hour. The surgery can be done under general or local anaesthesia, and the polyps are removed using endoscopic surgery. Recovery from this type of surgery is anywhere from 1 to 3 weeks. Mometasone furoate, commonly available as a nasal spray for treating common allergy symptoms, has been indicated in the United States by the FDA for the treatment of nasal polyps since December 2005.[13][14]

# Nosebleed

From Wikipedia, the free encyclopedia
(Redirected from Nose bleed)

*For other uses, see Nosebleed (disambiguation).*
*"Epistaxis" redirects here. It is not to be confused with Epitaxis.*

**Nosebleed**, also known as a **epistaxis**, is the common occurrence of bleeding from the nose. It is usually noticed when the blood drains out through the nostrils.

There are two types: anterior (the most common), and posterior (less common, more likely to require medical attention). Sometimes in more severe cases, the blood can come up the nasolacrimal duct and out from the eye. Fresh blood and clotted blood can also flow down into the stomach and cause nausea and vomiting.[1]

Although the sight of large amounts of blood can be alarming and may warrant medical attention, nosebleeds are rarely fatal, accounting for only 4 of the 2.4 million deaths in the U.S. in 1999.[2] About 60% of people have a nosebleed at some point in their life.[3] About 10% of nosebleeds are serious.[3]

## Cause [edit]

The causes of nosebleeds can generally be divided into two categories, local and general factors, although a significant number of nosebleeds occur with no obvious cause.

### Local factors [edit]

**Nosebleed**

**Synonyms**

A three year old with a minor nosebleed, from falling and hitting the floor with his face. Nosebleeds like this one normally resolve within a few minutes.

## Other possible factors [edit]

- Anatomical deformities (*e.g.* septal spurs or hereditary hemorrhagic telangiectasia)
- Insufflated drugs (particularly cocaine)
- Intranasal tumors (*e.g.* nasopharyngeal carcinoma or nasopharyngeal angiofibroma)
- Low relative humidity of inhaled air (particularly during cold winter seasons).[3] Evidence to support this however is weak.[4][5]
- Nasal cannula $O_2$ (tending to dry the nasal mucosa)
- Nasal sprays (particularly prolonged or improper use of nasal steroids)
- Middle ear barotrauma (such as from descent in aircraft or ascent in scuba diving)
- Surgery (*e.g.* septoplasty and functional endoscopic sinus surgery)

## Systemic factors [edit]

### Most common factors [edit]

- Infectious diseases (*e.g.* common cold)
- Hypertension

### Other possible factors [edit]

- Alcohol (due to vasodilation)
- Anemia
- Blood dyscrasias
- Connective tissue disease
- Drugs—aspirin, fexofenadine, warfarin, clopidogrel, prasugrel, isotretinoin, desmopressin and others
- Envenomation by mambas, taipans, kraits, and death adders
- Chronic liver disease—cirrhosis causes deficiency of factor II, VII, IX,& X
- Heart failure (due to an increase in venous pressure)
- Hematological malignancy (such as leukemia)
- Idiopathic thrombocytopenic purpura
- Pregnancy (rare, due to hypertension and hormonal changes)
- Vascular disorders
- Vitamin C and vitamin K deficiency
- Von Willebrand's disease
- Recurrent epistaxis is a feature of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome)
- Mediastinal compression by tumours (raised venous pressure)
- Hemophilia

- Thrombotic thrombocytopenic purpura

## Pathophysiology [edit]

Nosebleeds are due to the rupture of a blood vessel within the richly perfused nasal mucosa. Rupture may be spontaneous or initiated by trauma. Nosebleeds are reported in up to 60% of the population with peak incidences in those under the age of ten and over the age of 50 and appear to occur in males more than females.[6] An increase in blood pressure (e.g. due to general hypertension) tends to increase the duration of spontaneous epistaxis.[7] Anticoagulant medication and disorders of blood clotting can promote and prolong bleeding. Spontaneous epistaxis is more common in the elderly as the nasal mucosa (lining) becomes dry and thin and blood pressure tends to be higher. The elderly are also more prone to prolonged nose bleeds as their blood vessels are less able to constrict and control the bleeding.

The vast majority of nose bleeds occur in the anterior (front) part of the nose from the nasal septum. This area is richly endowed with blood vessels (Kiesselbach's plexus). This region is also known as Little's area. Bleeding farther back in the nose is known as a posterior bleed and is usually due to bleeding from Woodruff's plexus, a venous plexus situated in the posterior part of inferior meatus.[8] Posterior bleeds are often prolonged and difficult to control. They can be associated with bleeding from both nostrils and with a greater flow of blood into the mouth.[6]

Sometimes blood flowing from other sources of bleeding passes through the nasal cavity and exits the nostrils. It is thus blood coming from the nose but is not a true nosebleed, that is, not truly originating from the nasal cavity. Such bleeding is called pseudoepistaxis (*pseudo* + *epistaxis*). Examples include blood coughed up through the airway and ending up in the nasal cavity, then dripping out.

## Treatment [edit]

The flow of blood normally stops when the blood clots, which may be encouraged by direct pressure applied by pinching the soft fleshy part of the nose. This applies pressure to Little's area (Kiesselbach's area), the source of the majority of nose bleeds, and promotes clotting. Pressure should be firm and be applied for at least five minutes and up to 20 minutes; tilting the head forward helps decrease the chance of nausea and airway obstruction.[6] Swallowing excess blood can irritate the stomach and cause vomiting.

### Medications [edit]

The local application of a vasoconstrictive agent has been shown to reduce the bleeding time in benign cases of epistaxis. The drugs oxymetazoline or phenylephrine are widely available in over-the-counter nasal sprays for the treatment of allergic rhinitis, and they may be used for this purpose.[9]

### Procedures [edit]

If these simple measures do not work then medical intervention may be needed to stop bleeding. The use of silver nitrate to cauterize bleeding blood vessels is common but not very useful for those with more than mild bleeding.[10] It is also often painful even when freezing is used.[11]

There are two types of nasal packing, anterior nasal packing and posterior nasal packing.[12] There are a number of different types of anterior nasal packs. Some use gauze and others use balloons.[12] Posterior packing can be achieved by using a Foley catheter, blowing up the balloon when it is in the back of the throat, and applying traction.[12] Ribbon gauze or Merocel packing can also be used.[12] There are also several dissolvable packing materials, such as surgicel that function as a pack but are not removed and dissolve after a few days. Packing is generally left in for two to five days.[13]

Ongoing bleeding despite good nasal packing is a surgical emergency and can be treated by endoscopic evaluation of the nasal cavity under general anaesthesia to identify an elusive bleeding point or to directly ligate (tie off) the blood vessels supplying the nose. These blood vessels include the sphenopalatine, anterior and posterior ethmoidal arteries. More rarely the maxillary or a branch of the external carotid artery

can be ligated. The bleeding can also be stopped by intra-arterial embolization using a catheter placed in the groin and threaded up the aorta to the bleeding vessel by an interventional radiologist.[14] There is no difference in outcomes between embolization and ligation as treatment options, but embolization is considerably more expensive.[15] Continued bleeding may be an indication of more serious underlying conditions.[14]

### Other [edit]

The utility of local cooling of the head and neck is controversial.[16] Some state that applying ice to the nose or forehead is not useful.[17][18] Others feel that it may promote vasoconstriction of the nasal blood vessels and thus be useful.[19]

### Prevention [edit]

Application of a topical antibiotic ointment to the nasal mucosa has been shown to be an effective treatment for recurrent epistaxis.[20] One study found it as effective as nasal cautery in the prevention of recurrent epistaxis in people without active bleeding at the time of treatment—both had a success rate of approximately 50 percent.[21]

## Society and culture [edit]

In the visual language of Japanese comics (manga) and animation (anime), a sudden, violent nosebleed indicates that the bleeding person is sexually aroused.[22][23] Separately in Western fiction, nosebleeds often signify intense mental focus or effort, particularly during the use of psychic powers.[24][25]

In American and Canadian usage, "nosebleed section" or "nosebleed seats" are common slang for seating at sporting or other spectator events that are the highest up and farthest away from the event. The reference alludes to the propensity for nasal hemorrhage at high altitudes, usually owing to lower barometric pressure.

The oral history of the Native American Sioux tribe includes reference to women who experience nosebleeds as a result of a lover's playing of music, implying sexual arousal.[26]

In Finnish language, "begging for a nosebleed" is commonly used in abstract meaning to describe self-destructive behaviour, for example ignoring safety procedures or deliberately aggravating stronger parties.[27]

In Filipino slang, to "have a nosebleed" is to have serious difficulty conversing in English with a fluent or native English speaker. It can also refer to anxiety brought on by a stressful event such as an examination or a job interview.[28]

In the Dutch language, "pretending to have a nosebleed" is a saying that means pretending not to know anything about something, when actually being involved somehow.

### Etymology and pronunciation [edit]

The word *epistaxis* (/ˌɛpɪˈstæksɪs/) is from Greek: ἐπιστάζω *epistazo*, "to bleed from the nose" from ἐπί *epi*, "above, over" and στάζω *stazo*, "to drip [from the nostrils]".

# Otitis externa

From Wikipedia, the free encyclopedia

**Otitis externa**, also known as **swimmer's ear**,[1] is an inflammation of the external ear.[2] It often presents with ear pain, swelling of the ear canal, and occasionally decreased hearing.[2] Typically there is pain with movement of the outer ear.[2] A high fever is typically not present except in severe cases.[2]

Otitis externa may be acute (meaning less than six weeks) or chronic (meaning more than three months) in duration.[2] Acute cases are typically due to a bacterial infection while chronic cases are often due to allergies or autoimmune disorders.[2] Risk factors for acute cases include swimming, minor trauma from cleaning, using hearing aids or ear plugs, and other skin problems like psoriasis or dermatitis.[2][3] Those with diabetes are at risk of a severe form of disease known as malignant otitis externa. Diagnosis is based on the signs and symptoms. Culturing the ear canal may be useful in chronic or severe cases.[2]

Acetic acid ear drops may be used as a preventative measure.[3] Treatment of acute cases is typically with antibiotic drops such as ofloxacin or acetic acid.[2][3] Steroid drops may be used in addition to antibiotics. Pain medications such as ibuprofen may be used for the pain. Antibiotics by mouth are not recommended unless the person has poor immune function or there is infection of the skin around the ear.[2] Typically improvement occurs within a day of starting treatment. Treatment of chronic cases depends on the cause.[2]

Otitis externa affects 1-3% of people a year with more than 95% of cases being acute.[2] About 10% of people are affected at some point in their life.[3] It occurs most commonly among children between the ages of seven and twelve and among the elderly.[2][4] It occurs with near equal frequency in males and females.[4] Those who live in warm and wet climates are more often affected.[2]

## Signs and symptoms [edit]

Ear pain is the predominant complaint and the only symptom directly related to the severity of acute external otitis. Unlike other forms of ear infections, the pain of acute external otitis is worsened when the outer ear is touched or pulled gently. Pushing the tragus, the tablike portion of the auricle that projects out just in front of the ear canal opening, also typically causes pain in this condition as to be diagnostic of external otitis on physical examination. Patients may also experience ear discharge and itchiness. When enough swelling and discharge in the ear canal is present to block the opening, external otitis may cause temporary conductive hearing loss.

A mild case of otitis externa.

Because the symptoms of external otitis lead many people to attempt to clean out the ear canal (or scratch it) with slim implements, self-cleaning attempts generally lead to additional traumas of the injured skin, so rapid worsening of the condition often occurs.

## Causes [edit]

Swimming in polluted water is a common way to contract swimmer's ear, but it is also possible to contract swimmer's ear from water trapped in the ear canal after a shower, especially in a humid climate.[5] Constriction of the ear canal from bone growth (Surfer's ear) can trap debris leading to infection.[6] Saturation divers have reported Otitis externa during occupational exposure.[7][8][9] Even without exposure to water, the use of objects such as cotton swabs or other small objects to clear the ear canal is enough to cause breaks in the skin, and allow the condition to develop.[10] Once the skin of the ear canal is inflamed, external otitis can be drastically enhanced by either scratching the ear canal with an object, or by allowing water to remain in the ear canal for any prolonged length of time.

The two factors that are required for external otitis to develop are (1) the presence of germs that can infect the skin and (2) impairments in the integrity of the skin of the ear canal that allow an infection to occur. If the skin is healthy and uninjured, only exposure to a high concentration of pathogens, such as submersion in a pond contaminated by sewage, is likely to set off an episode. However, if there are chronic skin conditions that affect the ear canal skin, such as atopic dermatitis, seborrheic dermatitis, psoriasis or abnormalities of keratin production, or if there has been a break in the skin from trauma, even the normal bacteria found in the ear canal may cause infection and full-blown symptoms of external otitis.[11]

Fungal ear canal infections, also known as otomycosis, range from inconsequential to extremely severe. Fungi can be saprophytic, in which there are no symptoms and the fungus simply co-exists in the ear canal in a harmless parasitic relationship with the host, in which case the only physical finding is the presence of a fungus. If the fungus begins active reproduction, the ear canal can fill with dense fungal debris, causing pressure and ever-increasing pain that is unrelenting until the fungus is removed from the canal and anti-fungal medication is used. Most antibacterial ear drops also contain a steroid to hasten resolution of canal

edema and pain. Unfortunately, such drops make the fungal infection worse. Prolonged use of them promotes the growth of fungus in the ear canal. Antibacterial ear drops should be used a maximum of one week, but 5 days is usually enough. Otomycosis responds more than 95% of the time to a three-day course of the same over-the-counter anti-fungal solutions used for athlete's foot.

### Infections [edit]

The majority of cases are due to *Pseudomonas aeruginosa* and *Staphylococcus aureus*,[12] followed by a great number of other gram-positive and gram-negative species.[13] *Candida albicans* and *Aspergillus* species are the most common fungal pathogens responsible for the condition.

## Diagnosis [edit]

When the ear is inspected, the canal appears red and swollen in well-developed cases. The ear canal may also appear eczema-like, with scaly shedding of skin. Touching or moving the outer ear increases the pain, and this maneuver on physical exam is important in establishing the clinical diagnosis. It may be difficult to see the eardrum with an otoscope at the initial examination because of narrowing of the ear canal from inflammation and the presence of drainage and debris. Sometimes the diagnosis of external otitis is presumptive and return visits are required to fully examine the ear. The culture of the drainage may identify the bacteria or fungus causing infection, but is not part of the routine diagnostic evaluation. In severe cases of external otitis, there may be swelling of the lymph node(s) directly beneath the ear.

The diagnosis may be missed in most early cases because the examination of the ear, with the exception of pain with manipulation, is nearly normal. In some early cases, the most striking visual finding is the lack of cerumen. As a moderate or severe case of external otitis resolves, weeks may be required before the ear canal again shows a normal amount of cerumen.

### Classification [edit]

In contrast to the chronic otitis externa, acute otitis externa (AOE) is predominantly a bacterial infection,[14] occurs suddenly, rapidly worsens, and becomes painful. The ear canal has an abundant nerve supply, so the pain is often severe enough to interfere with sleep. Wax in the ear can combine with the swelling of the canal skin and any associated pus to block the canal and dampen hearing to varying degrees, creating a temporary conductive hearing loss. In more severe or untreated cases, the infection can spread to the soft tissues of the face that surround the adjacent parotid gland and the jaw joint, making chewing painful. In its mildest forms, otitis externa is so common that some ear nose and throat physicians have suggested that most people will have at least a brief episode at some point in life. While a small percentage of people seem to have an innate tendency toward chronic otitis externa, most people can avoid otitis externa altogether once they understand the intricate mechanisms of the disease.

The skin of the bony ear canal is unique, in that it is not movable but is closely attached to the bone, and it is almost paper thin. For these reasons, it is easily abraded or torn by even minimal physical force. Inflammation of the ear canal skin typically begins with a physical insult, most often from injury caused by attempts at self-cleaning or scratching with cotton swabs, pen caps, fingernails, hair pins, keys, or other small implements. Another causative factor for acute infection is prolonged water exposure in the forms of swimming or exposure to extreme humidity, which can compromise the protective barrier function of the canal skin, allowing bacteria to flourish; hence the name "swimmer's ear".

The strategies for preventing acute external otitis are similar to those for treatment.

- Avoid inserting *anything* into the ear canal: use of cotton buds or swabs is the most common event leading to acute otitis externa.
- Most normal ear canals have a self-cleaning and self-drying mechanism, the latter by simple evaporation.
- After prolonged swimming, a person prone to external otitis can dry the ears using a small battery-powered ear dryer, available at many retailers, especially shops catering to watersports enthusiasts. Alternatively, drops containing dilute acetic acid (vinegar diluted 3:1) or Burow's solution may be used. It is especially important NOT to instrument ears when the skin is saturated with water, as it is very susceptible to injury, which can lead to external otitis.
- Avoid swimming in polluted water.
- Avoid washing hair or swimming if very mild symptoms of acute external otitis begin
- Although the use of earplugs when swimming and shampooing hair may help prevent external otitis, there are important details in the use of plugs. Hard and poorly fitting ear plugs can scratch the ear canal skin and set off an episode. When earplugs are used during an acute episode, either disposable plugs are recommended, or used plugs must be cleaned and dried properly to avoid contaminating the healing ear canal with infected discharge.

# Treatment [edit]

## Medications [edit]

Effective solutions for the ear canal include acidifying and drying agents, used either singly or in combination.[15] When the ear canal skin is inflamed from the acute otitis externa, the use of dilute acetic acid may be painful.

Burow's solution is a very effective remedy against both bacterial and fungal external otitis. This is a buffered mixture of aluminum sulfate and acetic acid, and is available without prescription in the United States.[16]

Ear drops are the mainstays of treatment for external otitis. Some contain antibiotics, either antibacterial or antifungal, and others are simply designed to mildly acidify the ear canal environment to discourage bacterial growth. Some prescription drops also contain anti-inflammatory steroids, which help to resolve swelling and itching. Although there is evidence that steroids are effective at reducing the length of treatment time required, fungal otitis externa (also called otomycosis) may be caused or aggravated by overly prolonged use of steroid-containing drops.

Antibiotics by mouth should not be used to treat uncomplicated acute otitis externa.[17] Antibiotics by mouth are not a sufficient response to bacteria which cause this condition and have significant side effects including increased risk of opportunistic infection.[17] In contrast, topical products can treat this condition.[17] Oral anti-pseudomonal antibiotics can be used in case of severe soft tissue swelling extending into the face and neck and may hasten recovery.[*citation needed*]

Although the acute external otitis generally resolves in a few days with topical washes and antibiotics, complete return of hearing and cerumen gland function may take a few more days. Once healed completely, the ear canal is again self-cleaning. Until it recovers fully, it may be more prone to repeat infection from further physical or chemical insult.

Effective medications include ear drops containing antibiotics to fight infection, and corticosteroids to reduce itching and inflammation. In painful cases a topical solution of antibiotics such as aminoglycoside, polymyxin or fluoroquinolone is usually prescribed. Antifungal solutions are used in the case of fungal infections. External otitis is almost always predominantly bacterial or predominantly fungal, so that only one type of medication is necessary and indicated.

## Cleaning [edit]

Removal of debris (wax, shed skin, and pus) from the ear canal promotes direct contact of the prescribed

medication with the infected skin and shortens recovery time. When canal swelling has progressed to the point where the ear canal is blocked, topical drops may not penetrate far enough into the ear canal to be effective. The physician may need to carefully insert a wick of cotton or other commercially available, pre-fashioned, absorbent material called an ear wick and then saturate that with the medication. The wick is kept saturated with medication until the canal opens enough that the drops will penetrate the canal without it. Removal of the wick does not require a health professional. Antibiotic ear drops should be dosed in a quantity that allows coating of most of the ear canal and used for no more than 4 to 7 days. The ear should be left open. It is imperative that visualization of an intact tympanic membrane (eardrum) is noted. Use of certain medications with a ruptured tympanic membrane can cause tinnitus, vertigo, dizziness and hearing loss in some cases.

## Prognosis [edit]

Otitis externa responds well to treatment, but complications may occur if it is not treated. Individuals with underlying diabetes, disorders of the immune system, or history of radiation therapy to the base of the skull are more likely to develop complications, including malignant otitis externa.[18] In these individuals, rapid examination by an otolaryngologist (ear, nose, and throat physician) is very important.

- Chronic otitis externa
- Spread of infection to other areas of the body
- Necrotizing external otitis
- Otitis externa haemorhagica

### Necrotizing external otitis [edit]

Necrotizing external otitis (malignant otitis externa) is an uncommon form of external otitis that occurs mainly in elderly diabetics, being somewhat more likely and more severe when the diabetes is poorly controlled. Even less commonly, it can develop due to a severely compromised immune system. Beginning as infection of the external ear canal, there is an extension of the infection into the bony ear canal and the soft tissues deep to the bony canal. Unrecognized and untreated, it may result in death. The hallmark of malignant otitis externa (MOE) is unrelenting pain that interferes with sleep and persists even after swelling of the external ear canal may have resolved with topical antibiotic treatment.[18] It can also cause skull base osteomyelitis (SBO), manifested by multiple cranial nerve palsies, described below under the "Treatment" heading.

### Natural history [edit]

MOE follows a much more chronic and indolent course than ordinary acute otitis externa. There may be granulation involving the floor of the external ear canal, most often at the bony-cartilaginous junction. Paradoxically, the physical findings of MOE, at least in its early stages, are often much less dramatic than those of ordinary acute otitis externa. In later stages, there can be soft tissue swelling around the ear, even in the absence of significant canal swelling. While fever and leukocytosis might be expected in response to bacterial infection invading the skull region, MOE does not cause fever or elevation of white blood count.

### Treatment of MOE [edit]

Unlike ordinary otitis externa, MOE requires oral or intravenous antibiotics for cure. Pseudomonas is the most common offending pathogen. Diabetes control is also an essential part of treatment. When MOE goes unrecognized and untreated, the infection continues to smolder and over weeks or months can spread deeper into the head and involve the bones of the skull base, constituting skull base osteomyelitis (SBO). Multiple cranial nerve palsies can result, including the facial nerve (causing facial palsy), the recurrent laryngeal nerve (causing vocal cord paralysis)[*citation needed*], and the cochlear nerve (causing deafness). The infecting organism is almost always pseudomonas aeruginosa, but it can instead be fungal (aspergillus or mucor). MOE and SBO are not amenable to surgery, but exploratory surgery may facilitate the culture of unusual organism(s) that are not responding to empirically used anti-pseudomonal antibiotics (ciprofloxacin being the drug of choice). The usual surgical finding is diffuse cellulitis without localized abscess formation.

SBO can extend into the petrous apex of the temporal bone or more inferiorly into the opposite side of the skull base.

The use of hyperbaric oxygen therapy as an adjunct to antibiotic therapy remains controversial.[18]

### Complications [edit]

As the skull base is progressively involved, the adjacent exiting cranial nerves and their branches, especially the facial nerve and the vagus nerve, may be affected, resulting in facial paralysis and hoarseness, respectively. If both of the recurrent laryngeal nerves are paralyzed, shortness of breath may develop and necessitate tracheotomy. Profound deafness can occur, usually later in the disease course due to relative resistance of the inner ear structures. Gallium scans are sometimes used to document the extent of the infection but are not essential to disease management. Skull base osteomyelitis is a chronic disease that can require months of IV antibiotic treatment, tends to recur, and has a significant mortality rate.[18]

## Epidemiology [edit]

The incidence of otitis externa is high. In the Netherlands, it has been estimated at 12–14 per 1000 population per year, and has been shown to affect more than 1% of a sample of the population in the United Kingdom over a 12-month period.[19]

## History [edit]

During the Tektite Project in 1969 there was a great deal of otitis externa.[20] The Diving Medical Officer devised a prophylaxis that came to be known as, "Tektite Solution", equal parts of 15% tannic acid, 15% acetic acid and 50% isopropanol or ethanol. During Tektite ethanol was used because it was available in the lab for pickling specimens.

# Otitis media

From Wikipedia, the free encyclopedia

**Otitis media** is a group of inflammatory diseases of the middle ear.[1] The two main types are **acute otitis media** (**AOM**) and **otitis media with effusion** (**OME**).[2] AOM is an infection of abrupt onset that usually presents with ear pain. In young children this may result in pulling at the ear, increased crying, and poor sleep. Decreased eating and a fever may also be present. OME is typically not associated with symptoms.[3] Occasionally a feeling of fullness is described. It is defined as the presence of non-infectious fluid in the middle ear for more than three months. **Chronic suppurative otitis media** (**CSOM**) is middle ear inflammation of greater than two weeks that results in episodes of discharge from the ear. It may be a complication of acute otitis media. Pain is rarely present.[4] All three may be associated with hearing loss.[1][2] The hearing loss in OME, due to its chronic nature, may affect a child's ability to learn.[1]

The cause of AOM is related to childhood anatomy and immune function. Either bacteria or viruses may be involved. Risk factors include exposure to smoke, use of pacifiers, and attending daycare. It occurs more commonly in those who are Native American or who have Down syndrome.[4] OME frequently occurs following AOM and may be related to viral upper respiratory infections, irritants such as smoke, or allergies.[2][4] Looking at the eardrum is important for making the correct diagnosis.[5] Signs of AOM include bulging or a lack of movement of the tympanic membrane from a puff of air.[3][6] New discharge not related to otitis externa also indicates the diagnosis.[3]

A number of measures decrease the risk of otitis media including pneumococcal and influenza vaccination, exclusive breastfeeding for the first six months of life, and avoiding tobacco smoke.[3] The use of pain medications for AOM is important.[3] This may include paracetamol (acetaminophen), ibuprofen, benzocaine ear drops, or opioids.[3] In AOM, antibiotics may speed recovery but may result in side effects.[3] Antibiotics are often recommended in those with severe disease or under two years old. In those with less severe disease they may only be recommended in those who do not improve after two or three days.[6] The initial antibiotic of choice is typically amoxicillin. In those with frequent

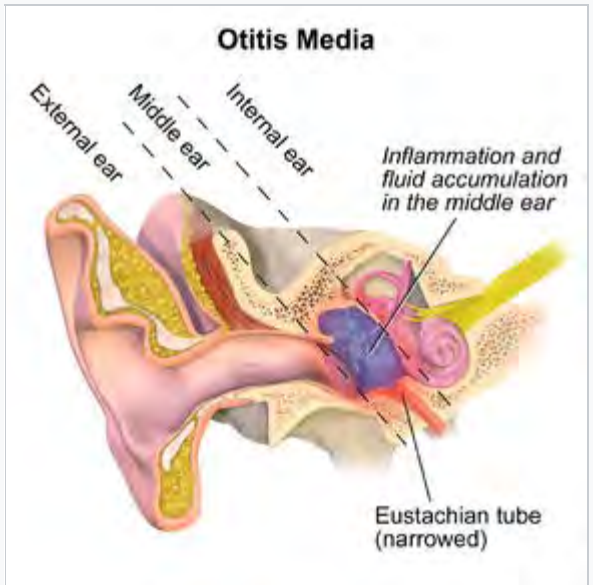
infections tympanostomy tubes may decrease recurrence.[3] In children with otitis media with effusion antibiotics may increase resolution of symptoms, but may cause diarrhoea, vomiting and skin rash.[8]

Worldwide AOM affect about 11% of people a year (about 325 to 710 million cases).[9][10] Half the cases involve children less than five years of age and it is more common among males.[4][9] Of those affected about 4.8% or 31 million develop chronic suppurative otitis media.[9] Before the age of ten OME affects about 80% of children at some point.[4] Otitis media resulted in 2,400 deaths in 2013 – down from 4,900 deaths in 1990.[11]

## Signs and symptoms [edit]

An integral symptom of acute otitis media is ear pain; other possible symptoms include fever, and irritability (in infants). Since an episode of otitis media is usually precipitated by an upper respiratory tract infection (URTI), there often are accompanying symptoms like a cough and nasal discharge.[12]

Discharge from the ear can be caused by acute otitis media with perforation of the ear drum, chronic suppurative otitis media, tympanostomy tube otorrhea, or acute otitis externa. Trauma, such as a basilar skull fracture, can also lead to discharge from the ear due to cerebral spinal drainage from the brain and its covering (meninges).



Otitis media.

## Causes [edit]

The common cause of all forms of otitis media is dysfunction of the Eustachian tube.[13] This is usually due to inflammation of the mucous membranes in the nasopharynx, which can be caused by a viral URI, strep throat, or possibly by allergies.[14] Because of the dysfunction of the Eustachian tube, the gas volume in the middle ear is trapped and parts of it are slowly absorbed by the surrounding tissues, leading

to negative pressure in the middle ear. Eventually, the negative middle-ear pressure can reach a point where fluid from the surrounding tissues is sucked into the middle ear's cavity (tympanic cavity), causing a middle-ear effusion. This is seen as a progression from a Type A tympanogram to a Type C to a Type B tympanogram.

By reflux or aspiration of unwanted secretions from the nasopharynx into the normally sterile middle-ear space, the fluid may then become infected — usually with bacteria. The virus that caused the initial URI can itself be identified as the pathogen causing the infection.[14]

## Diagnosis [edit]

As its typical symptoms overlap with other conditions, such as acute external otitis, clinical history alone is not sufficient to predict whether acute otitis media is present; it has to be complemented by visualization of the tympanic membrane.[15][16] Examiners use a pneumatic otoscope with a rubber bulb attached to assess the mobility of the tympanic membrane.

Perforation of the right tympanic membrane resulting from a previous severe acute otitis media

Acute otitis media in children with moderate to severe bulging of the tympanic membrane or new onset of otorrhea (drainage) is not due to external otitis. Also, the diagnosis may be made in children who have mild bulging of the ear drum and recent onset of ear pain (less than 48 hours) or intense erythema (redness) of the ear drum.

To confirm the diagnosis, middle-ear effusion and inflammation of the eardrum have to be identified; signs of these are fullness, bulging, cloudiness and redness of the eardrum.[12] It is important to attempt to differentiate between acute otitis media and otitis media with effusion (OME), as antibiotics are not recommended for OME.[12] It has been suggested that bulging of the tympanic membrane is the best sign to differentiate AOM from OME.[17]

Viral otitis may result in blisters on the external side of the tympanic membrane, which is called *bullous myringitis* (*myringa* being Latin for "eardrum").[18]

However, sometimes even examination of the eardrum may not be able to confirm the diagnosis, especially if the canal is small. If wax in the ear canal obscures a clear view of the eardrum it should be removed using a blunt cerumen curette or a wire loop. Also, an upset young child's crying can cause the eardrum to look inflamed due to distension of the small blood vessels on it, mimicking the redness associated with otitis media.

### Acute otitis media [edit]

The most common bacteria isolated from the middle ear in AOM are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*,[12] and *Staphylococcus aureus*.[19]

### Otitis media with effusion [edit]

Otitis media with effusion (OME), also known as serous otitis media (SOM) or secretory otitis media (SOM), and commonly referred to as glue ear,[20] is a collection of effusion (fluid) that occurs in the middle ear space due to the negative pressure produced by dysfunction of the Eustachian tube. This can occur purely from a viral URI or bacterial infection, or it can precede and/or follow acute bacterial otitis media.[21] Fluid in the middle ear frequently causes conductive hearing impairment but only when it interferes with the normal vibration of the eardrum by sound waves. Over weeks and months, middle-ear fluid can become very thick and glue-like, which increases the likelihood of its causing conductive hearing impairment.

Early-onset OME is associated with feeding of infants while lying down, early entry into group child care, parental smoking, lack, or too short a period of breastfeeding and greater amounts of time spent in group

child care, particularly those with a large number of children, increases the incidences and duration of OME in the first two years of life.[22]

### Chronic suppurative otitis media [edit]

Chronic suppurative otitis media, incorrectly called chronic otitis media or chronic ear infection, involves a hole in the tympanic membrane and active bacterial infection within the middle ear space for several weeks or more. There may be enough pus that it drains to the outside of the ear (otorrhea), or the pus may be minimal enough to only be seen on examination using the otoscope or, more effectively, with a binocular microscope. This disease is much more common in persons with poor Eustachian tube function and very common in certain races such as Native North Americans. Hearing impairment often accompanies this disease.

It is a primary cause of hearing loss that newly develops in children. An ear wick may be effective or, if not, antibiotics.[23]

### Adhesive otitis media [edit]

Adhesive otitis media occurs when a thin retracted ear drum becomes sucked into the middle-ear space and stuck (i.e., adherent) to the ossicles and other bones of the middle ear.

## Prevention [edit]

Long-term antibiotics, while they decrease rates of infection during treatment, have an unknown effect on long-term outcomes such as hearing loss.[24] This method of prevention has been associated with emergence of antibiotic-resistant otitic bacteria. They are thus not recommended.[12]

Pneumococcal conjugate vaccines when given during infancy decrease rates of acute otitis media by 6%–7% and, if implemented broadly, would have a significant public health benefit.[12][25][*needs update*] Influenza vaccine is recommended annually.[12]

Risk factors such as season, allergy predisposition and presence of older siblings are known to be

determinants of recurrent otitis media and persistent middle-ear effusions (MEE).[26] History of recurrence, environmental exposure to tobacco smoke, use of daycare, and lack of breastfeeding have all been associated with increased risk of development, recurrence, and persistent MEE.[27][28] Thus, cessation of smoking in the home should be encouraged, daycare attendance should be avoided or daycare facilities with the fewest attendees should be recommended, and breastfeeding should be promoted.[27][28]

There is some evidence that breastfeeding for the first year of life is associated with a reduction in the number and duration of OM infections.[29][30] Pacifier use, on the other hand, has been associated with more frequent episodes of AOM.[31]

Evidence does not support zinc supplementation as an effort to reduce otitis rates except maybe in those with severe malnutrition such as marasmus.[32]

## Management [edit]

Oral and topical pain killers are effective to treat the pain caused by otitis media. Oral agents include ibuprofen, paracetamol (acetaminophen), and opiates. Topical agents shown to be effective include antipyrine and benzocaine ear drops.[33] Decongestants and antihistamines, either nasal or oral, are not recommended due to the lack of benefit and concerns regarding side effects.[34] Half of cases of ear pain in children resolve without treatment in three days and 90% resolve in seven or eight days.[35] The use of steroids is not supported by the evidence for acute otitis media.[36]

### Antibiotics [edit]

It is important to weigh the benefits and harms before using antibiotics for acute otitis media. As over 80% of acute episodes settle without treatment, about 20 children must be treated to prevent one case of ear pain, 33 children to prevent one perforation, and 11 children to prevent one opposite-side ear infection. For every 14 children treated with antibiotics, one child has an episode of either vomiting, diarrhea or a rash.[37][*needs update*] If pain is present, treatment to reduce it should be initiated.

- Antibiotics should be prescribed for severe bilateral or unilateral disease in all infants and children with severe signs and symptoms, such as moderate to severe ear pain and high fever.
- For bilateral acute otitis media in infants younger than 24 months of age, without severe signs and symptoms, antibiotics should be prescribed.
- When non-severe unilateral acute otitis media is diagnosed in young children either antibiotic therapy is given or observation with close follow-up based on joint decision making between parent(s)/caregiver in infants 6 to 23 months of age. If the child worsens or fails to improve in 2 to 3 days antibiotics should be administered.
- Children 24 months or older with non-severe disease can have either antibiotics or observation.

The first line antibiotic treatment, if warranted, is amoxicillin.[12] If there is resistance or use of amoxicillin in the last 30 days then amoxicillin-clavulanate or another penicillin derivative plus beta lactamase inhibitor is recommended.[12] Taking amoxicillin once a day may be as effective as twice[38] or three times a day. While less than 7 days of antibiotics have less side effects, more than seven days appear to be more effective.[39] If there is no improvement after 2–3 days of treatment a change in therapy may be considered.[12]

A treatment option for chronic suppurative otitis media with discharge is topical antibiotics. A Cochrane review found that topical quinolone antibiotics can improve discharge better than oral antibiotics.[40] Safety is not really clear.[40]

### Tympanostomy tube [edit]

Tympanostomy tubes (also called "grommets") are recommended in those people who have three or more episodes of acute otitis media in 6 months or four or more in a year, with at least one episode or more [12]

attacks in the preceding 6 months. In chronic cases with effusions, insertion of tympanostomy tube into the eardrum reduces recurrence rates in the 6 months after placement[41] but has little effect on long-term hearing.[42] A common complication of having a tympanostomy tube is otorrhea, which is a discharge from the ear.[43]

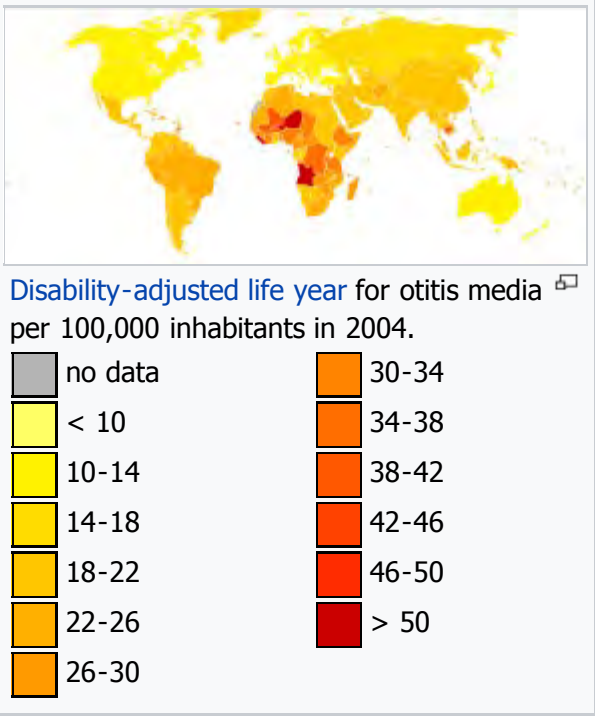
Oral antibiotics should not be used to treat uncomplicated acute tympanostomy tube otorrhea.[43] Oral antibiotics are not a sufficient response to bacteria that cause this condition and have significant side effects including increased risk of opportunistic infection.[43] In contrast, topical antibiotic eardrops can treat this condition.[43]

### Alternative medicine [edit]

Complementary and alternative medicine is not recommended for otitis media with effusion because there is no evidence of benefit.[21] An osteopathic manipulation technique called the Galbreath technique[44] was evaluated in one randomized controlled clinical trial; one reviewer concluded that it was promising, but a 2010 evidence report found the evidence inconclusive.[45]

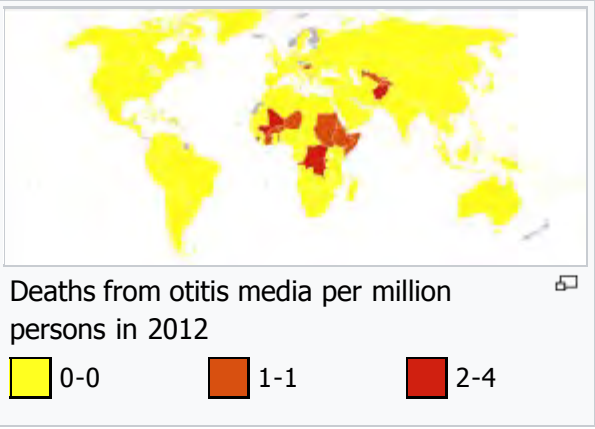
## Outcomes [edit]

Complications of acute otitis media consists of perforation of the ear drum, infection of the mastoid space behind the ear (mastoiditis), and more rarely intracranial complications can occur, such as bacterial meningitis, brain abscess, or dural sinus thrombosis.[46] It is estimated that each year 21,000 people die due to complications of otitis media.[47]



### Membrane rupture [edit]

In severe or untreated cases, the tympanic membrane may perforate, allowing the pus in the middle-ear space to drain into the ear canal. If there is enough, this drainage may be obvious. Even though the perforation of the tympanic membrane suggests a highly painful and traumatic process, it is almost always associated with a dramatic relief of pressure and pain. In a simple case of acute otitis media in an otherwise healthy person, the body's defenses are likely to resolve the infection and the ear drum nearly always heals. An option for severe acute otitis media in which analgesics are not controlling ear pain is to perform a tympanocentesis, i.e., needle aspiration through the tympanic membrane to relieve the ear pain and to identify the causative organism(s).



### Hearing loss [edit]

Children with recurrent episodes of acute otitis media and those with otitis media with effusion or chronic suppurative otitis media have higher risks of developing conductive and sensorineural hearing loss. Globally approximately 141 million people have mild hearing loss due to otitis media (2.1% of the population).[48] This is more common in males (2.3%) than females (1.8%).[48]

This hearing loss is mainly due to fluid in the middle ear or rupture of the tympanic membrane. Prolonged duration of otitis media is associated with ossicular complications and,

together with persistent tympanic membrane perforation, contributes to the severity of the disease and hearing loss. When a cholesteatoma or granulation tissue is present in the middle ear, the degree of hearing loss and ossicular destruction is even greater.[49]

Periods of conductive hearing loss from otitis media may have a detrimental effect on speech development in children.[50] Some studies have linked otitis media to learning problems, attention disorders, and problems with social adaptation.[51] Furthermore, it has been demonstrated that patients with otitis media have more depression/anxiety-related disorders compared to individuals with normal hearing.[52] Once the infections resolve and hearing thresholds return to normal, childhood otitis media may still cause minor and irreversible damage to the middle ear and cochlea.[53]

## Epidemiology [edit]

Acute otitis media is very common in childhood. It is the most common condition for which medical care is provided in children under five years of age in the US.[14] Acute otitis media affects 11% of people each year (709 million cases) with half occurring in those below five years.[47] Chronic suppurative otitis media affects about 5% or 31 million of these cases with 22.6% of cases occurring annually under the age of five years.[47] Otitis media resulted in 2,400 deaths in 2013 — down from 4,900 deaths in 1990.[11]

## Etymology [edit]

Otitis media is Latin for "inflammation of the middle ear".

# Pharyngitis

From Wikipedia, the free encyclopedia

*Not to be confused with laryngitis.*

**Pharyngitis** is inflammation of the back of the throat, known as the pharynx.[1] It typically results in a sore throat and fever.[1] Other symptoms may include a runny nose, cough, headache, a hoarse voice.[2] Symptoms usually last three to five days. Complications can include sinusitis and acute otitis media.[1] Pharyngitis is typically a type of respiratory tract infection.[3]

Most cases are caused by a viral infection. Strep throat is the cause in about 25% of children and 10% of adults.[1] Uncommon causes include other bacteria such as gonorrhea, fungus, irritants such as smoke, allergies, and gastroesophageal reflux disease.[1][4] Specific testing is not recommended in people who have clear symptoms of a viral infection such as a cold. Otherwise a rapid antigen detection test or throat swab is recommended. Other conditions that can produce similar symptoms include epiglottitis, thyroiditis, retropharyngeal abscess, and occasionally heart disease.[1]

NSAIDs, such as ibuprofen, can be used to help with the pain.[1] Topical lidocaine may also help.[4] Strep throat is typically treated with antibiotics, such as either penicillin or amoxicillin.[1] It is unclear if steroids are useful in acute pharyngitis, other than possibly in severe cases.[5][6]

About 7.5% of people have a sore throat in any three-month period.[7] This resulted in 15 million physician visits in the United States in 2007.[4] Pharyngitis is the most common cause of a sore throat.[8] On the average, adults get a sore throat two to three times a year and children about five times a year.[9][2] The word comes from the Greek word *pharynx* meaning "throat" and the suffix *-itis* meaning "inflammation".[10][11]

## Classification [edit]

Pharyngitis is a type of inflammation, most commonly caused by an upper respiratory tract infection. It may be classified as acute or chronic. Acute pharyngitis may be catarrhal, purulent or ulcerative, depending on the causative agent and the immune capacity of the affected individual. Chronic pharyngitis may be catarrhal, hypertrophic or atrophic.

Tonsillitis is a sub type of pharyngitis.[12] If the inflammation includes both the tonsils and other parts of the throat, it may be called pharyngotonsillitis.[13] Another sub classification is nasopharyngitis (the common cold).[14]

## Cause [edit]

The majority of cases are due to an infectious organism acquired from close contact with an infected individual.

### Viral [edit]

These comprise about 40–80% of all infectious cases and can be a feature of many different types of viral infections.[8][15]

- Adenovirus – the most common of the viral causes. Typically the degree of neck lymph node enlargement is modest and the throat often does not appear red, although it is painful.
- Orthomyxoviridae which cause influenza – present with rapid onset high temperature, headache and generalized ache. A sore throat may be associated.
- Infectious mononucleosis ("glandular fever") caused by the Epstein–Barr virus. This may cause significant lymph gland swelling and an exudative tonsillitis with marked redness and swelling of the throat. The heterophile test can be used if this is suspected.
- Herpes simplex virus can cause multiple mouth ulcers.
- Measles
- Common cold: rhinovirus, coronavirus, respiratory syncytial virus, parainfluenza virus can cause infection of the throat, ear, and lungs causing standard cold-like symptoms and often pain.

### Bacterial [edit]

A number of different bacteria can infect the human throat. The most common is Group A streptococcus, but others include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Bordetella pertussis*, *Bacillus anthracis*, *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, *Chlamydophila pneumoniae*, and *Mycoplasma pneumoniae*.[16]

#### Streptococcal pharyngitis

Streptococcal pharyngitis or strep throat is caused by group A beta-hemolytic streptococcus (GAS).[17] It is the most common bacterial cause of cases of pharyngitis (15–30%).[16] Common symptoms include fever, sore throat, and large lymph nodes. It is a contagious infection, spread by close contact with an infected individual. A definitive diagnosis is made based on the results of a throat culture. Antibiotics are useful to

A case of strep throat

both prevent complications and speed recovery.[18]

#### Fusobacterium necrophorum

*Fusobacterium necrophorum* is a normal inhabitant of the oropharyngeal flora and can occasionally create a peritonsillar abscess. In 1 out of 400 untreated cases, Lemierre's syndrome occurs.[19]

#### Diphtheria

Diphtheria is a potentially life-threatening upper respiratory infection caused by *Corynebacterium diphtheriae* which has been largely eradicated in developed nations since the introduction of childhood vaccination programs, but is still reported in the Third World and increasingly in some areas in Eastern Europe. Antibiotics are effective in the early stages, but recovery is generally slow.[*citation needed*]

#### Others

A few other causes are rare, but possibly fatal, and include parapharyngeal space infections: peritonsillar abscess ("quinsy"), submandibular space infection (Ludwig's angina), and epiglottitis.[20][21][22]

### Fungal [edit]

Some cases of pharyngitis are caused by fungal infection such as Candida albicans causing oral thrush.[*citation needed*]

### Non-infectious [edit]

Pharyngitis may also be caused by mechanical, chemical or thermal irritation, for example cold air or acid reflux. Some medications may produce pharyngitis such as pramipexole and antipsychotics.[23][24]

## Diagnostic approach [edit]

It is hard to differentiate a viral and a bacterial cause of a sore throat based on symptoms alone.[25] Thus often a throat swab is done to rule out a bacterial cause.[26]

**Modified Centor score**

| Points | Probability of Strep | Management |
|---|---|---|
| 1 or less | <10% | No antibiotic or culture needed |
| 2 | 11–17% | Antibiotic based on culture or RADT |
| 3 | 28–35% | |
| 4 or 5 | 52% | Empiric antibiotics |

The modified Centor criteria may be used to determine the management of people with pharyngitis. Based on 5 clinical criteria, it indicates the probability of a streptococcal infection.[18]

One point is given for each of the criteria:[18]

- Absence of a cough
- Swollen and tender cervical lymph nodes
- Temperature >38.0 °C (100.4 °F)
- Tonsillar exudate or swelling

Throat swab.

- Age less than 15 (a point is subtracted if age >44)

The McIsaac criteria adds to the Centor:[27]

- Age less than 15: add one point
- Age greater than 45: subtract one point

The Infectious Disease Society of America however recommends against empirical treatment and considers antibiotics only appropriate following positive testing.[25] Testing is not needed in children under three as both group A strep and rheumatic fever are rare, except if they have a sibling with the disease.[25]

# Management [edit]

The majority of time treatment is symptomatic. Specific treatments are effective for bacterial, fungal, and herpes simplex infections.

## Medications [edit]

- Pain medication such as NSAIDs and acetaminophen (paracetamol) can help reduce the pain associated with a sore throat. Aspirin may be used in adults but is not recommended in children due to the risk of Reye syndrome.[28]
- Steroids (such as dexamethasone) may be useful for severe pharyngitis.[29][6] Their general use however is poorly supported.[30]
- Viscous lidocaine relieves pain by numbing the mucus membranes.[31]
- Antibiotics are useful if a bacterial infection is the cause of the sore throat.[32][33] For viral infections, antibiotics have no effect. In the United States they are used in 25% of people before a bacterial infection has been detected.[34]
- Oral analgesic solutions, the active ingredient usually being phenol, but also less commonly benzocaine, cetylpyridinium chloride and/or menthol. Chloraseptic and Cēpacol are two examples of brands of these kinds of analgesics.

## Alternative [edit]

*See also: Alternative treatments used for the common cold*

Gargling salt water is often suggested but evidence looking at its usefulness is lacking.[4] Alternative medicines are promoted and used for the treatment of sore throats.[35] However, they are poorly supported by evidence.[35]

# Epidemiology [edit]

Acute pharyngitis is the most common cause of a sore throat and, together with cough, it is diagnosed in more than 1.9 million people a year in the United States.[8]

# Streptococcal pharyngitis

From Wikipedia, the free encyclopedia

(Redirected from Strep throat)

**Streptococcal pharyngitis**, also known as **strep throat**, is an infection of the back of the throat including the tonsils caused by *group A streptococcus*.[1] Common symptoms include fever, sore throat, red tonsils, and enlarged lymph nodes in the neck. A headache, and nausea or vomiting may also occur.[1] Some develop a sandpaper-like rash which is known as scarlet fever.[2] Symptoms typically begin one to three days after exposure and last seven to ten days.[2][3]

Strep throat is spread by respiratory droplets from an infected person. It may be spread directly or by touching something that has droplets on it and then touching the mouth, nose, or eyes. Some people may carry the bacteria without symptoms. It may also be spread by skin infected with group A strep.[1] The diagnosis is made based on the results of a rapid antigen detection test or throat culture in those who have symptoms.[4]

Prevention is by washing hands and not sharing eating utensils. There is no vaccine for the disease.[1] Treatment with antibiotics is only recommended in those with a confirmed diagnosis.[4] Those infected should stay away from other people for at least 24 hours after starting treatment.[1] Pain can be treated with paracetamol (acetaminophen) and non-steroidal antiinflammatory drugs (NSAIDS) such as ibuprofen.[5]

Strep throat is a common bacterial infection in children.[2] It is the cause of 15–40% of sore throats among children[6][7] and 5–15% among adults.[8] Cases are more common in late winter and early spring.[7] Potential complications include rheumatic fever and peritonsillar abscess.[1][2]

## Signs and symptoms

The typical symptoms of streptococcal pharyngitis are a sore throat, fever of greater than 38 °C (100 °F), tonsillar exudates (pus on the tonsils), and large cervical lymph nodes.[7]

Other symptoms include: headache, nausea and vomiting, abdominal pain,[9] muscle pain,[10] or a scarlatiniform rash or palatal petechiae, the latter being an uncommon but highly specific finding.[7]

Symptoms typically begin one to three days after exposure and last seven to ten days.[3][7]

Strep throat is unlikely when any of the symptoms of red eyes, hoarseness, runny nose, or mouth ulcers are present. It is also unlikely when there is no fever.[8]

Note the petechiae, or small red spots, on the soft palate. This is an uncommon but highly specific finding in streptococcal pharyngitis.[7]

## Cause

Strep throat is caused by group A beta-hemolytic streptococcus (GAS or S. pyogenes).[11] Other bacteria such as non–group A beta-hemolytic streptococci and fusobacterium may also cause pharyngitis.[7][10] It is spread by direct, close contact with an infected person; thus crowding, as may be found in the military and schools, increases the rate of transmission.[10][12] Dried bacteria in dust are not infectious, although moist bacteria on toothbrushes or similar items can persist for up to fifteen days.[10] Contaminated food can result in outbreaks, but this is rare.[10] Of children with no signs or symptoms, 12% carry GAS in their pharynx,[6] and, after treatment, approximately 15% of those remain positive, and are true "carriers".[13]

## Diagnosis

A number of scoring systems

exist to help with diagnosis; however, their use is controversial due to insufficient accuracy.[14] The modified Centor criteria are a set of five criteria; the total score indicates the probability of a streptococcal infection.[7]

**Modified Centor score**

| Points | Probability of Strep | Management |
|---|---|---|
| 1 or fewer | <10% | No antibiotic or culture needed |
| 2 | 11–17% | Antibiotic based on culture or RADT |
| 3 | 28–35% | |
| 4 or 5 | 52% | Empiric antibiotics |

One point is given for each of the criteria:[7]

- Absence of a cough
- Swollen and tender cervical lymph nodes
- Temperature >38.0 °C (100.4 °F)
- Tonsillar exudate or swelling
- Age less than 15 (a point is subtracted if age >44)

A score of one may indicated no treatment or culture is needed, or it may indicate the need to perform further testing if other high risk factors exist, such as a family member having the disease.[7]

The Infectious Disease Society of America recommends against empirical treatment and considers antibiotics only appropriate when given after a positive test.[8] Testing is not needed in children under three as both group A strep and rheumatic fever are rare, unless a child has a sibling with the disease.[8]

## Laboratory testing

A throat culture is the gold standard[15] for the diagnosis of streptococcal pharyngitis, with a sensitivity of 90–95%.[7] A rapid strep test (also called rapid antigen detection testing or RADT) may also be used. While the rapid strep test is quicker, it has a lower sensitivity (70%) and statistically equal specificity (98%) as a throat culture.[7] In areas of the world where rheumatic fever is uncommon, a negative rapid strep test is sufficient to rule out the disease.[16]

A positive throat culture or RADT in association with symptoms establishes a positive diagnosis in those in which the diagnosis is in doubt.[17] In adults, a negative RADT is sufficient to rule out the diagnosis. However, in children a throat culture is recommended to confirm the result.[8] Asymptomatic individuals should not be routinely tested with a throat culture or RADT because a certain percentage of the population persistently "carries" the streptococcal bacteria in their throat without any harmful results.[17]

## Differential diagnosis

*See also: Acute pharyngitis*

As the symptoms of streptococcal pharyngitis overlap with other conditions, it can be difficult to make the diagnosis clinically.[7] Coughing, nasal discharge, diarrhea, and red, irritated eyes in addition to fever and sore throat are more indicative of a viral sore throat than of strep throat.[7] The presence of marked lymph node enlargement along with sore throat, fever, and tonsillar enlargement may also occur in infectious mononucleosis.[18]

# Prevention

Tonsillectomy may be a reasonable preventive measure in those with frequent throat infections (more than three a year).[19] However, the benefits are small and episodes typically lessen in time regardless of measures taken.[20][21][*needs update*] Recurrent episodes of pharyngitis which test positive for GAS may also represent a person who is a chronic carrier of GAS who is getting recurrent viral infections.[8] Treating [8]

people who have been exposed but who are without symptoms is not recommended. Treating people who are carriers of GAS is not recommended as the risk of spread and complications is low.[8]

# Treatment

Untreated streptococcal pharyngitis usually resolves within a few days.[7] Treatment with antibiotics shortens the duration of the acute illness by about 16 hours.[7] The primary reason for treatment with antibiotics is to reduce the risk of complications such as rheumatic fever and retropharyngeal abscesses;[7] antibiotics are effective if given within 9 days of the onset of symptoms.[11]

## Pain medication

Pain medication such as non-steroidal anti-inflammatory drugs (NSAIDs) and paracetamol (acetaminophen) help in the management of pain associated with strep throat.[22] Viscous lidocaine may also be useful.[23] While steroids may help with the pain,[11][24] they are not routinely recommended.[8] Aspirin may be used in adults but is not recommended in children due to the risk of Reye's syndrome.[11]

## Antibiotics

The antibiotic of choice in the United States for streptococcal pharyngitis is penicillin V, due to safety, cost, and effectiveness.[7] Amoxicillin is preferred in Europe.[25] In India, where the risk of rheumatic fever is higher, intramuscular benzathine penicillin G is the first choice for treatment.[11]

Appropriate antibiotics decrease the average 3–5 day duration of symptoms by about one day, and also reduce contagiousness.[17] They are primarily prescribed to reduce rare complications such as rheumatic fever and peritonsillar abscess.[26] The arguments in favor of antibiotic treatment should be balanced by the consideration of possible side effects,[10] and it is reasonable to suggest that no antimicrobial treatment be given to healthy adults who have adverse reactions to medication or those at low risk of complications.[26][27] Antibiotics are prescribed for strep throat at a higher rate than would be expected from how common it is.[28]

Erythromycin and other macrolides or clindamycin are recommended for people with severe penicillin allergies.[7][8] First-generation cephalosporins may be used in those with less severe allergies[7] and some evidence supports cephalosporins as superior to penicillin.[29][30] Streptococcal infections may also lead to acute glomerulonephritis; however, the incidence of this side effect is not reduced by the use of antibiotics.[11]

# Prognosis

The symptoms of strep throat usually improve within three to five days, irrespective of treatment.[17] Treatment with antibiotics reduces the risk of complications and transmission; children may return to school 24 hours after antibiotics are administered.[7] The risk of complications in adults is low.[8] In children, acute rheumatic fever is rare in most of the developed world. It is, however, the leading cause of acquired heart disease in India, sub-Saharan Africa and some parts of Australia.[8]

Complications arising from streptococcal throat infections include:

- Acute rheumatic fever[9]
- Scarlet fever[31]
- Streptococcal toxic shock syndrome[31][32]
- Glomerulonephritis[33]
- PANDAS syndrome[33]
- Peritonsillar abscess[8]
- Cervical lymphadenitis[8]
- Mastoiditis[8]

The economic cost of the disease in the United States in children is approximately $350 million annually.[8]

# Epidemiology

Pharyngitis, the broader category into which Streptococcal pharyngitis falls, is diagnosed in 11 million people annually in the United States.[7] It is the cause of 15–40% of sore throats among children[6][7] and 5–15% in adults.[8] Cases usually occur in late winter and early spring.[7]

From Wikipedia, the free encyclopedia

**Tinnitus** is the hearing of [illegible] sound when no external sound is present.[1] While often described as a ringing, it may also sound like a clicking, hiss or roaring.[2] Rarely, unclear voices or music are heard.[3] The sound may be soft or loud, low pitched or high pitched and appear to be coming from one ear or both.[2] Most of the time, it comes on gradually.[3] In some people, the sound causes depression, anxiety or interferes with concentration.[2]

Tinnitus is not a disease but a symptom that can result from a number of underlying causes. One of the most common causes is noise-induced hearing loss. Other causes include: ear infections, disease of the heart or blood vessels, Ménière's disease, brain tumors, emotional stress, exposure to certain medications, a previous head injury, and earwax.[2][4] It is more common in those with depression.[3]

The diagnosis of tinnitus is usually based on the person's description. A number of questionnaires exist that assess how much tinnitus is interfering with a person's life.[3] The diagnosis is commonly assisted with an audiogram and neurological exam.[1][3] If certain problems are found, medical imaging, such as with MRI, may be performed. Other tests are suitable when tinnitus occurs with the same rhythm as the heartbeat. Occasionally, the sound may be heard by someone else using a stethoscope, in which case it is known as objective tinnitus.[3]

Prevention involves avoiding loud noise.[2] If there is an underlying cause, treating it may lead to improvements.[3] Otherwise, typically, management involves talk therapy.[5] Sound generators or hearing aids may help some.[2] As of 2013, there are no effective medications.[3] It is common, affecting about 10-15% of people. Most, however, tolerate it well with its being a significant problem in only 1–2% of people.[5] The word tinnitus is from the Latin *tinnīre* which means "to ring".[3]

# Signs and symptoms

Tinnitus can be perceived in one or both ears or in the head. Tinnitus is the description of a noise inside a person's head in the absence of auditory stimulation. The noise can be described in many different ways but the most common description of the tinnitus is a pure tone sound. It is usually described as a ringing noise but, in some patients, it takes the form of a high-pitched whining, electric buzzing, hissing, humming, tinging or whistling sound or as ticking, clicking, roaring, "crickets" or "tree frogs" or "locusts (cicadas)", tunes, songs, beeping, sizzling, sounds that slightly resemble human voices or even a pure steady tone like that heard during a hearing test and, in some cases, pressure changes from the interior ear.[6] It has also been described as a "whooshing" sound because of acute muscle spasms, as of wind or waves.[7] Tinnitus can be intermittent or it can be continuous: in the latter case, it can be the cause of great distress. In some individuals, the intensity can be changed by shoulder, head, tongue, jaw or eye movements.[8]

Most people with tinnitus have some degree of hearing loss:[9] they are often unable to clearly hear external sounds that occur within the same range of frequencies as their "phantom sounds".[10] This has led to the suggestion that one cause of tinnitus might be a homeostatic response of central dorsal cochlear nucleus auditory neurons that makes them hyperactive in compensation to auditory input loss.[11]

The sound perceived may range from a quiet background noise to one that can be heard even over loud external sounds. The specific type of tinnitus called pulsatile tinnitus is characterized by hearing the sounds of one's own pulse or muscle contractions, which is typically a result of sounds that have been created from the movement of muscles near to one's ear, changes within the canal of one's ear or issues related to blood flow of the neck or face.[12]

## Course

There has been little research on the course of tinnitus and most research has been retrospective. An Australian study of participants aged 49–97 years found that 35% of participants reported that their tinnitus was present all the time and 4% rated their tinnitus as annoying. Findings from a retrospective National Study of Hearing found that, for 25% of people surveyed, the perceived volume of their tinnitus increased over time while, for 75%, it did not. The rate of annoyance decreased for 31% of people from onset of tinnitus to the middle time. A study of the natural history of tinnitus in older adults found that, for women, tinnitus increased for 25%, decreased in 58%, leaving 17% unchanged. The study found that, for men, tinnitus increased in 8%, decreased in 39%, leaving 53% unchanged. Information about the course of tinnitus would benefit from prospective studies investigating change over time as these studies may potentially be more accurate.[13]

## Psychological

Persistent tinnitus may cause irritability, fatigue and, on occasions, clinical depression[14][15] and musical hallucinations.[16]

Tinnitus annoyance is more strongly associated with psychological condition than loudness or frequency range.[17][18][19] Other psychological problems such as depression, anxiety, sleep disturbances and concentration difficulties are common in those with worse tinnitus.[17][20][21] 45% of people with tinnitus have an anxiety disorder at some time in their life.[22]

As part of the idea that the central-auditory-system may be implicated into the tinnitus development, serotonin has also been implicated. Indeed, serotonin has been postulated to be involved in plastic changes in the brain. Serotonin re-uptake inhibitors (such as some anti-depressant drugs) have often been used for this reason.[23] However those medications do not benefit in a consistent fashion on non-depressant people.[24]

Psychological research has looked at the tinnitus distress reaction (TDR) to account for differences in tinnitus severity.[20] Research has stigmatized people with severe tinnitus by implying they have personality disorders, such as neuroticism, anxiety sensitivity, and catastrophic thinking, which all predispose increased TDR.[25][26][27] These findings suggest that at the initial perception of tinnitus, conditioning links tinnitus with negative emotions, such as fear and anxiety from unpleasant stimuli at the time. This enhances activity in the limbic system and autonomic nervous system, thus increasing tinnitus awareness and annoyance.[28]

# Causes

There are two types of tinnitus: subjective tinnitus and objective tinnitus.[3] Tinnitus is usually subjective, meaning that others cannot hear it.[3] Subjective tinnitus has been also called "tinnitus aurium" "nonauditory" and "nonvibratory" tinnitus. Occasionally, tinnitus may be heard by someone else using a stethoscope: in which case, it is objective tinnitus.[3] Objective tinnitus has been called "pseudo-tinnitus" or "vibratory" tinnitus.

## Subjective tinnitus

Subjective tinnitus is the most frequent type of tinnitus. It can have many possible causes but, most commonly, results from hearing loss. A frequent cause of subjective tinnitus is noise exposure which damages hair cells in the inner ear causing tinnitus. Subjective tinnitus can only be heard by the affected person and is caused by otology, neurology, infection or drugs.[29]

There is a growing body of evidence suggesting that tinnitus is a consequence of neuroplastic alterations in the central auditory pathway. These alterations are assumed to result from a disturbed sensory input, caused by hearing loss.[30] Hearing loss could indeed cause a homeostatic response of neurons in the central auditory system, and therefore cause tinnitus.[31]

Despite the opinion amongst researchers that tinnitus is primarily a central nervous system pathology, there certainly exists a class of people whose tinnitus is peripherally based.[32]

## Hearing loss

The most common cause of tinnitus is noise-induced hearing loss. Hearing loss may be implicated even for people with normal audiograms.[31]

Hearing loss may have many different causes; but among tinnitus subjects, the major cause is cochlear damage.[30]

Ototoxic drugs (such as aspirin) can also cause subjective tinnitus, as they may cause hearing loss, or increase the damage done by exposure to loud noise. Those damages can occur even at doses that are not [33]

considered ototoxic. Tinnitus is also a classical side effect of quinidine, a Class IA anti-arrhythmic. Over 260 medications have been reported to cause tinnitus as a side effect.[34] In many cases, however, no underlying cause can be identified.[2]

Tinnitus can also occur due to the discontinuation of therapeutic doses of benzodiazepines. It can sometimes be a protracted symptom of benzodiazepine withdrawal and may persist for many months.[35][36]

## Associated factors

This section contains embedded lists that **may be poorly defined, unverified or indiscriminate**. Please help to clean it up to meet Wikipedia's quality standards. Where appropriate, incorporate items into the main body of the article. *(November 2015)*

Factors associated with tinnitus include:[37]

- ear problems and hearing loss:
  - conductive hearing loss
    - external ear infection
    - acoustic shock
    - loud noise or music[38]
    - cerumen (earwax) impaction
    - middle ear effusion
    - superior canal dehiscence
  - sensorineural hearing loss
    - excessive or loud noise
    - presbycusis (age-associated hearing loss)
    - Ménière's disease
    - endolymphatic hydrops
    - acoustic neuroma
    - mercury or lead poisoning
    - ototoxic medications
- neurologic disorders:
  - Arnold–Chiari malformation
  - multiple sclerosis
  - head injury
    - skull fracture
    - closed head injury
    - whiplash injury
    - temporomandibular joint dysfunction
    - giant cell arteritis
- metabolic disorders:
  - thyroid disease
  - hyperlipidemia
  - vitamin $B_{12}$ deficiency[39]
  - iron deficiency anemia
- psychiatric disorders
  - depression
  - anxiety disorders
- other factors:
  - tension myositis syndrome
  - fibromyalgia

- vasculitis
- hypertonia (muscle tension)
- thoracic outlet syndrome
- Lyme disease
- hypnagogia
- migraine
- sleep paralysis
- glomus tympanicum tumor
- anthrax vaccines which contain the anthrax protective antigen
- Some psychedelic drugs can produce temporary tinnitus-like symptoms as a side effect
  - 5-MeO-DET[40]
  - diisopropyltryptamine (DiPT)[41]
- benzodiazepine withdrawal[35][36]
- nasal congestion
- intracranial hyper or hypotension caused by, for example, encephalitis or a cerebrospinal fluid leak

### Objective tinnitus

Objective tinnitus can be detected by other people and is usually caused by myoclonus or a vascular condition. In some cases, tinnitus is generated by a self-sustained oscillation within the ear. This is called objective tinnitus which can arise from muscle spasms around the middle ear.[42] Homeostatic control mechanisms exist to correct the problem within a minute after onset and is normally accompanied by a slight reduction in hearing sensitivity followed by a feeling of fullness in the ear.[43]

Objective tinnitus can most often can be heard as a sound outside the ear, as spontaneous otoacoustic emissions (SOAEs) that can form beats with and lock into external tones.[44] The majority of the people are unaware of their SOAEs; whereas portions of 1-9% perceive a SOAE as an annoying tinnitus.[45]

### Pulsatile tinnitus

Pulsatile tinnitus can be a symptom of intracranial vascular abnormalities and should be evaluated for bruits. Some people experience a sound that beats in time with their pulse (pulsatile tinnitus, or vascular tinnitus).[46] Pulsatile tinnitus is usually objective in nature, resulting from altered blood flow, increased blood turbulence near the ear (such as from atherosclerosis, venous hum,[47] but it can also arise as a subjective phenomenon from an increased awareness of blood flow in the ear.[46] Rarely, pulsatile tinnitus may be a symptom of potentially life-threatening conditions such as carotid artery aneurysm[48] or carotid artery dissection.[49] Pulsatile tinnitus may also indicate vasculitis, or more specifically, giant cell arteritis. Pulsatile tinnitus may also be an indication of idiopathic intracranial hypertension.[50]

## Pathophysiology

One of the possible mechanisms relies on otoacoustic emissions. The inner ear contains tens of thousands of minute inner hair cells with stereocilia which vibrate in response to sound waves and outer hair cells which convert neural signals into tension on the vibrating basement membrane. The sensing cells are connected with the vibratory cells through a neural feedback loop, whose gain is regulated by the brain. This loop is normally adjusted just below onset of self-oscillation, which gives the ear spectacular sensitivity and selectivity. If something changes, it is easy for the delicate adjustment to cross the barrier of oscillation and, then, tinnitus results. Exposure to excessive sound kills hair cells and studies have shown that, as hair cells are lost, different neurons are activated, activating auditory parts of the brain and giving the perception of sound.[*citation needed*]

Another possible mechanism underlying tinnitus is damage to the receptor cells. Although receptor cells can be regenerated from the adjacent supporting Deiters cells after injury in birds, reptiles and amphibians, it is believed that, in mammals, they can be produced only during embryogenesis. Although mammalian Deiters

cells reproduce and position themselves appropriately for regeneration, they have not been observed to transdifferentiate into receptor cells except in tissue culture experiments.[51][52] Therefore, if these hairs become damaged, through prolonged exposure to excessive sound levels, for instance, then deafness to certain frequencies results. In tinnitus, they may relay information that an externally audible sound is present at a certain frequency when it is not.

The mechanisms of subjective tinnitus are often obscure. While it is not surprising that direct trauma to the inner ear can cause tinnitus, other apparent causes (e.g., temporomandibular joint dysfunction and dental disorders) are difficult to explain. Research has proposed there are two distinct categories of subjective tinnitus: otic tinnitus, caused by disorders of the inner ear or the acoustic nerve, and somatic tinnitus, caused by disorders outside the ear and nerve, but still within the head or neck. It is further hypothesized somatic tinnitus may be due to "central crosstalk" within the brain, as certain head and neck nerves enter the brain near regions known to be involved in hearing.[53]

It may be caused by increased neural activity in the auditory brainstem where the brain processes sounds, causing some auditory nerve cells to become over-excited. The basis of this theory is most people with tinnitus also have hearing loss,[9] and the frequencies they cannot hear are similar to the subjective frequencies of their tinnitus.[10] Models of hearing loss and the brain support the idea a homeostatic response of central dorsal cochlear nucleus neurons could result in them being hyperactive in a compensation process to the loss of hearing input.[11]

# Diagnosis

Even when tinnitus is the primary complaint, audiological evaluation is usually preceded by examination by an ENT to diagnose treatable conditions like middle ear infection, acoustic neuroma, concussion, otosclerosis, etc.[54]

Evaluation of tinnitus will include a hearing test (audiogram), measurement of acoustic parameters of the tinnitus like pitch and loudness, and psychological assessment of comorbid conditions like depression, anxiety, and stress that are associated with severity of the tinnitus.

The accepted definition of chronic tinnitus, as compared to normal ear noise experience, is five minutes of ear noise occurring at least twice a week.[55] However, people with chronic tinnitus often experience the noise more frequently than this and can experience it continuously or regularly, such as during the night when there is less environmental noise to mask the sound.

## Audiology

Since most persons with tinnitus also have hearing loss, a pure tone hearing test resulting in an audiogram may help diagnose a cause, though some persons with tinnitus do not have hearing loss. An audiogram may also facilitate fitting of a hearing aid in those cases where hearing loss is significant. The pitch of tinnitus is often in the range of the hearing loss. A hearing aid boosting the attentuated frequencies may at least partly mask tinnitus by raising the background level of sound in the tuned frequency range.

## Psychoacoustics

Acoustic qualification of tinnitus will include measurement of several acoustic parameters like pitch, or frequency in cases of monotone tinnitus, or frequency range and bandwidth in cases of narrow band noise tinnitus, loudness in dB above hearing threshold at the indicated frequency, mixing-point, and minimum masking level.[56] In most cases, tinnitus pitch or frequency range is between 5000 Hz and 8000 Hz, and loudness less than 10 dB above the hearing threshold.[*medical citation needed*]

Another relevant parameter of tinnitus is residual inhibition, the temporary suppression and/or disappearance of tinnitus following a period of masking. The degree of residual inhibition may indicate how effective tinnitus maskers would be as a treatment modality.[57]

An assessment of hyperacusis, a frequent accompaniment of tinnitus, may also be made. The measured

parameter is Loudness Discomfort Level in dB, the subjective level of acute discomfort at specified frequencies over the frequency range of hearing. This defines a dynamic range between the hearing threshold at that frequency and the loudnes discomfort level. A compressed dynamic range over a particular frequency range is associated with subjectve hyperacusis.[58] Normal hearing threshold is generally defined as 0–20 decibels (dB). Normal loudness discomfort levels are 85–90+ dB, with some authorities citing 100 dB. A dynamic range of 55 dB or less is indicative of hyperacusis.

### Severity

The condition is often rated on a scale from "slight" to "catastrophic" according to the effects it has, such as interference with sleep, quiet activities and normal daily activities.[59] In an extreme case a man committed suicide after being told there was no cure.[60]

Assessment of psychological processes related to tinnitus involves measurement of tinnitus severity and distress (i.e. nature and extent of tinnitus-related problems), measured subjectively by validated self-report tinnitus questionnaires.[20] These questionnaires measure the degree of psychological distress and handicap associated with tinnitus, including effects on hearing, lifestyle, health and emotional functioning.[61][62][63][64] A broader assessment of general functioning, such as levels of anxiety, depression, stress, life stressors and sleep difficulties, is also important in the assessment of tinnitus due to higher risk of negative well-being across these areas, which may be affected by and/or exacerbate the tinnitus symptoms for the individual.[65] Overall, current assessment measures are aimed to identify individual levels of distress and interference, coping responses and perceptions of tinnitus in order to inform treatment and monitor progress. However, wide variability, inconsistencies and lack of consensus regarding assessment methodology are evidenced in the literature, limiting comparison of treatment effectiveness.[66] Developed to guide diagnosis or classify severity, most tinnitus questionnaires have also been shown to be treatment-sensitive outcome measures.[67]

### Pulsatile tinnitus

If the examination reveals a bruit (sound due to turbulent blood flow), imaging studies such as transcranial doppler (TCD) or magnetic resonance angiography (MRA) should be performed.[68]

### Auditory evoked response

Tinnitus can be evaluated with most auditory evoked potentials: however, results may be inconsistent. Results must be compared to age and hearing matched control subjects to be reliable. This inconsistent reporting may be due to many reasons: differences in the origin of the tinnitus, ABR recording methods and selection criteria of control groups. Since research shows conflicting evidence, more research on the relationship between tinnitus and auditory evoked potentials should be carried out before these measurements are used clinically.

### Differential diagnosis

Other potential sources of the sounds normally associated with tinnitus should be ruled out. For instance, two recognized sources of high-pitched sounds might be electromagnetic fields common in modern wiring and various sound signal transmissions. A common and often misdiagnosed condition that mimics tinnitus is radio frequency (RF) hearing, in which subjects have been tested and found to hear high-pitched transmission frequencies that sound similar to tinnitus.[69]

## Prevention

Prolonged exposure to loud sound or noise levels can lead to tinnitus.[70] Ear plugs or other measures can help with prevention.

Several medicines have ototoxic effects, and can have a cumulative effect that can increase the damage

done by noise. If ototoxic medications must be administered, close attention by the physician to prescription details, such as dose and dosage interval, can reduce the damage done.[71]

# Management

If there is an underlying cause, treating it may lead to improvements.[3] Otherwise, the primary treatment for tinnitus is talk therapy[5] and sound therapy; there are no effective medications.[3]

## Psychological

The best supported treatment for tinnitus is a type of counseling called cognitive behavioral therapy (CBT) which can be delivered via the internet or in person.[5][72] It decreases the amount of stress those with tinnitus feel.[73] These benefits appear to be independent of any effect on depression or anxiety in an individual.[72] Acceptance and commitment therapy (ACT) also shows promise in the treatment of tinnitus.[74] Relaxation techniques may also be useful.[3] A clinical protocol called Progressive Tinnitus Management for treatment of tinnitus has been developed by the United States Department of Veterans Affairs.[75]

## Medications

As of 2014 there were no medications effective for tinnitus.[3][70] There is not enough evidence to determine if antidepressants[76] or acamprosate is useful.[77] While there is tentative evidence for benzodiazepines, it is insufficient to support usage.[3] Anticonvulsants have not been found to be useful.[3] Steroids injections into the middle ear also do not seem to be effective.[78][79]

Botulinum toxin injection has been tried with some success in cases of objective tinnitus from a palatal tremor.[80]

## Other

The use of sound therapy by either hearing aids or tinnitus maskers helps the brain ignore the specific tinnitus frequency. Although these methods are poorly supported by evidence, there are no negative effects.[3][81] There is some tentative evidence supporting tinnitus retraining therapy.[3] There is little evidence supporting the use of transcranial magnetic stimulation.[3][82] It is thus not recommended.[70]

## Alternative medicine

*Ginkgo biloba* does not appear to be effective.[83] The American Academy of Otolaryngology recommends against taking melatonin or zinc supplements to relieve symptoms of tinnitus.[70] In addition, a 2016 Cochrane Review concluded that evidence is not sufficient to support taking zinc supplements to reduce symptoms associated with tinnitus.[84]

# Prognosis

While there is no cure, most people with tinnitus get used to it over time; for a minority, it remains a significant problem.[5]

# Epidemiology

Tinnitus affects 10–15% of people.[5] About a third of North Americans over 55 experience tinnitus.[85] Tinnitus affects one third of adults at some time in their lives, whereas ten to fifteen percent are disturbed

enough to seek medical evaluation.[86]

### Children

Tinnitus is commonly thought of as a symptom of adulthood, and is often overlooked in children. Children with hearing loss have a high incidence of tinnitus, even though they do not express the condition or its effect on their lives.[87] Children do not generally report tinnitus spontaneously and their complaints may not be taken seriously.[88] Among those children who do complain of tinnitus, there is an increased likelihood of associated otological or neurological pathology such as migraine, juvenile Meniere's disease or chronic suppurative otitis media.[89] Its reported prevalence varies from 12% to 36% in children with normal hearing thresholds and up to 66% in children with a hearing loss and approximately 3–10% of children have been reported to be troubled by tinnitus.[90]

*This article is about the medical condition. For other uses, see Vertigo (disambiguation).*
*Not to be confused with agrophobia, an extreme or irrational fear of heights.*

**Vertigo** is when a person feels as if they or the objects around them are moving when they are not.[1] Often it feels like a spinning or swaying movement.[1][2] This may be associated with nausea, vomiting, sweating, or difficulties walking. It is typically worsened when the head is moved. Vertigo is the most common type of dizziness.[2]

The most common diseases that result in vertigo are benign paroxysmal positional vertigo, Ménière's disease, and labyrinthitis.[1][2] Less common causes include stroke, brain tumors, brain injury, multiple sclerosis, and migraines.[2] Physiologic vertigo may occur following being exposed to motion for a prolonged period such as when on a ship or simply following spinning with the eyes closed.[3][4] Other causes may include toxin exposures such as to carbon monoxide, alcohol, or aspirin.[5] Vertigo is a problem in a part of the vestibular system. Other causes of dizziness include presyncope, disequilibrium, and non-specific dizziness.[2]

Benign paroxysmal positional vertigo is more likely in someone who gets repeated episodes of vertigo with movement and are otherwise normal between these episodes.[6] The episodes of vertigo should last less than one minute.[2] The Dix-Hallpike test typically produces a period of rapid eye movements known as nystagmus in this condition.[1] In Ménière's disease there is often ringing in the ears, hearing loss, and the attacks of vertigo last more than twenty minutes. In labyrinthitis the onset of vertigo is sudden and the nystagmus occurs without movement.[6] In this condition vertigo can last for days.[2] More severe causes should also be considered.[6] This is especially true if other problems such as weakness, headache, double vision, or numbness occur.[2]

Dizziness affects approximately 20–40% of people at some point in time, while about 7.5–10% have vertigo.[7] About 5% have vertigo in a given year. It becomes more common with age and affects women two to three times more often than men. Vertigo accounts for about 2–3% of emergency department visits in the developed world.[8]

# Classification [edit]

Vertigo is classified into either peripheral or central depending on the location of the dysfunction of the vestibular pathway,[9] although it can also be caused by psychological factors.[10]

Vertigo can also be classified into objective, subjective, and pseudovertigo. Objective vertigo describes when the person has the sensation that stationary objects in the environment are moving.[11][12] Subjective vertigo refers to when the person feels as if they are moving.[11][12] The third type is known as pseudovertigo, an intensive sensation of rotation inside the person's head. While this classification appears in textbooks, it has little to do with the pathophysiology or treatment of vertigo.[13]

## Peripheral [edit]

Vertigo that is caused by problems with the inner ear or vestibular system, which is composed of the semicircular canals, the vestibule (utricle and saccule), and the vestibular nerve is called "peripheral", "otologic" or "vestibular" vertigo.[11][14] The most common cause is benign paroxysmal positional vertigo (BPPV), which accounts for 32% of all peripheral vertigo.[14] Other causes include Ménière's disease (12%), superior canal dehiscence syndrome, labyrinthitis, and visual vertigo.[14][15] Any cause of inflammation such as common cold, influenza, and bacterial infections may cause transient vertigo if it involves the inner ear, as may chemical insults (e.g., aminoglycosides)[16] or physical trauma (e.g., skull fractures). Motion sickness is sometimes classified as a cause of peripheral vertigo.

People with peripheral vertigo typically present with mild to moderate imbalance, nausea, vomiting, hearing loss, tinnitus, fullness, and pain in the ear.[14] In addition, lesions of the internal auditory canal may be associated with facial weakness on the same side.[14] Due to a rapid compensation process, acute vertigo as a result of a peripheral lesion tends to improve in a short period of time (days to weeks).[14]

## Central [edit]

Vertigo that arises from injury to the balance centers of the central nervous system (CNS), often from a lesion in the brainstem or cerebellum,[6][11][17] is called "central" vertigo and is generally associated with less prominent movement illusion and nausea than vertigo of peripheral origin.[18] Central vertigo may have accompanying neurologic deficits (such as slurred speech and double vision), and pathologic nystagmus (which is pure vertical/torsional).[14][18] Central pathology can cause disequilibrium which is the sensation of being off balance. The balance disorder associated with central lesions causing vertigo is often so severe that many patients are unable to stand or walk.[14]

A number of conditions that involve the central nervous system may lead to vertigo including: lesions caused by infarctions or hemorrhage, tumors present in the cerebellopontine angle such as a vestibular schwannoma or cerebellar tumors,[6][9] epilepsy,[19] cervical spine disorders such as cervical spondylosis,[9] degenerative ataxia disorders,[6] migraine headaches,[6] lateral medullary syndrome, Chiari malformation,[6] multiple sclerosis,[6] parkinsonism, as well as cerebral dysfunction.[14] Central vertigo may not improve or may do so more slowly than vertigo caused by disturbance to peripheral structures.[14]

## Signs and symptoms [edit]

Vertigo is a sensation of spinning while stationary.[20] It is commonly associated with nausea or vomiting,[19] unsteadiness (postural instability),[17] falls,[21] changes to a person's thoughts, and difficulties in walking.[22] Recurrent episodes in those with vertigo are common and frequently impair the quality of life.[8] Blurred vision, difficulty in speaking, a lowered level of consciousness, and hearing loss may also occur. The signs and symptoms of vertigo can present as a persistent (insidious) onset or an episodic (sudden) onset.[23]

Persistent onset vertigo is characterized by symptoms lasting for longer than one day[23] and is caused by degenerative changes that affect balance as people age. Naturally, the nerve conduction slows with aging and a decreased vibratory sensation is common.[24] Additionally, there is a degeneration of the ampulla and otolith organs with an increase in age.[25] Persistent onset is commonly paired with central vertigo signs and systems.[23]

The characteristics of an episodic onset vertigo is indicated by symptoms lasting for a smaller, more memorable amount of time, typically lasting for only seconds to minutes.[23] Typically, episodic vertigo is correlated with peripheral symptoms and can be the result of but not limited to diabetic neuropathy or autoimmune disease.

### Motion sickness [edit]

Motion sickness is one of the most prominent symptoms of vertigo and develops most often in persons with inner ear problems. The feeling of dizziness and lightheadedness is often accompanied by nystagmus (an involuntary movement of the eye characterized by a smooth pursuit eye movement followed by a rapid saccade in the opposite direction of the smooth pursuit eye movement). During a single episode of vertigo, this action will occur repeatedly. Symptoms can fade while sitting still with the eyes closed.

## Diagnostic approach [edit]

Tests for vertigo often attempt to elicit nystagmus and to differentiate vertigo from other causes of dizziness such as presyncope, hyperventilation syndrome, disequilibrium, or psychiatric causes of lightheadedness.[1] Tests of vestibular system (balance) function include: electronystagmography (ENG),[1] Dix-Hallpike maneuver,[1] rotation tests, head-thrust test,[6] caloric reflex test,[6][26] and computerized dynamic posturography (CDP).[27] The HINTS test, which is a combination of three physical exam tests that may be performed by physicians at the bedside has been deemed helpful in differentiating between central and peripheral causes of vertigo. The HINTS test involves: the horizontal head impulse test, observation of nystagmus on primary gaze, and the test of skew.[28] CT scans or MRIs are sometimes used by physicians when diagnosing vertigo.[19]

Tests of auditory system (hearing) function include pure tone audiometry, speech audiometry, acoustic reflex, electrocochleography (ECoG), otoacoustic emissions(OAE), and the auditory brainstem response test.[27]

A number of specific conditions can cause vertigo. In the elderly, however, the condition is often multifactorial.[8]

## Peripheral causes [edit]

### Benign paroxysmal positional vertigo [edit]

Benign paroxysmal positional vertigo (BPPV) is the most common vestibular disorder[7] and occurs when loose calcium carbonate debris has broken off of the otoconial membrane and enters a semicircular canal thereby creating the sensation of motion.[1][6] Patients with BPPV may experience brief periods of vertigo, usually under a minute,[6] which occur with change in position.[29] This is the most common etiology of vertigo.[8] It occurs in 0.6% of the population yearly with 10% having an attack during their lifetime.[8] It is believed to be due to a mechanical malfunction of the inner ear.[8] BPPV may be diagnosed with the Dix-Hallpike test and can be effectively treated with repositioning movements such as the Epley maneuver.[8][29][30][31]

### Ménière's disease [edit]

Ménière's disease is a vestibular disorder of unknown origin, but is thought to be caused by an increase in the amount of endolymphatic fluid present in the inner ear (endolymphatic hydrops).[1] However, this idea has not been directly confirmed with histopathologic studies but electrophysiologic studies have been suggestive of this mechanism.[32] Ménière's disease frequently presents with recurrent, spontaneous attacks of severe vertigo in combination with ringing in the ears (tinnitus), a feeling of pressure or fullness in the ear (aural fullness), severe nausea or vomiting, imbalance, and hearing loss.[6][23][32] As the disease worsens, hearing loss will progress.

### Labyrinthitis [edit]

Labyrinthitis presents with severe vertigo[8] with associated nausea, vomiting, and generalized imbalance and is believed to be caused by a viral infection of the inner ear though several theories have been put forward and the etiology remains uncertain.[6][33] Individuals with vestibular neuritis do not typically have auditory symptoms but may experience a sensation of aural fullness or tinnitus.[33] Persisting balance problems may remain in 30% of people affected.[8]

### Vestibular migraine [edit]

Vestibular migraine is the association of vertigo and migraines and is one of the most common causes of recurrent, spontaneous episodes of vertigo.[7][8] The etiology of vestibular migraines is currently unclear;[7] however, one hypothesized cause is that the stimulation of the trigeminal nerve leads to nystagmus in individuals suffering from migraines.[1] Other suggested causes of vestibular migraines include the following: unilateral neuronal instability of the vestibular nerve, idiopathic asymmetric activation of the vestibular nuclei in the brainstem, and vasospasm of the blood vessels supplying the labyrinth or central vestibular pathways resulting in ischemia to these structures.[19] Vestibular migraines are estimated to affect 1-3% of the general population[1][8] and may affect 10% of migraine patients.[1] Additionally, vestibular migraines tend to occur more often in women and rarely affect individuals after the sixth decade of life.[7]

## Central causes [edit]

### Stroke [edit]

A stroke (either ischemic or hemorrhagic) involving the posterior fossa is a cause of central vertigo.[28] Risk factors for a stroke as a cause of vertigo include increasing age and known vascular risk factors. Presentation may more often involve headache or neck pain, additionally, those who have had multiple episodes of dizziness in the months leading up to presentation are suggestive of stroke with prodromal TIAs.[28] The HINTS exam as well as imaging studies of the brain (CT, CT angiogram, and/or MRI) are

helpful in diagnosis of posterior fossa stroke.[28]

## Pathophysiology [edit]

The neurochemistry of vertigo includes six primary neurotransmitters that have been identified between the three-neuron arc[34] that drives the vestibulo-ocular reflex (VOR). Glutamate maintains the resting discharge of the central vestibular neurons, and may modulate synaptic transmission in all three neurons of the VOR arc. Acetylcholine appears to function as an excitatory neurotransmitter in both the peripheral and central synapses. Gamma-Aminobutyric acid (GABA) is thought to be inhibitory for the commissures of the medial vestibular nucleus, the connections between the cerebellar Purkinje cells, and the lateral vestibular nucleus, and the vertical VOR.

Three other neurotransmitters work centrally. Dopamine may accelerate vestibular compensation. Norepinephrine modulates the intensity of central reactions to vestibular stimulation and facilitates compensation. Histamine is present only centrally, but its role is unclear. Dopamine, histamine, serotonin, and acetylcholine are neurotransmitters thought to produce vomiting.[6] It is known that centrally acting antihistamines modulate the symptoms of acute symptomatic vertigo.[35]

## Management [edit]

Definitive treatment depends on the underlying cause of vertigo.[6] Ménière's disease patients have a variety of treatment options to consider when receiving treatment for vertigo and tinnitus including: a low-salt diet and intratympanic injections of the antibiotic gentamicin or surgical measures such as a shunt or ablation of the labyrinth in refractory cases.[36] Common drug treatment options for vertigo may include the following:[37]

- Anticholinergics such as hyoscine hydrobromide (scopolamine)[38]
- Anticonvulsants such as topiramate or valproic acid for vestibular migraines
- Antihistamines such as betahistine, dimenhydrinate, or meclizine, which may have antiemetic properties[39]
- Beta blockers such as metoprolol for vestibular migraine
- Corticosteroids such as methylprednisolone for inflammatory conditions such as vestibular neuritis or dexamethasone as a second-line agent for Ménière's disease

## Etymology [edit]

Vertigo is from the Latin word *vertō* which means "a whirling or spinning movement".[40]

## Media treatment [edit]

In the Alfred Hitchcock film *Vertigo*, the hero, played by James Stewart, has to resign from the police force after an incident which causes him to develop both acrophobia and vertigo. Early on in the film he faints while climbing a stepladder. There are numerous references throughout the film to fear of heights and falling, The dolly zoom camera effect, also called the "vertigo effect", was first used in this film.

# Addison's disease

From Wikipedia, the free encyclopedia

**Addison's disease**, also known as **primary adrenal insufficiency** and **hypocortisolism**, is a long-term endocrine disorder in which the adrenal glands do not produce enough steroid hormones.[1] Symptoms generally come on slowly and may include abdominal pain, weakness, and weight loss. Darkening of the skin in certain areas may also occur. Under certain circumstances, an adrenal crisis may occur with low blood pressure, vomiting, lower back pain, and loss of consciousness. An adrenal crisis can be triggered by stress, such as from an injury, surgery, or infection. Death may occur without treatment.[1]

Addison's disease arises from problems with the adrenal gland such that not enough of the steroid hormone cortisol and possibly aldosterone are produced,[1] most often due to damage by the body's own immune system in the developed world and tuberculosis in the developing world.[2] Other causes include certain medications, sepsis, and bleeding into both adrenal glands.[1][2] Secondary adrenal insufficiency is caused by not enough adrenocorticotropic hormone (ACTH) (produced by the pituitary gland) or CRH (produced by the hypothalamus). Despite this distinction, adrenal crises can happen in all forms of adrenal insufficiency. Addison's disease is generally diagnosed by blood tests, urine tests, and medical imaging.[1]

Treatment involves replacing the absent hormones.[1] This involves taking a corticosteroid such as hydrocortisone and fludrocortisone.[1][3] These medications are usually taken by mouth.[1] Lifelong, continuous steroid replacement therapy is required, with regular follow-up treatment and monitoring for other health problems.[4] A high-salt diet may also be useful in some people. If symptoms worsen, an injection of corticosteroid is recommended and people should carry a dose with them. Often, large amounts of intravenous fluids with the sugar dextrose are also required. Without treatment, an adrenal crisis can result in death.[1]

Addison's disease affects about 0.9 to 1.4 per 10,000 people in the developed world.[1][5] It occurs most frequently in middle-aged females.[1] Secondary adrenal insufficiency is more common.[5] Long-term outcomes with treatment are typically good.[6] It is named after Thomas Addison, a graduate of the University of Edinburgh Medical School, who first described the condition in 1855.[7] The adjective "addisonian" is used to describe features of the condition, as well as people with Addison's disease.[8]

# Signs and symptoms [edit]

The symptoms of Addison's disease develop gradually and may become established before they are recognized. They can be nonspecific and are potentially attributable to other medical conditions.

The signs and symptoms include fatigue; lightheadedness upon standing or difficulty standing, muscle weakness, fever, weight loss, anxiety, nausea, vomiting, diarrhea, headache, sweating, changes in mood or personality, and joint and muscle pains. Some patients have cravings for salt or salty foods due to the loss of sodium through their urine.[8] Hyperpigmentation of the skin may be seen, particularly when the patient lives in a sunny area, as well as darkening of the palmar crease, sites of friction, recent scars, the vermilion border of the lips, and genital skin.[9] These skin changes are not encountered in secondary and tertiary hypoadrenalism.[10]

On physical examination, these clinical signs may be noticed:[8]

- Low blood pressure with or without orthostatic hypotension (blood pressure that decreases with standing)
- Darkening (hyperpigmentation) of the skin, including areas not exposed to the sun. Characteristic sites of darkening are skin creases (e.g., of the hands), nipple, and the inside of the cheek (buccal mucosa); also, old scars may darken. This occurs because melanocyte-stimulating hormone (MSH) and ACTH share the same precursor molecule, pro-opiomelanocortin (POMC). After production in the anterior pituitary gland, POMC gets cleaved into gamma-MSH, ACTH, and beta-lipotropin. The subunit ACTH undergoes further cleavage to produce alpha-MSH, the most important MSH for skin pigmentation. In secondary and tertiary forms of adrenal insufficiency, skin darkening does not occur, as ACTH is not overproduced.

Addison's disease is associated with the development of other autoimmune diseases, such as type I diabetes, thyroid disease (Hashimoto's thyroiditis), and vitiligo. The presence of Addison's in addition to one of these is called autoimmune polyendocrine syndrome.

## Addisonian crisis [edit]

*Main article: Adrenal crisis*

An "Addisonian crisis" or "adrenal crisis" is a constellation of symptoms that indicates severe adrenal

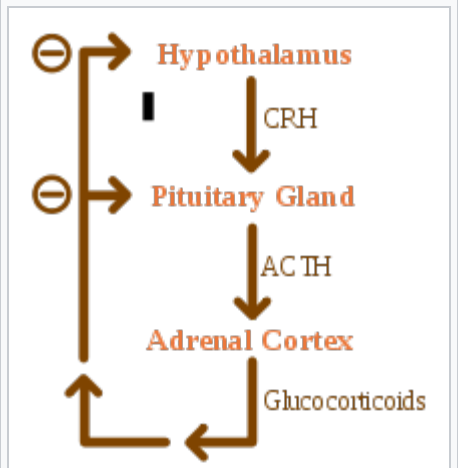
insufficiency. This may be the result of either previously undiagnosed Addison's disease, a disease process suddenly affecting adrenal function (such as adrenal hemorrhage), or an intercurrent problem (e.g., infection, trauma) in someone known to have Addison's disease. It is a medical emergency and potentially life-threatening situation requiring immediate emergency treatment.

Characteristic symptoms are:[11]

- Sudden penetrating pain in the legs, lower back, or abdomen
- Severe vomiting and diarrhea, resulting in dehydration
- Low blood pressure
- Syncope (loss of consciousness and ability to stand)
- Hypoglycemia (reduced level of blood glucose)
- Confusion, psychosis, slurred speech
- Severe lethargy
- Hyponatremia (low sodium level in the blood)
- Hyperkalemia (elevated potassium level in the blood)
- Hypercalcemia (elevated calcium level in the blood)
- Convulsions
- Fever

## Causes [edit]

Causes of adrenal insufficiency can be categorized by the mechanism through which they cause the adrenal glands to produce insufficient cortisol. These are adrenal dysgenesis (the gland has not formed adequately during development), impaired steroidogenesis (the gland is present but is biochemically unable to produce cortisol) or adrenal destruction (disease processes leading to glandular damage).[8]



The negative feedback loop for glucocorticoids

### Adrenal destruction [edit]

Autoimmune adrenalitis is the most common cause of Addison's disease in the industrialized world. Autoimmune destruction of the adrenal cortex is caused by an immune reaction against the enzyme 21-hydroxylase (a phenomenon first described in 1992).[12] This may be isolated or in the context of autoimmune polyendocrine syndrome (APS type 1 or 2), in which other hormone-producing organs, such as the thyroid and pancreas, may also be affected.[13]

Adrenal destruction is also a feature of adrenoleukodystrophy, and when the adrenal glands are involved in metastasis (seeding of cancer cells from elsewhere in the body, especially lung), hemorrhage (e.g., in Waterhouse-Friderichsen syndrome or antiphospholipid syndrome), particular infections (tuberculosis, histoplasmosis, coccidioidomycosis), or the deposition of abnormal protein in amyloidosis.[14]

### Adrenal dysgenesis [edit]

All causes in this category are genetic, and generally very rare. These include mutations to the *SF1* transcription factor, congenital adrenal hypoplasia due to *DAX-1* gene mutations and mutations to the ACTH receptor gene (or related genes, such as in the Triple A or Allgrove syndrome). *DAX-1* mutations may cluster in a syndrome with glycerol kinase deficiency with a number of other symptoms when *DAX-1* is deleted together with a number of other genes.[8]

### Impaired steroidogenesis [edit]

To form cortisol, the adrenal gland requires cholesterol, which is then converted biochemically into steroid

hormones. Interruptions in the delivery of cholesterol include Smith-Lemli-Opitz syndrome and abetalipoproteinemia.

Of the synthesis problems, congenital adrenal hyperplasia is the most common (in various forms: 21-hydroxylase, 17α-hydroxylase, 11β-hydroxylase and 3β-hydroxysteroid dehydrogenase), lipoid CAH due to deficiency of StAR and mitochondrial DNA mutations.[8] Some medications interfere with steroid synthesis enzymes (e.g., ketoconazole), while others accelerate the normal breakdown of hormones by the liver (e.g., rifampicin, phenytoin).[8]

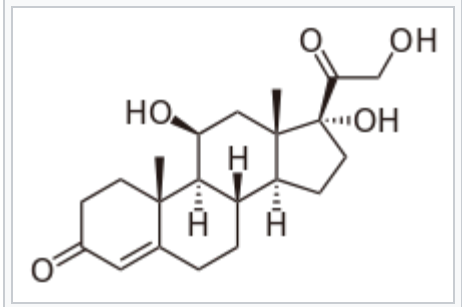
# Diagnosis [edit]

## Suggestive features [edit]

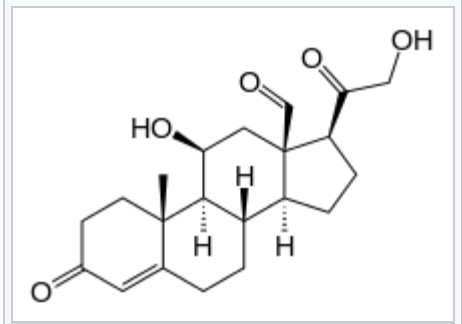
Routine laboratory investigations may show:[8]

- Hypercalcemia
- Hypoglycemia, low blood sugar (worse in children due to loss of glucocorticoid's glucogenic effects)
- Hyponatremia (low blood sodium levels), due to loss of production of the hormone aldosterone, to the kidney's inability to excrete free water in the absence of sufficient cortisol, and also the effect of corticotropin-releasing hormone to stimulate secretion of ADH.
- Hyperkalemia (raised blood potassium levels), due to loss of production of the hormone aldosterone.
- Eosinophilia and lymphocytosis (increased number of eosinophils or lymphocytes, two types of white blood cells)
- Metabolic acidosis (increased blood acidity), also is due to loss of the hormone aldosterone because sodium reabsorption in the distal tubule is linked with acid/hydrogen ion ($H^+$) secretion. Low levels of aldosterone stimulation of the renal distal tubule leads to sodium wasting in the urine and $H^+$ retention in the serum.

## Testing [edit]



Cortisol



Aldosterone

In suspected cases of Addison's disease, demonstration of low adrenal hormone levels even after appropriate stimulation (called the ACTH stimulation test) with synthetic pituitary ACTH hormone tetracosactide is needed for the diagnosis. Two tests are performed, the short and the long test. It should be noted that dexamethasone does not cross-react with the assay and can be administered concomitantly during testing.

The short test compares blood cortisol levels before and after 250 micrograms of tetracosactide (intramuscular or intravenous) is given. If, one hour later, plasma cortisol exceeds 170 nmol/l and has risen by at least 330 nmol/l to at least 690 nmol/l, adrenal failure is excluded. If the short test is abnormal, the long test is used to differentiate between primary adrenal insufficiency and secondary adrenocortical insufficiency.

The long test uses 1 mg tetracosactide (intramuscular). Blood is taken 1, 4, 8, and 24 hr later. Normal plasma cortisol level should reach 1000 nmol/l by 4 hr. In primary Addison's disease, the cortisol level is reduced at all stages, whereas in secondary corticoadrenal insufficiency, a delayed but normal response is seen.

Other tests may be performed to distinguish between various causes of hypoadrenalism, including renin and adrenocorticotropic hormone levels, as well as medical imaging - usually in the form of ultrasound, computed tomography or magnetic resonance imaging.

Adrenoleukodystrophy, and the milder form, adrenomyeloneuropathy, cause adrenal insufficiency combined with neurological symptoms. These diseases are estimated to be the cause of adrenal insufficiency in about

35% of male patients with idiopathic Addison's disease, and should be considered in the differential diagnosis of any male with adrenal insufficiency. Diagnosis is made by a blood test to detect very long chain fatty acids.[15]

## Treatment [edit]

Corticosteroids to replace cortisols not secreted by the adrenal glands.

### Maintenance [edit]

Treatment for Addison's disease involves replacing the missing cortisol, sometimes in the form of hydrocortisone tablets, or prednisone tablets in a dosing regimen that mimics the physiological concentrations of cortisol. Alternatively, one-quarter as much prednisolone may be used for equal glucocorticoid effect as hydrocortisone. Treatment is usually lifelong. In addition, many patients require fludrocortisone as replacement for the missing aldosterone.

People with Addison's are often advised to carry information on them (e.g., in the form of a MedicAlert bracelet or information card) for the attention of emergency medical services personnel who might need to attend to their needs.[16][17] It is also recommended that a needle, syringe, and injectable form of cortisol be carried for emergencies.[17] People with Addison's disease are advised to increase their medication during periods of illness or when undergoing surgery or dental treatment.[17] Immediate medical attention is needed when severe infections, vomiting, or diarrhea occur, as these conditions can precipitate an Addisonian crisis. A patient who is vomiting may require injections of hydrocortisone instead.[18]

### Crisis [edit]

Standard therapy involves intravenous injections of glucocorticoids and large volumes of intravenous saline solution with dextrose (glucose). This treatment usually brings rapid improvement. If intravenous access is not immediately available, intramuscular injection of glucocorticoids can be used. When the patient can take fluids and medications by mouth, the amount of glucocorticoids is decreased until a maintenance dose is reached. If aldosterone is deficient, maintenance therapy also includes oral doses of fludrocortisone acetate.[19]

## Epidemiology [edit]

The frequency rate of Addison's disease in the human population is sometimes estimated at roughly one in 100,000.[20] Some put the number closer to 40–144 cases per million population (1/25,000–1/7,000).[1][21] Addison's can affect persons of any age, sex, or ethnicity, but it typically presents in adults between 30 and 50 years of age.[22] Research has shown no significant predispositions based on ethnicity.[21]

## Prognosis [edit]

Outcomes are typically good when treated. Most can expect to live relatively normal lives. Someone with the disease should be observant of symptoms of an "Addison's crisis" while the body is strained, as in rigorous exercise or being sick, the latter often needing emergency treatment with intravenous injections to treat the crisis.[23]

Individuals with Addison's disease has more than a doubled mortality rate.[24] Furthermore, individuals with Addison's disease and diabetes mellitus have a almost 4 time increase in mortality compared to individuals with only diabetes.[25]

## History [edit]

## Discovery [edit]

Addison's disease is named after Thomas Addison, the British physician who first described the condition in *On the Constitutional and Local Effects of Disease of the Suprarenal Capsules* (1855).[26] All of Addison's six original patients had tuberculosis of the adrenal glands.[27] While Addison's six patients in 1855 all had adrenal tuberculosis, the term "Addison's disease" does not imply an underlying disease process.

The condition was initially considered a form of anemia associated with the adrenal glands. Because little was known at the time about the adrenal glands (then called "Supra-Renal Capsules"), Addison's monograph describing the condition was an isolated insight. As the adrenal function became better known, Addison's monograph became known as an important medical contribution and a classic example of careful medical observation.[28]

## Notable cases [edit]

United States president John F. Kennedy (1917-1963), probably the single most famous case of Addison's disease

- John F. Kennedy, the 35th President of the United States, was one of the best-known people with Addison's disease and was possibly one of the first to survive major surgery.[29] Substantial secrecy surrounded his health during his years as president.[30]
- Eunice Kennedy Shriver, one of John F. Kennedy's sisters, was believed to have Addison's disease as well.[31]
- Popular singer Helen Reddy[32]
- Scientist Eugene Merle Shoemaker, co-discoverer of the Comet Shoemaker-Levy 9.[33]
- French Carmelite nun and religious writer Blessed Elizabeth of the Trinity[34]
- American artist Ferdinand Louis Schlemmer died from Addison's disease.
- Some have suggested Jane Austen was an *avant la lettre* case, but others have disputed this.[35]
- According to Carl Abbott, a Canadian medical researcher, Charles Dickens may also have been affected.[36]
- Australia's youngest rugby league football international, Geoff Starling[37]
- Osama bin Laden may have had Addison's. Lawrence Wright noted that bin Laden exhibited the key symptoms of Addison's, including "low blood pressure, weight loss, muscle fatigue, stomach irritability, sharp back pains, dehydration, and an abnormal craving for salt". Bin Laden was also known to have consumed large amounts of sulbutiamine to treat his symptoms.[38]
- Basque nationalist and founder of the Basque Nationalist Party, Sabino Arana died in Sukarrieta at the age of 38 after falling ill with Addison's disease during time spent in prison.
- A cappella singer/arranger/producer Deke Sharon[39]
- One of Canada's top gymnasts, Nathan Gafuik, was diagnosed with Addison's disease when he was 15.[40]
- South Korean President Park Geun-hye is reported to have Addison's disease.[41]

# Other animals [edit]

*Main article: Addison's disease in canines*

The condition has been diagnosed in all breeds of dogs. In general, it is underdiagnosed, and one must clinically suspect it as an underlying disorder for many presenting complaints. Females are overrepresented, and the disease often appears in middle age (4–7 yr), although any age or either gender may be

affected.[*citation needed*]

Hypoadrenocorticism is treated with fludrocortisone or a monthly injection called Percorten V (desoxycorticosterone pivlate (DOCP)) and prednisone. Routine blood work is necessary in the initial stages until a maintenance dose is established. Most of the medications used in the therapy of hypoadrenocorticism cause excessive thirst and urination, making it important to provide enough drinking water. If the owner knows about an upcoming stressful situation (shows, traveling, etc.), patients generally need an increased dose of prednisone to help deal with the added stress. Avoidance of stress is important for dogs with hypoadrenocorticism.

# Cushing's syndrome

From Wikipedia, the free encyclopedia

*Not to be confused with Cushing's triad, due to increased intracranial pressure.*

**Cushing's syndrome** is a collection of signs and symptoms due to prolonged exposure to cortisol.[2][3] Signs and symptoms may include: high blood pressure, abdominal obesity but with thin arms and legs, reddish stretch marks, a round red face, a fat lump between the shoulders, weak muscles, weak bones, acne, and fragile skin that heals poorly. Women may have more hair and irregular menstruation. Occasionally there may be changes in mood, headaches, and a chronic feeling of tiredness.[4]

Cushing's syndrome is caused by either excessive cortisol-like medication such as prednisone or a tumor that either produces or results in the production of excessive cortisol by the adrenal glands.[5] Cases due to a pituitary adenoma are known as Cushing's disease. It is the second most common cause of Cushing's syndrome after medication.[2] A number of other tumors may also cause Cushing's.[2][6] Some of these are associated with inherited disorders such as multiple endocrine neoplasia type 1 and Carney complex.[7] Diagnosis requires a number of steps. The first step is to check the medications a person takes. The second step is to measure levels of cortisol in the urine, saliva or in the blood after taking dexamethasone. If this test is abnormal, the cortisol may be measured late at night. If the cortisol remains high, a blood test for ACTH may be done to determine if the pituitary is involved.[8]

Most cases can be treated and cured.[9] If due to medications, these can often be slowly stopped.[10] If caused by a tumor, it may be treated by a combination of surgery, chemotherapy, and/or radiation. If the pituitary was affected, other medications may be required to replace its lost function. With treatment, life expectancy is usually normal.[9] Some, in whom surgery is unable to remove the entire tumor, have an increased risk of death.[11]

About two to three people per million are affected each year.[7] It most commonly affects people who are 20 to 50 years of age.[2] Women are affected three times more often than men.[7] A mild degree of overproduction of cortisol without obvious symptoms, however, is more common.[12]

Cushing's syndrome was first described by Harvey Cushing in [13]

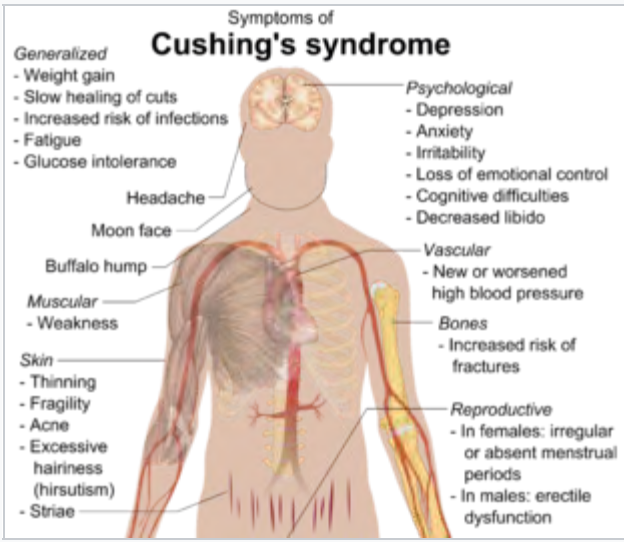
## Signs and symptoms [edit]



Symptoms of Cushing's syndrome[16]

Symptoms include rapid weight gain, particularly of the trunk and face with sparing of the limbs (central obesity). Common signs include the growth of fat pads along the collarbone, on the back of the neck ("buffalo hump" or lipodystrophy), and on the face ("moon face"). Other symptoms include excess sweating, dilation of capillaries, thinning of the skin (which causes easy bruising and dryness, particularly the hands) and mucous membranes, purple or red striae (the weight gain in Cushing's syndrome stretches the skin, which is thin and weakened, causing it to hemorrhage) on the trunk, buttocks, arms, legs, or breasts, proximal muscle weakness (hips, shoulders), and hirsutism (facial male-pattern hair growth), baldness and/or extremely dry and brittle hair. In rare cases, Cushing's can cause hypocalcemia. The excess cortisol may also affect other endocrine systems and cause, for example, insomnia, inhibited aromatase, reduced libido, impotence in men, and amenorrhoea/oligomenorrhea and infertility in women due to elevations in androgens. Studies have also shown that the resultant amenorrhea is due to hypercortisolism, which feeds back onto the hypothalamus resulting in decreased levels of GnRH release.[18]

Cognitive conditions, including memory and attention dysfunctions, as well as depression, are commonly associated with elevated cortisol,[19] and may be early indicators of exogenous or endogenous Cushing's. Depression and anxiety disorders are also common.[20]

Other striking and distressing skin changes that may appear in Cushing's syndrome include facial acne, susceptibility to superficial fungus (dermatophyte and malassezia) infections, and the characteristic purplish, atrophic striae on the abdomen.[21]:500

Other signs include increased urination (and accompanying increased thirst), persistent high blood pressure (due to cortisol's enhancement of epinephrine's vasoconstrictive effect) and insulin resistance (especially common with ACTH production outside the pituitary), leading to high

Increased hair and stria in a person with medication-induced Cushing's syndrome[1]

Features of Cushing syndrome including a round face, acne, reddish skin, central obesity, and poor muscle tone[17]

blood sugar and insulin resistance which can lead to diabetes mellitus. Insulin resistance is accompanied by skin changes such as acanthosis nigricans in the axilla and around the neck, as well as skin tags in the axilla. Untreated Cushing's syndrome can lead to heart disease and increased mortality. Cortisol can also exhibit mineralocorticoid activity in high concentrations, worsening the hypertension and leading to hypokalemia (common in ectopic ACTH secretion). Furthermore, excessive cortisol may lead to gastrointestinal disturbances, opportunistic infections, and impaired wound healing related to cortisol's suppression of the immune and inflammatory responses. Osteoporosis is also an issue in Cushing's syndrome since osteoblast activity is inhibited. Additionally, Cushing's syndrome may cause sore and aching joints, particularly in the hip, shoulders, and lower back. Cushing's syndrome includes all the causes of increased cortisol leading to the diseased state. Cushing's disease is a specific type of Cushing's syndrome caused by a pituitary tumor leading to excessive production of ACTH (adrenocorticotropic hormone). Excessive ACTH stimulates the adrenal cortex to produce high levels of cortisol, producing the disease state. Cushing's disease due to excess ACTH may also result in hyperpigmentation. This is due to Melanocyte-Stimulating Hormone production as a byproduct of ACTH synthesis from Pro-opiomelanocortin (POMC). Alternatively, it is proposed that the high levels of ACTH, β-lipotropin, and γ-lipotropin, which contain weak MSH function, can act on the melanocortin 1 receptor. A variant of Cushing's disease can be caused by ectopic, i.e. extrapituitary, ACTH production from, for example, a small-cell lung cancer. When Cushing's syndrome is caused by an increase of cortisol at the level of the adrenal glands (via an adenoma or hyperplasia), negative feedback ultimately reduces ACTH production in the pituitary. In these cases, ACTH levels remain low and no hyperpigmentation develops. While all Cushing's disease gives Cushing's syndrome, not all Cushing's syndrome is due to Cushing's disease.

Brain changes such as cerebral atrophy may occur.[22] This atrophy is associated with areas of high glucocorticoid receptor concentrations such as the hippocampus and correlates highly with psychopathological personality changes.[23][24][25][26]

## Causes [edit]

Several possible causes of Cushing's syndrome are known.

### External versus internal [edit]

The most common cause of Cushing's syndrome is the taking of glucocorticoids prescribed by a health care practitioner to treat other diseases (called iatrogenic Cushing's syndrome). This can be an effect of corticosteroid treatment of a variety of disorders such as asthma and rheumatoid arthritis, or in immunosuppression after an organ transplant. Administration of synthetic ACTH is also possible, but ACTH is less often prescribed due to cost and lesser utility. Although rare, Cushing's syndrome can also be due to the use of medroxyprogesterone acetate.[27][28] In this form of Cushing's, the adrenal glands atrophy due to lack of stimulation by ACTH, since glucocorticoids downregulate production of ACTH. Cushing's syndrome in childhood usually results from use of glucocorticoid medication.[29]

Endogenous Cushing's syndrome results from some derangement of the body's own system of secreting cortisol. Normally, ACTH is released from the pituitary gland when necessary to stimulate the release of cortisol from the adrenal glands.

- In pituitary Cushing's, a benign pituitary adenoma secretes ACTH. This is also known as Cushing's disease and is responsible for 70% of endogenous Cushing's syndrome.[30]
- In adrenal Cushing's, excess cortisol is produced by adrenal gland tumors, hyperplastic adrenal glands, or adrenal glands with nodular adrenal hyperplasia.
- Tumors outside the normal pituitary-adrenal system can produce ACTH (occasionally with CRH) that affects the adrenal glands. This etiology is called ectopic or paraneoplastic Cushing's disease and is seen in diseases such as small cell lung cancer.[31]
- Finally, rare cases of CRH-secreting tumors (without ACTH secretion) have been reported, which stimulates pituitary ACTH production.[32]

### Pseudo-Cushing's syndrome [edit]

Elevated levels of total cortisol can also be due to estrogen found in oral contraceptive pills that contain a mixture of estrogen and progesterone, leading to Pseudo-Cushing's syndrome. Estrogen can cause an increase of cortisol-binding globulin and thereby cause the total cortisol level to be elevated. However, the total free cortisol, which is the active hormone in the body, as measured by a 24-hour urine collection for urinary free cortisol, is normal.[33]

## Pathophysiology [edit]

The hypothalamus is in the brain and the pituitary gland sits just below it. The paraventricular nucleus (PVN) of the hypothalamus releases corticotropin-releasing hormone (CRH), which stimulates the pituitary gland to release adrenocorticotropin (ACTH). ACTH travels via the blood to the adrenal gland, where it stimulates the release of cortisol. Cortisol is secreted by the cortex of the adrenal gland from a region called the zona fasciculata in response to ACTH. Elevated levels of cortisol exert negative feedback on CRH in the hypothalamus, which decreases the amount of ACTH released from the anterior pituitary gland.

Strictly, Cushing's syndrome refers to excess cortisol of any etiology (as syndrome means a group of

symptoms). One of the causes of Cushing's syndrome is a cortisol-secreting adenoma in the cortex of the adrenal gland (primary hypercortisolism/hypercorticism). The adenoma causes cortisol levels in the blood to be very high, and negative feedback on the pituitary from the high cortisol levels causes ACTH levels to be very low.

Cushing's disease refers only to hypercortisolism secondary to excess production of ACTH from a corticotroph pituitary adenoma (secondary hypercortisolism/hypercorticism) or due to excess production of hypothalamus CRH (Corticotropin releasing hormone) (tertiary hypercortisolism/hypercorticism). This causes the blood ACTH levels to be elevated along with cortisol from the adrenal gland. The ACTH levels remain high because the tumor is unresponsive to negative feedback from high cortisol levels.

When Cushing's syndrome is due to extra ACTH it is known as ectopic Cushing syndrome.[34] This may be seen in a paraneoplastic syndrome.

When Cushing's syndrome is suspected, either a dexamethasone suppression test (administration of dexamethasone and frequent determination of cortisol and ACTH level), or a 24-hour urinary measurement for cortisol offers equal detection rates.[35] Dexamethasone is a glucocorticoid and simulates the effects of cortisol, including negative feedback on the pituitary gland. When dexamethasone is administered and a blood sample is tested, cortisol levels >50 nmol/l (1.81 µg/dl) would be indicative of Cushing's syndrome because an ectopic source of cortisol or ACTH (such as adrenal adenoma) exists which is not inhibited by the dexamethasone. A novel approach, recently cleared by the US FDA, is sampling cortisol in saliva over 24 hours, which may be equally sensitive, as late-night levels of salivary cortisol are high in cushingoid patients. Other pituitary hormone levels may need to be ascertained. Performing a physical examination to determine any visual field defect may be necessary if a pituitary lesion is suspected, which may compress the optic chiasm, causing typical bitemporal hemianopia.

When any of these tests is positive, CT scanning of the adrenal gland and MRI of the pituitary gland are performed to detect the presence of any adrenal or pituitary adenomas or incidentalomas (the incidental discovery of harmless lesions). Scintigraphy of the adrenal gland with iodocholesterol scan is occasionally necessary. Occasionally, determining the ACTH levels in various veins in the body by venous catheterization, working towards the pituitary (petrosal sinus sampling) is necessary. In many cases, the tumors causing Cushing's disease are less than 2 mm in size and difficult to detect using MRI or CT imaging. In one study of 261 patients with confirmed pituitary Cushing's disease, only 48% of pituitary lesions were identified using MRI prior to surgery.[36]

Plasma CRH levels are inadequate at diagnosis (with the possible exception of tumors secreting CRH) because of peripheral dilution and binding to CRHBP.[37]

## Treatment [edit]

Most Cushing's syndrome cases are caused by corticosteroid medications (iatrogenic), such as those used for asthma, arthritis, and other inflammatory conditions. Consequently, most patients are effectively treated by carefully tapering off (and eventually stopping) the medication that causes the symptoms.

If an adrenal adenoma is identified, it may be removed by surgery. An ACTH-secreting corticotrophic pituitary adenoma should be removed after diagnosis. Regardless of the adenoma's location, most patients require steroid replacement postoperatively at least in the interim, as long-term suppression of pituitary ACTH and normal adrenal tissue does not recover immediately. Clearly, if both adrenals are removed, replacement with hydrocortisone or prednisolone is imperative.

In those patients not suited for or unwilling to undergo surgery, several drugs have been found to inhibit cortisol synthesis (e.g. ketoconazole, metyrapone) but they are of limited efficacy.[*citation needed*] Mifepristone is a powerful glucocorticoid type II receptor antagonist and, since it does not interfere with normal cortisol homeostatis type I receptor transmission, may be especially useful for treating the cognitive effects of Cushing's syndrome.[38] However, the medication faces considerable controversy due to its use as an abortifacient. In February 2012, the FDA approved mifepristone to control high blood sugar levels (hyperglycemia) in adult patients who are not candidates for surgery, or who did not respond to prior surgery, with the warning that mifepristone should never be used by pregnant women.[39]

Removal of the adrenals in the absence of a known tumor is occasionally performed to eliminate the production of excess cortisol. In some occasions, this removes negative feedback from a previously occult pituitary adenoma, which starts growing rapidly and produces extreme levels of ACTH, leading to hyperpigmentation. This clinical situation is known as Nelson's syndrome.[40]

## Epidemiology [edit]

Iatrogenic Cushing's syndrome (caused by treatment with corticosteroids) is the most common form of Cushing's syndrome. Cushing's disease is rare; a Danish study found an incidence of less than one case per million people per year.[41] However, asymptomatic microadenomas (less than 10 mm in size) of the pituitary are found in about one in six individuals.[42]

People with Cushing's syndrome have increased morbidity and mortality as compared to the general population. The most common cause of mortality in Cushing's syndrome is cardiovascular events. People with Cushing's syndrome have nearly 4 times increased cardiovascular mortality as compared to the general population.

## Variants

**Delirium tremens** (**DTs**) is a rapid onset of confusion usually caused by withdrawal from alcohol. When it occurs, it is often three days into the withdrawal symptoms and lasts for two to three days. People may also see or hear things other people do not.[1] Physical effects may include shaking, shivering, irregular heart rate, and sweating.[2] Occasionally, a very high body temperature or seizures may result in death.[1] Alcohol is one of the most dangerous drugs to withdraw from.[3]

Delirium tremens typically only occurs in people with a high intake of alcohol for more than a month.[4] A similar syndrome may occur with benzodiazepine and barbiturate withdrawal.[5] Withdrawal from stimulants such as cocaine does not have major medical complications.[6] In a person with delirium tremens it is important to rule out other associated problems such as electrolyte abnormalities, pancreatitis, and alcoholic hepatitis.[1]

Prevention is by treating withdrawal symptoms. If delirium tremens occurs, aggressive treatment improves outcomes. Treatment in a quiet intensive care unit with sufficient light is often recommended. Benzodiazepines are the medication of choice with diazepam, lorazepam, chlordiazepoxide, and oxazepam all commonly used.[4] They should be given until a person is lightly sleeping. The antipsychotic haloperidol may also be used. The vitamin thiamine is recommended.[1]

Mortality without treatment is between 15% and 40%.[7] Currently death occurs in about 1% to 4% of cases.[1]

About half of people with alcoholism will develop withdrawal symptoms upon reducing their use. Of these, three to five percent develop DTs or have seizures.[1] The name delirium tremens was first used in 1813; however, the symptoms were well described since the 1700s.[4] The word "delirium" is Latin for "going off the furrow," a plowing metaphor. It is also called shaking frenzy and Saunders-Sutton syndrome.[7] Nicknames include the shakes, barrel-fever, blue horrors, bottleache, bats, drunken horrors, elephants, gallon distemper, quart mania, and pink spiders, among others.[8]

## Signs and symptoms [edit]

The main symptoms of delirium tremens are nightmares, agitation, global confusion, disorientation, visual and auditory hallucinations, tactile hallucinations, fever, high blood pressure, heavy sweating, and other signs of autonomic hyperactivity (fast heart rate and high blood pressure). These symptoms may appear suddenly, but typically develop two to three days after the stopping of heavy drinking, being worst on the fourth or fifth day.[10] Also, these "symptoms are characteristically worse at night".[11] In general, DT is considered the most severe manifestation of alcohol withdrawal and occurs 3–10 days following the last drink.[9] Other common symptoms include intense perceptual disturbance such as visions of insects, snakes, or rats. These may be hallucinations, or illusions related to the environment, e.g., patterns on the wallpaper or in the peripheral vision that the patient falsely perceives as a resemblance to the morphology of an insect, and are also associated with tactile hallucinations such as sensations of something crawling on the subject—a phenomenon known as formication. Delirium tremens usually includes extremely intense feelings of "impending doom". Severe anxiety and feelings of imminent death are common DT symptoms.

DT can sometimes be associated with severe, uncontrollable tremors of the extremities and secondary symptoms such as anxiety, panic attacks and paranoia. Confusion is often noticeable to onlookers as those with DT will have trouble forming simple sentences or making basic logical calculations. In many cases, people who rarely speak out of turn will have an increased tendency for gaffes even though they are sober.[*citation needed*]

DT should be distinguished from alcoholic hallucinosis, the latter of which occurs in approximately 20% of hospitalized alcoholics and does not carry a significant mortality. In contrast, DT occurs in 5–10% of alcoholics and carries up to 15% mortality with treatment and up to 35% mortality without treatment.[12] DT is characterized by the presence of altered sensorium; that is, a complete hallucination without any recognition of the real world. DT has extreme autonomic hyperactivity (high pulse, blood pressure, and rate of breathing), and 35-60% of patients have a fever. Some patients experience seizures.[*citation needed*]

## Causes [edit]

Delirium tremens is mainly caused by a long period of drinking being stopped abruptly. Withdrawal leads to a biochemical regulation cascade. It may also be triggered by head injury, infection, or illness in people with a history of heavy use of alcohol.[*citation needed*]

Another cause of delirium tremens is abrupt stopping of tranquilizer drugs of the barbiturate or benzodiazepine classes in a person with a relatively strong addiction to them.[*citation needed*] Because these tranquilizers' primary pharmacological and physiological effects stem from their manipulation of the GABA chemical and transmitter somatic system, the same neurotransmitter system affected by alcohol, delirium tremens can occur upon abrupt decrease of dosage in those who are heavily dependent. These DTs are much the same as those caused by alcohol and so is the attendant withdrawal syndrome of which they are a manifestation. That is the primary reason benzodiazepines are such an effective treatment for DTs, despite also being the cause of them in many cases. Because ethanol and tranquilizers such as barbiturates and benzodiazepines function as positive allosteric modulators at $GABA_A$ receptors, the brain, in its desire to equalize an unbalanced chemical system, triggers the abrupt stopping of the production of endogenous GABA. This decrease becomes more and more marked as the addiction becomes stronger and as higher

doses are needed to cause intoxication. In addition to having sedative properties, GABA is an immensely important regulatory neurotransmitter that controls the heart rate, blood pressure, and seizure threshold among myriad other important autonomic nervous subsystems.[*citation needed*]

Delirium tremens is most common in people who have a history of alcohol withdrawal, especially in those who drink the equivalent of 7 to 8 US pints (3 to 4 l) of beer or 1 US pint (0.5 l) of distilled beverage daily. Delirium tremens also commonly affects those with a history of habitual alcohol use or alcoholism that has existed for more than 10 years.[13]

The exact pharmacology of ethanol is not fully understood; however, it is theorized that delirium tremens is caused by the effect of alcohol on GABA receptors. Constant consumption of alcoholic beverages (and the consequent chronic sedation) causes a counterregulatory response in the brain in an attempt to regain homeostasis.

This causes downregulation of these receptors, as well as an up-regulation in the production of excitatory neurotransmitters, primarily glutamate, and also such as norepinephrine, dopamine, epinephrine, and serotonin, all of which further the drinker's tolerance to alcohol. When alcohol is no longer consumed, these down-regulated $GABA_A$ receptor complexes are so insensitive to GABA that the typical amount of GABA produced has little effect; compounded with the fact that GABA normally inhibits action potential formation, there are not as many receptors for GABA to bind to, meaning that sympathetic activation is unopposed. This is also known as an "adrenergic storm", the effects of which can include (but are not limited to) tachycardia, hypertension, fever, night sweats, hyperreflexia, excessive sweating, heart attack, cardiac arrhythmia, stroke, anxiety, panic attacks, paranoia, and agitation.[*citation needed*]

This is all made worse by excitatory neurotransmitter up-regulation, so not only is sympathetic nervous system over-activity unopposed by GABA, there is also more of the serotonin, norepinephrine, dopamine, epinephrine, and particularly glutamate. Excitory NMDA receptors are also up-regulated, contributing to the delirium and neurotoxicity (by excitotoxicity) of withdrawal. Direct measurements of central norepinephrine and its metabolites are in direct correlation to the severity of the alcohol withdrawal syndrome.[14] It is possible that psychological (i.e., non-physical) factors also play a role, in addition to other factors such as infections, malnutrition, or other underlying medical disorders, often related to alcoholism.[*citation needed*]

## Treatment [edit]

Delirium tremens due to alcohol withdrawal can be treated with benzodiazepines. High doses may be necessary to prevent death.[15] Amounts given are based on the symptoms. Typically the person is kept sedated with benzodiazepines, such as diazepam, lorazepam, chlordiazepoxide, or oxazepam.

In some cases antipsychotics, such as haloperidol may also be used. Older drugs such as paraldehyde and clomethiazole were formerly the traditional treatment but have now largely been superseded by the benzodiazepines.

Acamprosate is occasionally used in addition to other treatments, and is then carried on into long term use to reduce the risk of relapse. If status epilepticus occurs it is treated in the usual way. It can also be helpful to control environmental stimuli, by providing a well-lit but relaxing environment for minimizing distress and visual hallucinations.[*citation needed*]

Alcoholic beverages can also be prescribed as a treatment for delirium tremens,[16] but this practice is not universally supported.[17]

High doses of thiamine often by the intravenous route is also recommended.[18]

## Society and culture [edit]

Nicknames include "the horrors", "the shakes", "the bottleache", "quart mania", "ork orks", "gallon distemper", "the zoots", "barrel fever", "the 750 itch", "pint paralysis", seeing pink elephants. Another nickname is

"the Brooklyn Boys" found in Eugene O'Neill's one-act play *Hughie* set In 1920's Times Square.[19]

Writer Jack Kerouac details his experiences with delirium tremens in his book *Big Sur*.[20]

One of the characters in Joseph Conrad's novel *Lord Jim* experiences "DTs of the worst kind" with symptoms that include seeing millions of pink frogs.

# Diabetes mellitus

From Wikipedia, the free encyclopedia
(Redirected from Diabetes)

*"Diabetes" redirects here. For other uses, see Diabetes (disambiguation).*

**Diabetes mellitus** (**DM**), commonly referred to as **diabetes**, is a group of metabolic diseases in which there are high blood sugar levels over a prolonged period.[2] Symptoms of high blood sugar include frequent urination, increased thirst, and increased hunger. If left untreated, diabetes can cause many complications.[3] Acute complications can include diabetic ketoacidosis, nonketotic hyperosmolar coma, or death.[4] Serious long-term complications include heart disease, stroke, chronic kidney failure, foot ulcers, and damage to the eyes.[3]

Diabetes is due to either the pancreas not producing enough insulin or the cells of the body not responding properly to the insulin produced.[5] There are three main types of diabetes mellitus:

- Type 1 DM results from the pancreas's failure to produce enough insulin. This form was previously referred to as "insulin-dependent diabetes mellitus" (IDDM) or "juvenile diabetes". The cause is unknown.[3]
- Type 2 DM begins with insulin resistance, a condition in which cells fail to respond to insulin properly.[3] As the disease progresses a lack of insulin may also develop.[6] This form was previously referred to as "non insulin-dependent diabetes mellitus" (NIDDM) or "adult-onset diabetes". The primary cause is excessive body weight and not enough exercise.[3]
- Gestational diabetes is the third main form and occurs when pregnant women without a previous history of diabetes develop high blood-sugar levels.[3]

Prevention and treatment involve maintaining a healthy diet, regular physical exercise, a normal body weight, and avoiding use of tobacco. Control of blood pressure and maintaining proper foot care are important for people with the disease. Type 1 DM must be managed with insulin injections.[3] Type 2 DM may be treated with medications with or without insulin.[7] Insulin and some oral medications can cause low blood sugar.[8] Weight loss surgery in those with obesity is sometimes an effective measure in those with type 2 DM.[9] Gestational diabetes usually resolves after the birth of the baby.[10]

As of 2015, an estimated 415 million people had diabetes worldwide,[11] with type 2 DM making up about

90% of the cases.[12][13] This represents 8.3% of the adult population,[13] with equal rates in both women and men.[14] As of 2014, trends suggested the rate would continue to rise.[15] Diabetes at least doubles a person's risk of early death.[3] From 2012 to 2015, approximately 1.5 to 5.0 million deaths each year resulted from diabetes.[7][11] The global economic cost of diabetes in 2014 was estimated to be US$612 billion.[16] In the United States, diabetes cost $245 billion in 2012.[17]

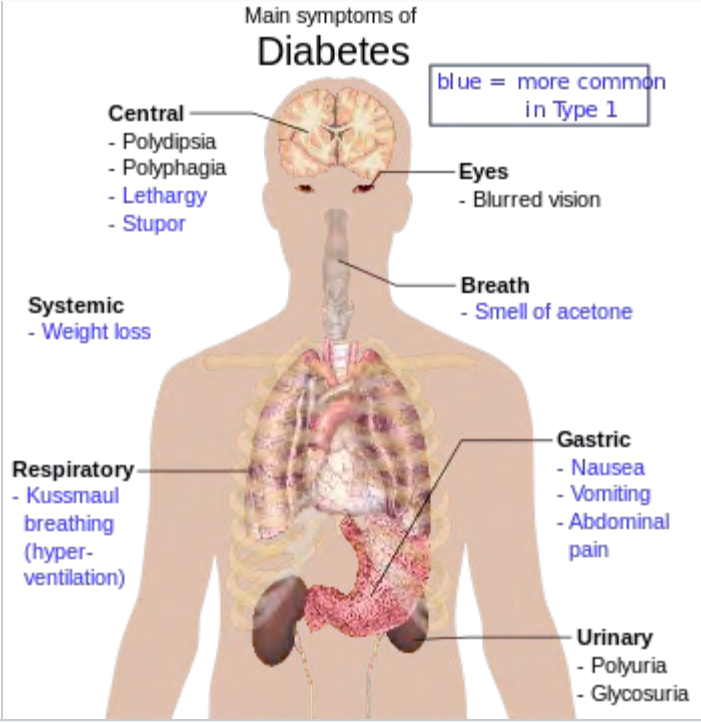
# Signs and symptoms

The classic symptoms of untreated diabetes are weight loss, polyuria (increased urination), polydipsia (increased thirst), and polyphagia (increased hunger).[18] Symptoms may develop rapidly (weeks or months) in type 1 DM, while they usually develop much more slowly and may be subtle or absent in type 2 DM.

Several other signs and symptoms can mark the onset of diabetes although they are not specific to the disease. In addition to the known ones above, they include blurry vision, headache, fatigue, slow healing of cuts, and itchy skin. Prolonged high blood glucose can cause glucose absorption in the lens of the eye, which leads to changes in its shape, resulting in vision changes. A number of skin rashes that can occur in diabetes are collectively known as diabetic dermadromes.



Overview of the most significant symptoms of diabetes

## Diabetic emergencies

Low blood sugar is common in persons with type 1 and type 2 DM. Most cases are mild and are not considered medical emergencies. Effects can range from feelings of unease, sweating, trembling, and increased appetite in mild cases to more serious issues such as confusion, changes in behavior such as aggressiveness, seizures, unconsciousness, and (rarely) permanent brain damage or death in severe cases.[19][20] Moderate hypoglycemia may easily be mistaken for drunkenness;[21] rapid breathing and sweating, cold, pale skin are characteristic of hypoglycemia but not definitive.[22] Mild to moderate cases are self-treated by eating or drinking something high in sugar. Severe cases can lead to unconsciousness and must be treated with intravenous glucose or injections with glucagon.

People (usually with type 1 DM) may also experience episodes of diabetic ketoacidosis, a metabolic disturbance characterized by nausea, vomiting and abdominal pain, the smell of acetone on the breath, deep breathing known as Kussmaul breathing, and in severe cases a decreased level of consciousness.[23]

A rare but equally severe possibility is hyperosmolar nonketotic state, which is more common in type 2 DM and is mainly the result of dehydration.[23]

## Complications

*Main article: Complications of diabetes mellitus*

All forms of diabetes increase the risk of long-term complications. These typically develop after many years (10–20) but may be the first symptom in those who have otherwise not received a diagnosis before that time.

The major long-term complications relate to damage to blood vessels. Diabetes doubles the risk of cardiovascular disease[24] and about 75% of deaths in diabetics are due to coronary artery disease.[25] Other "macrovascular" diseases are stroke, and peripheral vascular disease.

The primary complications of diabetes due to damage in small blood vessels include damage to the eyes, kidneys, and nerves.[26] Damage to the eyes, known as diabetic retinopathy, is caused by damage to the blood vessels in the retina of the eye, and can result in gradual vision loss and blindness.[26] Damage to the kidneys, known as diabetic nephropathy, can lead to tissue scarring, urine protein loss, and eventually chronic kidney disease, sometimes requiring dialysis or kidney transplant.[26] Damage to the nerves of the body, known as diabetic neuropathy, is the most common complication of diabetes.[26] The symptoms can include numbness, tingling, pain, and altered pain sensation, which can lead to damage to the skin.

Diabetes-related foot problems (such as diabetic foot ulcers) may occur, and can be difficult to treat, occasionally requiring amputation. Additionally, proximal diabetic neuropathy causes painful muscle wasting and weakness.

There is a link between cognitive deficit and diabetes. Compared to those without diabetes, those with the disease have a 1.2 to 1.5-fold greater rate of decline in cognitive function.[27]

# Causes

Diabetes mellitus is classified into four broad categories: type 1, type 2, gestational diabetes, and "other specific types".[5] The "other specific types" are a collection of a few dozen individual causes.[5] Diabetes is a more variable disease than once thought and people may have combinations of forms.[29] The term "diabetes", without qualification, usually refers to diabetes mellitus.

## Type 1

*Main article: Diabetes mellitus type 1*

Type 1 diabetes mellitus is characterized by loss of the insulin-producing beta cells of the islets of Langerhans in the pancreas, leading to insulin deficiency. This type can be further classified as immune-mediated or idiopathic. The majority of type 1 diabetes is of the immune-mediated nature, in which a T-cell-mediated autoimmune attack leads to the loss of beta cells and thus insulin.[30] It causes approximately 10% of diabetes mellitus cases in North America and Europe. Most affected people are otherwise healthy and of a healthy weight when onset occurs. Sensitivity and responsiveness to insulin are usually normal, especially in the early stages. Type 1 diabetes can affect children or adults, but was traditionally termed "juvenile diabetes" because a majority of these diabetes cases were in children.

"Brittle" diabetes, also known as unstable diabetes or labile diabetes, is a term that was traditionally used to describe the dramatic and recurrent swings in glucose levels, often occurring for no apparent reason in insulin-dependent diabetes. This term, however, has no biologic basis and should not be used.[31] Still, type 1 diabetes can be accompanied by irregular and unpredictable high blood sugar levels, frequently with ketosis, and sometimes with serious low blood sugar levels. Other complications include an impaired counterregulatory response to low blood sugar, infection, gastroparesis (which leads to erratic absorption of dietary carbohydrates), and endocrinopathies (e.g., Addison's disease).[31] These phenomena are believed to occur no more frequently than in 1% to 2% of persons with type 1 diabetes.[32]

Type 1 diabetes is partly inherited, with multiple genes, including certain HLA genotypes, known to influence the risk of diabetes. The increase of incidence of type 1 diabetes reflects the modern lifestyle.[33] In genetically susceptible people, the onset of diabetes can be triggered by one or more environmental factors,[34] such as a viral infection or diet. Several viruses have been implicated, but to date there is no stringent evidence to support this hypothesis in humans.[34][35] Among dietary factors, data suggest that gliadin (a protein present in gluten) may play a role in the development of type 1 diabetes, but the mechanism is not fully understood.[36][37]

## Type 2

*Main article: Diabetes mellitus type 2*

Type 2 DM is characterized by insulin resistance, which may be combined with relatively reduced insulin secretion.[5] The defective responsiveness of body tissues to insulin is believed to involve the insulin receptor. However, the specific defects are not known. Diabetes mellitus cases due to a known defect are classified separately. Type 2 DM is the most common type of diabetes mellitus.

In the early stage of type 2, the predominant abnormality is reduced insulin sensitivity. At this stage, high blood sugar can be reversed by a variety of measures and medications that improve insulin sensitivity or reduce the liver's glucose production.

Type 2 DM is due primarily to lifestyle factors and genetics.[38] A number of lifestyle factors are known to be important to the development of type 2 DM, including obesity (defined by a body mass index of greater than 30), lack of physical activity, poor diet, stress, and urbanization.[12] Excess body fat is associated with 30% of cases in those of Chinese and Japanese descent, 60–80% of cases in those of European and African descent, and 100% of Pima Indians and Pacific Islanders.[5] Even those who are not obese often have a high waist–hip ratio.[5]

Dietary factors also influence the risk of developing type 2 DM. Consumption of sugar-sweetened drinks in excess is associated with an increased risk.[39][40] The type of fats in the diet is also important, with saturated fats and trans fatty acids increasing the risk and polyunsaturated and monounsaturated fat decreasing the risk.[38] Eating lots of white rice also may increase the risk of diabetes.[41] A lack of exercise is believed to cause 7% of cases.[42]

## Gestational diabetes

*Main article: Gestational diabetes*

Gestational diabetes mellitus (GDM) resembles type 2 DM in several respects, involving a combination of relatively inadequate insulin secretion and responsiveness. It occurs in about 2–10% of all pregnancies and may improve or disappear after delivery.[43] However, after pregnancy approximately 5–10% of women with gestational diabetes are found to have diabetes mellitus, most commonly type 2.[43] Gestational diabetes is fully treatable, but requires careful medical supervision throughout the pregnancy. Management may include dietary changes, blood glucose monitoring, and in some cases, insulin may be required.

Though it may be transient, untreated gestational diabetes can damage the health of the fetus or mother. Risks to the baby include macrosomia (high birth weight), congenital heart and central nervous system abnormalities, and skeletal muscle malformations. Increased levels of insulin in a fetus's blood may inhibit fetal surfactant production and cause respiratory distress syndrome. A high blood bilirubin level may result from red blood cell destruction. In severe cases, perinatal death may occur, most commonly as a result of poor placental perfusion due to vascular impairment. Labor induction may be indicated with decreased placental function. A Caesarean section may be performed if there is marked fetal distress or an increased risk of injury associated with macrosomia, such as shoulder dystocia.[*citation needed*]

## Other types

Prediabetes indicates a condition that occurs when a person's blood glucose levels are higher than normal but not high enough for a diagnosis of type 2 DM. Many people destined to develop type 2 DM spend many years in a state of prediabetes.

Latent autoimmune diabetes of adults (LADA) is a condition in which type 1 DM develops in adults. Adults with LADA are frequently initially misdiagnosed as having type 2 DM, based on age rather than etiology.

Some cases of diabetes are caused by the body's tissue receptors not responding to insulin (even when insulin levels are normal, which is what separates it from type 2 diabetes); this form is very uncommon. Genetic mutations (autosomal or mitochondrial) can lead to defects in beta cell function. Abnormal insulin action may also have been genetically determined in some cases. Any disease that causes extensive damage to the pancreas may lead to diabetes (for example, chronic pancreatitis and cystic fibrosis). Diseases associated with excessive secretion of insulin-antagonistic hormones can cause diabetes (which is typically resolved once the hormone excess is removed). Many drugs impair insulin secretion and some toxins damage pancreatic beta cells. The ICD-10 (1992) diagnostic entity, *malnutrition-related diabetes*

*mellitus* (MRDM or MMDM, ICD-10 code E12), was deprecated by the World Health Organization when the current taxonomy was introduced in 1999.[44]

Other forms of diabetes mellitus include congenital diabetes, which is due to genetic defects of insulin secretion, cystic fibrosis-related diabetes, steroid diabetes induced by high doses of glucocorticoids, and several forms of monogenic diabetes.

"Type 3 diabetes" has been suggested as a term for Alzheimer's disease as the underlying processes may involve insulin resistance by the brain.[45]

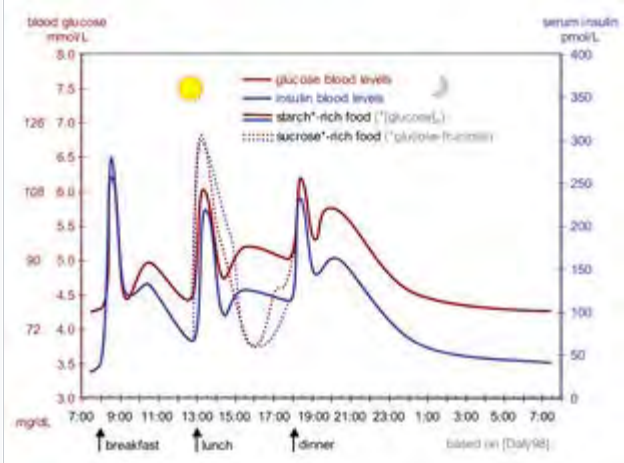
# Pathophysiology

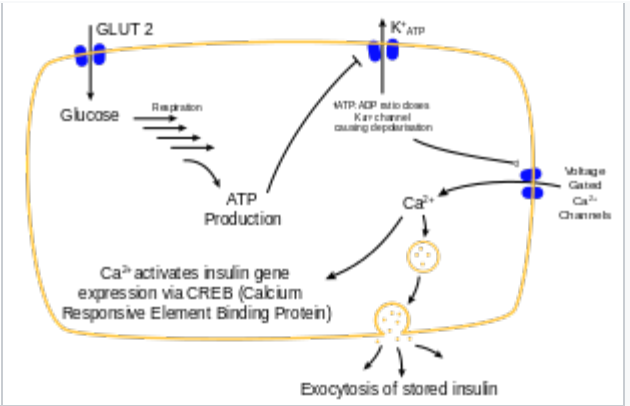
Insulin is the principal hormone that regulates the uptake of glucose from the blood into most cells of the body, especially liver, adipose tissue and muscle, except smooth muscle, in which insulin acts via the IGF-1. Therefore, deficiency of insulin or the insensitivity of its receptors plays a central role in all forms of diabetes mellitus.[48]

The body obtains glucose from three main places: the intestinal absorption of food, the breakdown of glycogen, the storage form of glucose found in the liver, and gluconeogenesis, the generation of glucose from non-carbohydrate substrates in the body.[49] Insulin plays a critical role in balancing glucose levels in the body. Insulin can inhibit the breakdown of glycogen or the process of gluconeogenesis, it can stimulate the transport of glucose into fat and muscle cells, and it can stimulate the storage of glucose in the form of glycogen.[49]

Insulin is released into the blood by beta cells (β-cells), found in the islets of Langerhans in the pancreas, in response to rising levels of blood glucose, typically after eating. Insulin is used by about two-thirds of the body's cells to absorb glucose from the blood for use as fuel, for conversion to other needed molecules, or for storage. Lower glucose levels result in decreased insulin release from the beta cells and in the breakdown of glycogen to glucose. This process is mainly controlled by the hormone glucagon,



The fluctuation of blood sugar (red) and the sugar-lowering hormone insulin (blue) in humans during the course of a day with three meals — one of the effects of a sugar-rich vs a starch-rich meal is highlighted.



Mechanism of insulin release in normal pancreatic beta cells — insulin production is more or less constant within the beta cells. Its release is triggered by food, chiefly food containing absorbable glucose.

which acts in the opposite manner to insulin.[50]

If the amount of insulin available is insufficient, if cells respond poorly to the effects of insulin (insulin insensitivity or insulin resistance), or if the insulin itself is defective, then glucose will not be absorbed properly by the body cells that require it, and it will not be stored appropriately in the liver and muscles. The net effect is persistently high levels of blood glucose, poor protein synthesis, and other metabolic derangements, such as acidosis.[49]

When the glucose concentration in the blood remains high over time, the kidneys will reach a threshold of reabsorption, and glucose will be excreted in the urine (glycosuria).[51] This increases the osmotic pressure of the urine and inhibits reabsorption of water by the kidney, resulting in increased urine production (polyuria) and increased fluid loss. Lost blood volume will be replaced osmotically from water held in body cells and other body compartments, causing dehydration and increased thirst (polydipsia).[49]

Diabetes mellitus is characterized by recurrent or persistent high blood sugar, and is diagnosed by demonstrating any one of the following:[44]

- Fasting plasma glucose level ≥ 7.0 mmol/l (126 mg/dl)
- Plasma glucose ≥ 11.1 mmol/l (200 mg/dl) two hours after a 75 g oral glucose load as in a glucose tolerance test
- Symptoms of high blood sugar and casual plasma glucose ≥ 11.1 mmol/l (200 mg/dl)
- Glycated hemoglobin ($HbA_{1C}$) ≥ 48 mmol/mol (≥ 6.5 DCCT %).[54]

A positive result, in the absence of unequivocal high blood sugar, should be confirmed by a repeat of any of the above methods on a different day. It is preferable to measure a fasting glucose level because of the ease of measurement and the considerable time commitment of formal glucose tolerance testing, which takes two hours to complete and offers no prognostic advantage over the fasting test.[55] According to the current definition, two fasting glucose measurements above 126 mg/dl (7.0 mmol/l) is considered diagnostic for diabetes mellitus.

Per the World Health Organization people with fasting glucose levels from 6.1 to 6.9 mmol/l (110 to 125 mg/dl) are considered to have impaired fasting glucose.[56] people with plasma glucose at or above

7.8 mmol/l (140 mg/dl), but not over 11.1 mmol/l (200 mg/dl), two hours after a 75 g oral glucose load are considered to have impaired glucose tolerance. Of these two prediabetic states, the latter in particular is a major risk factor for progression to full-blown diabetes mellitus, as well as cardiovascular disease.[57] The American Diabetes Association since 2003 uses a slightly different range for impaired fasting glucose of 5.6 to 6.9 mmol/l (100 to 125 mg/dl).[58]

Glycated hemoglobin is better than fasting glucose for determining risks of cardiovascular disease and death from any cause.[59]

The rare disease diabetes insipidus has similar symptoms to diabetes mellitus, but without disturbances in the sugar metabolism (*insipidus* means "without taste" in Latin) and does not involve the same disease mechanisms. Diabetes is a part of the wider condition known as metabolic syndrome.

# Prevention

*See also: Prevention of diabetes mellitus type 2*

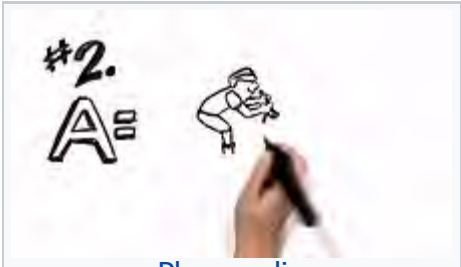
There is no known preventive measure for type 1 diabetes.[3] Type 2 diabetes — which accounts for 85-90% of all cases — can often be prevented or delayed by maintaining a normal body weight, engaging in physical exercise, and consuming a healthful diet.[3] Higher levels of physical activity (more than 90 minutes per day) reduce the risk of diabetes by 28%.[60] Dietary changes known to be effective in helping to prevent diabetes include maintaining a diet rich in whole grains and fiber, and choosing good fats, such as the polyunsaturated fats found in nuts, vegetable oils, and fish.[61] Limiting sugary beverages and eating less red meat and other sources of saturated fat can also help prevent diabetes.[61] Tobacco smoking is also associated with an increased risk of diabetes and its complications, so smoking cessation can be an important preventive measure as well.[62]

The relationship between type 2 diabetes and the main modifiable risk factors (excess weight, unhealthy diet, physical inactivity and tobacco use) is similar in all regions of the world. There is growing evidence that the underlying determinants of diabetes are a reflection of the major forces driving social, economic and cultural change: globalization, urbanization, population aging, and the general health policy environment.[63]

# Management

*Main article: Diabetes management*

Diabetes mellitus is a chronic disease, for which there is no known cure except in very specific situations.[64] Management concentrates on keeping blood sugar levels as close to normal, without causing low blood sugar. This can usually be accomplished with a healthy diet, exercise, weight loss, and use of appropriate medications (insulin in the case of type 1 diabetes; oral medications, as well as possibly insulin, in type 2 diabetes).



Play media
Overview of management

Learning about the disease and actively participating in the treatment is important, since complications are far less common and less severe in people who have well-managed blood sugar levels.[65][66] The goal of treatment is an $HbA_{1C}$ level of 6.5%, but should not be lower than that, and may be set higher.[67] Attention is also paid to other health problems that may accelerate the negative effects of diabetes. These include smoking, elevated cholesterol levels, obesity, high blood pressure, and lack of regular exercise.[67] Specialized footwear is widely used to reduce the risk of ulceration, or re-ulceration, in at-risk diabetic feet. Evidence for the efficacy of this remains equivocal, however.[68]

## Lifestyle

*See also: Diabetic diet*

People with diabetes can benefit from education about the disease and treatment, good nutrition to achieve a normal body weight, and exercise, with the goal of keeping both short-term and long-term blood glucose levels within acceptable bounds. In addition, given the associated higher risks of cardiovascular disease, lifestyle modifications are recommended to control blood pressure.[69]

## Medications

*See also: Anti-diabetic medication*

Medications used to treat diabetes do so by lowering blood sugar levels. There are a number of different classes of anti-diabetic medications. Some are available by mouth, such as metformin, while others are only available by injection such as GLP-1 agonists. Type 1 diabetes can only be treated with insulin, typically with a combination of regular and NPH insulin, or synthetic insulin analogs.[*citation needed*]

Metformin is generally recommended as a first line treatment for type 2 diabetes, as there is good evidence that it decreases mortality.[70] It works by decreasing the liver's production of glucose.[71] Several other groups of drugs, mostly given by mouth, may also decrease blood sugar in type II DM. These include agents that increase insulin release, agents that decrease absorption of sugar from the intestines, and agents that make the body more sensitive to insulin.[71] When insulin is used in type 2 diabetes, a long-acting formulation is usually added initially, while continuing oral medications.[70] Doses of insulin are then increased to effect.[70][72]

Since cardiovascular disease is a serious complication associated with diabetes, some have recommended blood pressure levels below 130/80 mmHg.[73] However, evidence supports less than or equal to somewhere between 140/90 mmHg to 160/100 mmHg; the only additional benefit found for blood pressure targets beneath this range was an isolated decrease in stroke risk, and this was accompanied by an increased risk of other serious adverse events.[74][75] A 2016 review found potential harm to treating lower than 140 mmHg.[76] Among medications that lower blood pressure, angiotensin converting enzyme inhibitors (ACEIs) improve outcomes in those with DM while the similar medications angiotensin receptor blockers (ARBs) do not.[77] Aspirin is also recommended for people with cardiovascular problems, however routine use of aspirin has not been found to improve outcomes in uncomplicated diabetes.[78]

## Surgery

A pancreas transplant is occasionally considered for people with type 1 diabetes who have severe complications of their disease, including end stage kidney disease requiring kidney transplantation.[79]

Weight loss surgery in those with obesity and type two diabetes is often an effective measure.[80] Many are able to maintain normal blood sugar levels with little or no medications following surgery[81] and long-term mortality is decreased.[82] There however is some short-term mortality risk of less than 1% from the surgery.[83] The body mass index cutoffs for when surgery is appropriate are not yet clear.[82] It is recommended that this option be considered in those who are unable to get both their weight and blood sugar under control.[84]

## Support

In countries using a general practitioner system, such as the United Kingdom, care may take place mainly outside hospitals, with hospital-based specialist care used only in case of complications, difficult blood sugar control, or research projects. In other circumstances, general practitioners and specialists share care in a team approach. Home telehealth support can be an effective management technique.[85]

# Epidemiology

*Main article: Epidemiology of diabetes mellitus*

As of 2016, 422 million people have diabetes worldwide,[86] up from an estimated 382 million people in 2013[13] and from 108 million in 1980.[86] Accounting for the shifting age structure of the global population, the prevalence of diabetes is 8.5% among adults, nearly double the rate of 4.7% in 1980.[86] Type 2 makes up about 90% of the cases.[12][14] Some data indicate rates are roughly equal in women and men,[14] but male excess in diabetes has been found in many populations with higher type 2 incidence, possibly due to sex-related differences in insulin sensitivity, consequences of obesity and regional body fat deposition, and other contributing factors such as high blood pressure, tobacco smoking, and alcohol intake.[87][88]

The World Health Organization (WHO) estimates that diabetes mellitus resulted in 1.5 million deaths in 2012, making it the 8th leading cause of death.[7][86] However another 2.2 million deaths worldwide were attributable to high blood glucose and the increased risks of cardiovascular disease and other associated complications (e.g. kidney failure), which often lead to premature death and are often listed as the underlying cause on death certificates rather than diabetes.[86][89] For example, in 2014, the International Diabetes Federation (IDF) estimated that diabetes resulted in 4.9 million deaths worldwide,[15] using modeling to estimate the total amount of deaths that could be directly or indirectly attributed to diabetes.[16]

Diabetes mellitus occurs throughout the world but is more common (especially type 2) in more developed countries. The greatest increase in rates has however been seen in low- and middle-income countries,[86] where more than 80% of diabetic deaths occur.[90] The fastest prevalence increase is expected to occur in Asia and Africa, where most people with diabetes will probably live in 2030.[91] The increase in rates in developing countries follows the trend of urbanization and lifestyle changes, including increasingly sedentary lifestyles, less physically demanding work and the global nutrition transition, marked by increased intake of foods that are high energy-dense but nutrient-poor (often high in sugar and saturated fats, sometimes referred to as the "Western-style" diet).[86][91]

# History

*Main article: History of diabetes*

Diabetes was one of the first diseases described,[92] with an Egyptian manuscript from c. 1500 BCE mentioning "too great emptying of the urine".[93] The Ebers papyrus includes a recommendation for a drink to be taken in such cases.[94] The first described cases are believed to be of type 1 diabetes.[93] Indian physicians around the same time identified the disease and classified it as *madhumeha* or "honey urine", noting the urine would attract ants.[93][94]

The term "diabetes" or "to pass through" was first used in 230 BCE by the Greek Apollonius of Memphis.[93] The disease was considered rare during the time of the Roman empire, with Galen commenting he had only seen two cases during his career.[93] This is possibly due to the diet and lifestyle of the ancients, or because the clinical symptoms were observed during the advanced stage of the disease. Galen named the disease "diarrhea of the urine" (diarrhea urinosa).[95]

The earliest surviving work with a detailed reference to diabetes is that of Aretaeus of Cappadocia (2nd or early 3rd century CE). He described the symptoms and the course of the disease, which he attributed to the moisture and coldness, reflecting the beliefs of the "Pneumatic School". He hypothesized a correlation of diabetes with other diseases and he discussed differential diagnosis from the snakebite which also provokes excessive thirst. His work remained unknown in the West until 1552, when the first Latin edition was published in Venice.[95]

Type 1 and type 2 diabetes were identified as separate conditions for the first time by the Indian physicians Sushruta and Charaka in 400-500 CE with type 1 associated with youth and type 2 with being overweight.[93] The term "mellitus" or "from honey" was added by the Briton John Rolle in the late 1700s to separate the condition from diabetes insipidus, which is also associated with frequent urination.[93] Effective treatment was not developed until the early part of the 20th century, when Canadians Frederick Banting and Charles Herbert Best isolated and purified insulin in 1921 and 1922.[93] This was followed by the development of the long-acting insulin NPH in the 1940s.[93]

### Etymology

The word *diabetes* (/ˌdaɪ.əˈbiːtiːz/ or /ˌdaɪ.əˈbiːtɪs/) comes from Latin *diabētēs*, which in turn comes from Ancient Greek διαβήτης (*diabētēs*) which literally means "a passer through; a siphon."[96] Ancient Greek physician Aretaeus of Cappadocia (fl. 1st century CE) used that word, with the intended meaning "excessive discharge of urine", as the name for the disease.[97][98] Ultimately, the word comes from Greek διαβαίνειν (*diabainein*), meaning "to pass through,"[96] which is composed of δια- (*dia-*), meaning "through" and βαίνειν (*bainein*), meaning "to go".[97] The word "diabetes" is first recorded in English, in the form *diabete*, in a medical text written around 1425.

The word *mellitus* (/mɪˈlaɪtəs/ or /ˈmɛlɪtəs/) comes from the classical Latin word *mellītus*, meaning "mellite"[99] (i.e. sweetened with honey;[99] honey-sweet[100]). The Latin word comes from *mell-*, which comes from *mel*, meaning "honey";[99][100] sweetness;[100] pleasant thing,[100] and the suffix *-ītus*,[99] whose meaning is the same as that of the English suffix "-ite".[101] It was Thomas Willis who in 1675 added "mellitus" to the word "diabetes" as a designation for the disease, when he noticed the urine of a diabetic had a sweet taste (glycosuria). This sweet taste had been noticed in urine by the ancient Greeks, Chinese, Egyptians, Indians, and Persians.

## Society and culture

The 1989 "St. Vincent Declaration"[102][103] was the result of international efforts to improve the care accorded to those with diabetes. Doing so is important not only in terms of quality of life and life expectancy but also economically—expenses due to diabetes have been shown to be a major drain on health—and productivity-related resources for healthcare systems and governments.

Several countries established more and less successful national diabetes programmes to improve treatment of the disease.[104]

People with diabetes who have neuropathic symptoms such as numbness or tingling in feet or hands are twice as likely to be unemployed as those without the symptoms.[105]

In 2010, diabetes-related emergency room (ER) visit rates in the United States were higher among people from the lowest income communities (526 per 10,000 population) than from the highest income

communities (236 per 10,000 population). Approximately 9.4% of diabetes-related ER visits were for the uninsured.[106]

### Naming

The term "type 1 diabetes" has replaced several former terms, including childhood-onset diabetes, juvenile diabetes, and insulin-dependent diabetes mellitus (IDDM). Likewise, the term "type 2 diabetes" has replaced several former terms, including adult-onset diabetes, obesity-related diabetes, and noninsulin-dependent diabetes mellitus (NIDDM). Beyond these two types, there is no agreed-upon standard nomenclature.

Diabetes mellitus is also occasionally known as "sugar diabetes" to differentiate it from diabetes insipidus.[107]

## Other animals

*Main articles: Diabetes in dogs and Diabetes in cats*

In animals, diabetes is most commonly encountered in dogs and cats. Middle-aged animals are most commonly affected. Female dogs are twice as likely to be affected as males, while according to some sources, male cats are also more prone than females. In both species, all breeds may be affected, but some small dog breeds are particularly likely to develop diabetes, such as Miniature Poodles.[108] The symptoms may relate to fluid loss and polyuria, but the course may also be insidious. Diabetic animals are more prone to infections. The long-term complications recognized in humans are much rarer in animals. The principles of treatment (weight loss, oral antidiabetics, subcutaneous insulin) and management of emergencies (e.g. ketoacidosis) are similar to those in humans.[108]

## Research

Inhalable insulin has been developed.[109] The original products were withdrawn due to side effects.[109] Afrezza, under development by pharmaceuticals company MannKind Corporation, was approved by the FDA for general sale in June 2014.[110] An advantage to inhaled insulin is that it may be more convenient and easy to use.[111]

Transdermal insulin in the form of a cream has been developed and trials are being conducted on people with type 2 diabetes.[112][113]

# Diabetes mellitus type 1

From Wikipedia, the free encyclopedia
(Redirected from DM type 1)

**Diabetes mellitus type 1** (also known as **type 1 diabetes**) is a form of diabetes mellitus in which not enough insulin is produced.[4] The lack of insulin results in high blood sugar levels.[1] The classical symptoms are frequent urination, increased thirst, increased hunger, and weight loss.[4] Additional symptoms may include blurry vision, feeling tired, and poor healing.[2] Symptoms typically develop over a short period of time.[1]

The cause of type 1 diabetes is unknown.[4] It however is believed to involve a combination of genetic and environmental factors.[1] Risk factors include having a family member with the condition.[5] The underlying mechanism involves an autoimmune destruction of the insulin-producing beta cells in the pancreas.[2] Diabetes is diagnosed by testing the level of sugar or A1C in the blood.[5][6] Type 1 diabetes may be distinguished from type 2 by autoantibody testing.[5]

There is no known way to prevent type 1 diabetes.[4] Treatment with insulin is typically required for survival.[1] Insulin therapy is usually given by injection just under the skin but can also be delivered by an insulin pump.[7] A diabetic diet and exercise are an important part of management.[2] Untreated, diabetes can cause many complications.[4] Complications of relatively rapid onset include diabetic ketoacidosis and nonketotic hyperosmolar coma.[5] Long-term complications include heart disease, stroke, kidney failure, foot ulcers and damage to the eyes.[4] Furthermore, complications may arise from low blood sugar caused by excessive insulin treatment.[5]

Type 1 diabetes makes up an estimated 5–10% of all diabetes cases.[8] The number of people affected globally is unknown, although it is estimated that about 80,000 children develop the disease each year.[5] Within the United States the number of people affected is estimated at one to three million.[5][9] Rates of disease vary widely with approximately 1 new case per 100,000 per year in East Asia and Latin America and around 30 new cases per 100,000 per year in Scandinavia and Kuwait.[10][11] It typically begins in children and young adults.[1]

Video explanation of the various types of diabetes

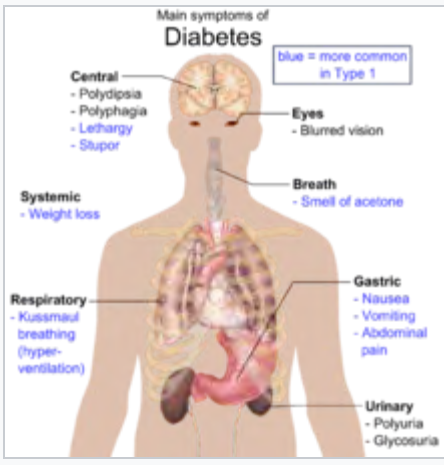
## Signs and symptoms [edit]

The classical symptoms of type 1 diabetes include: polyuria (excessive urination), polydipsia (increased thirst), dry mouth, polyphagia (increased hunger), fatigue, and weight loss.[4]

Many type 1 diabetics are diagnosed when they present with diabetic ketoacidosis. The signs and symptoms of diabetic ketoacidosis include dry skin, rapid deep breathing, drowsiness, increased thirst, frequent urination, abdominal pain, and vomiting.[12]

About 12 percent of people with type 1 diabetes have clinical depression.[13]

About 6 percent of people with type 1 diabetes have celiac disease, but in most cases there are no digestive symptoms[14][15] or are mistakenly attributed to poor control of diabetes, gastroparesis or diabetic neuropathy.[14] In most cases, celiac disease is diagnosed after onset of type 1 diabetes. The association of celiac disease with type 1 diabetes increases the risk of complications, such as retinopathy and mortality. This association can be explained by shared genetic factors, and inflammation or nutritional deficiencies caused by untreated celiac disease, even if type 1 diabetes is diagnosed first.[15]



Overview of the most significant symptoms of diabetes

## Cause [edit]

The cause of type 1 diabetes is unknown.[4] A number of explanatory theories have been put forward, and

the cause may be one or more of the following: genetic susceptibility, a diabetogenic trigger, and exposure to an antigen.[16]

## Genetics [edit]

*Main article: Genetic causes of diabetes mellitus type 1*

Type 1 diabetes is a disease that involves many genes. The risk of a child developing type 1 diabetes is about 5% if the father has it, about 8% if a sibling has it, about 3% if the mother has type 1 diabetes.[17] If one identical twin is affected there is about a 50% chance the other will also be affected.[18] Some studies of heritability has estimated it at 80 to 86%.[19][20]

More than 50 genes are associated with type 1 diabetes.[21] Depending on locus or combination of loci, they can be dominant, recessive, or somewhere in between. The strongest gene, *IDDM1*, is located in the MHC Class II region on chromosome 6, at staining region 6p21. Certain variants of this gene increase the risk for decreased histocompatibility characteristic of type 1. Such variants include DRB1 0401, DRB1 0402, DRB1 0405, DQA 0301, DQB1 0302 and DQB1 0201, which are common in North Americans of European ancestry and in Europeans.[22] Some variants also appear to be protective.[22]

## Environmental [edit]

Environmental factors can influence expression of type 1. For identical twins, when one twin has type 1 diabetes, the other twin only has it 30%–50% of the time. Thus for 50%-70% of identical twins where one has the disease, the other will not, despite having exactly the same genome; this suggests environmental factors, in addition to genetic factors, can influence the disease's prevalence.[23] Other indications of environmental influence include the presence of a 10-fold difference in occurrence among Caucasians living in different areas of Europe, and that people tend to acquire the rate of disease of their particular destination country.[16]

### Virus [edit]

One theory proposes that type 1 diabetes is a virus-triggered autoimmune response in which the immune system attacks virus-infected cells along with the beta cells in the pancreas.[24][25] Several viruses have been implicated, including enteroviruses (especially coxsackievirus B), cytomegalovirus, Epstein–Barr virus, mumps virus, rubella virus and rotavirus, but to date there is no stringent evidence to support this hypothesis in humans.[26] A 2011 systematic review and meta-analysis showed an association between enterovirus infections and type 1 diabetes, but other studies have shown that, rather than triggering an autoimmune process, enterovirus infections, as coxsackievirus B, could protect against onset and development of type 1 diabetes.[27]

## Chemicals and drugs [edit]

Some chemicals and drugs selectively destroy pancreatic cells. Pyrinuron (Vacor), a rodenticide introduced in the United States in 1976, selectively destroys pancreatic beta cells, resulting in type 1 diabetes after accidental poisoning.[28] Pyrinuron was withdrawn from the U.S. market in 1979 and it is not approved by the Environmental Protection Agency for use in the U.S.[29] Streptozotocin (Zanosar), an antineoplastic agent, is selectively toxic to the beta cells of the pancreatic islets. It is used in research for inducing type 1 diabetes on rodents[30] and for treating metastatic cancer of the pancreatic islet cells in patients whose cancer cannot be removed by surgery.[31] Other pancreatic problems, including trauma, pancreatitis, or tumors (either malignant or benign) can also lead to loss of insulin production.

## Gluten [edit]

Data suggest that gliadin (a protein present in gluten) may play a role in the development of type 1 diabetes, but the mechanism is not fully understood.[32][33] Increased intestinal permeability caused by

gluten and the subsequent loss of intestinal barrier function, which allows the passage of pro-inflammatory substances into the blood, may induce the autoimmune response in genetically predisposed individuals to type 1 diabetes.[15][33] Early introduction of gluten-containing cereals in the diet increases the risk of developing islet cell autoantibodies, which are responsible for the destruction of the insulin-producing beta cells in the pancreas.[33]

## Pathophysiology [edit]

The pathophysiology in diabetes type 1 is a destruction of beta cells in the pancreas, regardless of which risk factors or causative entities have been present.

Individual risk factors can have separate pathophysiological processes to, in turn, cause this beta cell destruction. Still, a process that appears to be common to most risk factors is an autoimmune response towards beta cells, involving an expansion of autoreactive CD4+ T helper cells and CD8+ T cells, autoantibody-producing B cells and activation of the innate immune system.[22][34]

After starting treatment with insulin a person's own insulin levels may temporarily improve.[35] This is believed to be due to altered immunity and is known as the "honeymoon phase".[35]

## Diagnosis [edit]

**WHO diabetes diagnostic criteria**[36][37] edit

| Condition | 2 hour glucose | Fasting glucose | $HbA_{1c}$ | |
|---|---|---|---|---|
| Unit | mmol/l(mg/dl) | mmol/l(mg/dl) | mmol/mol | DCCT % |
| Normal | <7.8 (<140) | <6.1 (<110) | <42 | <6.0 |
| Impaired fasting glycaemia | <7.8 (<140) | ≥6.1(≥110) & <7.0(<126) | 42-46 | 6.0–6.4 |
| Impaired glucose tolerance | ≥7.8 (≥140) | <7.0 (<126) | 42-46 | 6.0–6.4 |
| Diabetes mellitus | ≥11.1 (≥200) | ≥7.0 (≥126) | ≥48 | ≥6.5 |

Diabetes mellitus is characterized by recurrent or persistent hyperglycemia, and is diagnosed by demonstrating any one of the following:[38]

- Fasting plasma glucose level at or above 7.0 mmol/L (126 mg/dL).
- Plasma glucose at or above 11.1 mmol/L (200 mg/dL) two hours after a 75 g oral glucose load as in a glucose tolerance test.
- Symptoms of hyperglycemia and casual plasma glucose at or above 11.1 mmol/L (200 mg/dL).
- Glycated hemoglobin (hemoglobin A1C) at or above 48 mmol/mol (≥ 6.5 DCCT %). (This criterion was recommended by the American Diabetes Association in 2010, although it has yet to be adopted by the WHO.)[39]

About a quarter of people with new type 1 diabetes have developed some degree of diabetic ketoacidosis (a type of metabolic acidosis which is caused by high concentrations of ketone bodies, formed by the breakdown of fatty acids and the deamination of amino acids) by the time the diabetes is recognized. The diagnosis of other types of diabetes is usually made in other ways. These include ordinary health screening, detection of hyperglycemia during other medical investigations, and secondary symptoms such as vision changes or unexplained fatigue. Diabetes is often detected when a person suffers a problem that may be caused by diabetes, such as a heart attack, stroke, neuropathy, poor wound healing or a foot ulcer, certain eye problems, certain fungal infections, or delivering a baby with macrosomia or hypoglycemia (low blood sugar).

A positive result, in the absence of unequivocal hyperglycemia, should be confirmed by a repeat of any of

the above-listed methods on a different day. Most physicians prefer to measure a fasting glucose level because of the ease of measurement and the considerable time commitment of formal glucose tolerance testing, which takes two hours to complete and offers no prognostic advantage over the fasting test.[40] According to the current definition, two fasting glucose measurements above 126 mg/dL (7.0 mmol/L) is considered diagnostic for diabetes mellitus.

In type 1, pancreatic beta cells in the islets of Langerhans are destroyed, decreasing endogenous insulin production. This distinguishes type 1's origin from type 2. Type 2 diabetes is characterized by insulin resistance, while type 1 diabetes is characterized by insulin deficiency, generally without insulin resistance. Another hallmark of type 1 diabetes is islet autoreactivity, which is generally measured by the presence of autoantibodies directed towards the beta cells.

### Autoantibodies [edit]

The appearance of diabetes-related autoantibodies has been shown to be able to predict the appearance of diabetes type 1 before any hyperglycemia arises, the main ones being islet cell autoantibodies, insulin autoantibodies, autoantibodies targeting the 65-kDa isoform of glutamic acid decarboxylase (GAD), autoantibodies targeting the phosphatase-related IA-2 molecule, and zinc transporter autoantibodies (ZnT8).[16] By definition, the diagnosis of diabetes type 1 can be made first at the appearance of clinical symptoms and/or signs, but the emergence of autoantibodies may itself be termed "latent autoimmune diabetes". Not everyone with autoantibodies progresses to diabetes type 1, but the risk increases with the number of antibody types, with three to four antibody types giving a risk of progressing to diabetes type 1 of 60%–100%.[16] The time interval from emergence of autoantibodies to clinically diagnosable diabetes can be a few months in infants and young children, but in some people it may take years – in some cases more than 10 years.[16] Islet cell autoantibodies are detected by conventional immunofluorescence, while the rest are measured with specific radiobinding assays.[16]

## Prevention [edit]

Type 1 diabetes is not currently preventable.[41] Some researchers believe it might be prevented at the latent autoimmune stage, before it starts destroying beta cells.[22]

### Immunosuppressive drugs [edit]

Cyclosporine A, an immunosuppressive agent, has apparently halted destruction of beta cells (on the basis of reduced insulin usage), but its kidney toxicity and other side effects make it highly inappropriate for long-term use.[22]

Anti-CD3 antibodies, including teplizumab and otelixizumab, had suggested evidence of preserving insulin production (as evidenced by sustained C-peptide production) in newly diagnosed type 1 diabetes patients.[22] A probable mechanism of this effect was believed to be preservation of regulatory T cells that suppress activation of the immune system and thereby maintain immune system homeostasis and tolerance to self-antigens.[22] The duration of the effect is still unknown, however.[22] In 2011, Phase III studies with otelixizumab and teplizumab both failed to show clinical efficacy, potentially due to an insufficient dosing schedule.[42][43]

An anti-CD20 antibody, rituximab, inhibits B cells and has been shown to provoke C-peptide responses three months after diagnosis of type 1 diabetes, but long-term effects of this have not been reported.[22]

### Diet [edit]

Some research has suggested breastfeeding decreases the risk in later life[44][45] and early introduction of gluten-containing cereals in the diet increases the risk of developing islet cell autoantibodies;[33] various other nutritional risk factors are being studied, but no firm evidence has been found.[46] Giving children 2000 IU of vitamin D daily during their first year of life is associated with reduced risk of type 1 diabetes,

though the causal relationship is obscure.[47]

Children with antibodies to beta cell proteins (i.e. at early stages of an immune reaction to them) but no overt diabetes, and treated with niacinamide (vitamin $B_3$), had less than half the diabetes onset incidence in a seven-year time span than did the general population, and an even lower incidence relative to those with antibodies as above, but who received no niacinamide.[48]

People with type 1 diabetes and undiagnosed celiac disease have worse glycaemic control and a higher prevalence of nephropathy and retinopathy. Gluten-free diet, when performed strictly, improves diabetes symptoms and appears to have a protective effect against developing long-term complications. Nevertheless, dietary management of both these diseases is challenging and these patients have poor compliance of the diet.[49]

## Management [edit]

*Further information: Diabetes management*

### Lifestyle [edit]

A low-carbohydrate diet, in addition to medications, is useful in type 1 DM.[50] There are camps for children to teach them how and when to use or monitor their insulin without parental help.[51] As psychological stress may have a negative effect on diabetes, a number of measures have been recommended including: exercising, taking up a new hobby, or joining a charity among others.[52]

### Insulin [edit]

*Main article: Insulin therapy*

There are four main types of insulin: rapid acting insulin, short acting insulin, intermediate acting insulin, and long acting insulin. The rapid acting insulin is used as a bolus dosage. The action onsets in 15 minutes with peak actions in 30 to 90 minutes. Short acting insulin action onsets within 30 minutes with the peak action around 2 to 4 hours. Intermediate acting insulin action onsets within 1 to 2 hours with peak action of 4 to 10 hours. Long acting insulin is usually given once per day. The action onset is roughly 1 to 2 hours with a sustained action of up to 24 hours.

Injections of insulin—either via subcutaneous injection or insulin pump— are necessary for those living with type 1 diabetes because it cannot be treated by diet and exercise alone.[53] In addition to insulin therapy dietary management is important. This includes keeping track of the carbohydrate content of food and careful monitoring of blood glucose levels using glucose meters. Today, the most common insulins are biosynthetic products produced using genetic recombination techniques; formerly, cattle or pig insulins were used, and even sometimes insulin from fish.[54]

Untreated type 1 diabetes can commonly lead to diabetic ketoacidosis which is a diabetic coma which can be fatal if untreated.[55] Diabetic ketoacidosis can cause cerebral edema (accumulation of liquid in the brain). This is a life-threatening issue and children are at a higher risk for cerebral edema than adults, causing ketoacidosis to be the most common cause of death in pediatric diabetes.[56]

Treatment of diabetes focuses on lowering blood sugar or glucose (BG) to the near normal range, approximately 80–140 mg/dl (4.4–7.8 mmol/L).[57] The ultimate goal of normalizing BG is to avoid long-term complications that affect the nervous system (e.g. peripheral neuropathy leading to pain and/or loss of feeling in the extremities), and the cardiovascular system (e.g. heart attacks, vision loss). This level of control over a prolonged period of time can be varied by a target $HbA_{1c}$ level of less than 7.5%.[5]

People with type 1 diabetes always need to use insulin, but treatment can lead to low BG (hypoglycemia), i.e. BG less than 70 mg/dl (3.9 mmol/l). Hypoglycemia is a very common occurrence in people with diabetes, usually the result of a mismatch in the balance among insulin, food and physical activity. Mild cases are self-treated by eating or drinking something high in sugar. Severe cases can lead to

unconsciousness and are treated with intravenous glucose or injections with glucagon. Continuous glucose monitors can alert patients to the presence of dangerously high or low blood sugar levels, but technical issues have limited the effect these devices have had on clinical practice.[*citation needed*]

As of 2016 an artificial pancreas looks promising with safety issues still being studied.[58]

### Pancreas transplantation [edit]

*Main article: Pancreas transplantation*

In some cases, a pancreas transplant can restore proper glucose regulation. However, the surgery and accompanying immunosuppression required may be more dangerous than continued insulin replacement therapy, so is generally only used with or some time after a kidney transplant. One reason for this is that introducing a new kidney requires taking immunosuppressive drugs such as cyclosporine. Nevertheless, this allows the introduction of a new pancreas to a person with diabetes without any additional immunosuppressive therapy. However, pancreas transplants alone may be beneficial in people with extremely labile type 1 diabetes mellitus.[59]

### Islet cell transplantation [edit]

*Main article: Islet cell transplantation*

Islet cell transplantation may be an option for some people with type 1 diabetes that are not well controlled with insulin.[60] Difficulties include finding donors that are a compatible, getting the new islets to survive, and the side effects from the medications used to prevent rejection.[60] Success rates, defined as not needing insulin at 3 years follow the procedure occurred in 44% in on registry from 2010.[60]

## Complications [edit]

*Further information: Complications of diabetes mellitus*

Complications of poorly managed type 1 diabetes mellitus may include cardiovascular disease, diabetic neuropathy, and diabetic retinopathy, among others. However, cardiovascular disease[61] as well as neuropathy[62] may have an autoimmune basis, as well. Women with type 1 DM have a 40% higher risk of death as compared to men with type 1 DM.[63] The life expectancy of an individual with type 1 diabetes is 11 years less for men and 14 years less for women.[64]

### Urinary tract infection [edit]

People with diabetes show an increased rate of urinary tract infection.[65] The reason is bladder dysfunction that is more common in diabetics than in non-diabetics due to diabetic nephropathy. When present, nephropathy can cause a decrease in bladder sensation, which in turn, can cause increased residual urine, a risk factor for urinary tract infections.[66]

### Sexual dysfunction [edit]

Sexual dysfunction in diabetics is often a result of physical factors such as nerve damage and/or poor circulation, and psychological factors such as stress and/or depression caused by the demands of the disease.[67][68]

#### Males [edit]

The most common sexual issues in diabetic males are problems with erections and ejaculation: "With diabetes, blood vessels supplying the penis's erectile tissue can get hard and narrow, preventing the adequate blood supply needed for a firm erection. The nerve damage caused by poor blood glucose control can also cause ejaculate to go into the bladder instead of through the penis during ejaculation, called

retrograde ejaculation. When this happens, semen leaves the body in the urine."[67] Another cause for erectile dysfunction are the reactive oxygen species created as a result of the disease. Antioxidants can be used to help combat this.[69]

### Females [edit]

While there is less material on the correlation between diabetes and female sexual dysfunction than male sexual dysfunction, studies have shown there to be a significant prevalence of sexual problems in diabetic women.[68] Common problems include reduced sensation in the genitals, dryness, difficulty/inability to orgasm, pain during sex, and decreased libido.[67] In some cases diabetes has been shown to decrease oestrogen levels in females, which can affect vaginal lubrication.[68]

Oral contraceptives can be taken by diabetics. Sometimes, contraceptive pills can cause a blood sugar imbalance, but this usually can be corrected by a dosage change.[68] As with any medication, side effects should be taken into account and monitored to prevent serious complications with diabetes.[68]

Women with type 1 diabetes show a higher than normal rate of polycystic ovarian syndrome (PCOS).[70] The reason may be that the ovaries are exposed to high insulin concentrations since women with type 1 diabetes can have frequent hyperglycemia.[71]

## Epidemiology [edit]

Type 1 diabetes makes up an estimated 5–10% of all diabetes cases[8] or 11–22 million worldwide.[41] In 2006 it affected 440,000 children under 14 years of age and was the primary cause of diabetes in those less than 10 years of age.[72] The incidence of type 1 diabetes has been increasing by about 3% per year.[72]

Rates vary widely by country. In Finland, the incidence is a high of 57 per 100,000 per year, in Japan and China a low of 1 to 3 per 100,000 per year, and in Northern Europe and the U.S., an intermediate of 8 to 17 per 100,000 per year.[73][74]

In the United States, type 1 diabetes affected about 208,000 youths under the age of 20 in 2015. Over 18,000 youths are diagnosed with Type 1 diabetes every year. Compared to non-Hispanic whites, Asian Americans, Hispanic Americans and Hispanic-Black Americans have greater odds of being diagnosed with diabetes. Every year about 234,051 Americans die due to diabetes or diabetes-related complications, with 69,071 having it as the primary cause of death.[75]

## History [edit]

Type 1 diabetes was described as an autoimmune disease in the 1970s, based on observations that autoantibodies against islets were discovered in diabetics with other autoimmune deficiencies.[76] It was also shown in the 1980s that immunosuppressive therapies could slow disease progression, further supporting the idea that type 1 diabetes is an autoimmune disorder.[77] The name *juvenile diabetes* was used earlier as it often first is diagnosed in childhood.

In Australia, approximately one million Australians have been diagnosed with type 1 diabetes and Australia ranks 7th-highest in the world with children under 14 years of age. Between 2000 and 2013, 31,895 new cases were established, with 2,323 in 2013, a rate of 10–13 cases per 100,00 people each year. Aboriginals and Torres Strait Islander people are less affected.[78][79]

## Society and culture [edit]

*See also: List of people with diabetes mellitus type 1*

The disease was estimated to cause $10.5 billion in annual medical costs ($875 per month per diabetic) and an additional $4.4 billion in indirect costs ($366 per month per person with diabetes) in the U.S.[80] In the United States $245 billion every year is attributed to diabetes. Individuals diagnosed with diabetes have 2.3 times the health care costs as individuals who do not have diabetes. One in 10 health care dollars are spent on individuals with diabetes.[75]

## Research [edit]

Funding for research into type 1 diabetes originates from government, industry (e.g., pharmaceutical companies), and charitable organizations. Government funding in the United States is distributed via the National Institute of Health, and in the UK via the National Institute for Health Research or the Medical Research Council. JDRF, originally founded by parents of children with type 1 diabetes, is the world's largest provider of charity based funding for type 1 diabetes research. Other charities include the American Diabetes Association, Diabetes UK, Diabetes Research and Wellness Foundation,[81] Diabetes Australia, the Canadian Diabetes Association.

### Treatments [edit]

A number of approaches have been explored to provide treatments for type 1.

### Stem cells [edit]

Pluripotent stem cells can be used to generate beta cells but previously these cells did not function as well as normal beta cells.[82] In 2014 more mature beta cells were produced which released insulin in response to blood sugar when transplanted into mice.[83][84] Before these techniques can be used in humans more evidence of safety and effectiveness is needed.[82]

### Vaccine [edit]

Vaccines to treat or prevent Type 1 diabetes are designed to induce immune tolerance to insulin or pancreatic beta cells.[85] While Phase II clinical trials of a vaccine containing alum and recombinant GAD65, an autoantigen involved in type 1 diabetes, were promising, as of 2014 Phase III had failed.[85] As of 2014, other approaches, such as a DNA vaccine encoding proinsulin and a peptide fragment of insulin, were in early clinical development.[85]

### Diet [edit]

There is evidence from experiments conducted in animal models that removal of gluten from the diet may prevent the onset type 1 diabetes[32][86] but there has been conflicting research in humans.[86]

## Labile diabetes [edit]

Insulin-dependent diabetes characterized by dramatic and recurrent swings in glucose levels, often occurring for no apparent reason, is sometimes known as brittle diabetes, unstable diabetes or labile diabetes, although some experts say the "brittle diabetes" concept "has no biologic basis and should not be used".[87] The results of such swings can be irregular and unpredictable hyperglycemias, sometimes involving ketoacidosis, and sometimes serious hypoglycemias. Brittle diabetes occurs no more frequently than in 1% to 2% of diabetics.[88] In a small study, 10 of 20 brittle diabetic patients aged 18–23 years who could be traced had died within 22 years, and the remainder, though suffering high rates of complications, were no longer brittle.[89] These results were similar to those of an earlier study by the same authors which found a 19% mortality in 26 patients after 10.5 years.[90]

Because labile diabetes is defined as "episodes of hypoglycemia or hyperglycemia that, whatever their [91]

cause, constantly disrupt a patient's life", it can have many causes, some of which include:

- errors in diabetes management, which can include too much insulin being given, in relation to carbohydrate being consumed
- interactions with other medical conditions
- psychological problems
- biological factors that interfere with how insulin is processed within the body
- hypoglycemia and hyperglycemia due to strenuous exercise; however, hypoglycemia is more frequent
- insulin exposed to higher temperatures that reduces effectiveness of the insulin hormone in the body
- spontaneous production of insulin in the body due to activity in the beta cells during the period shortly after diagnosis of type 1 diabetes

Exercise related hyperglycemia is caused when hormones (such as adrenaline and cortisol) are released during moderate to strenuous exercise. This happens when the muscles signal the liver to release glucose into the bloodstream by converting stored glycogen into glucose. The cause of exercise related hypoglycemia, on the other hand, occurs when the muscle group being exercised uses up glucose faster than it can be replenished by the body.

One of these biological factors is the production of insulin autoantibodies. High antibody titers can cause episodes of hyperglycemia by neutralizing the insulin, thereby causing clinical insulin resistance requiring doses of over 200 IU/day. However, antibodies may also fail to buffer the release of the injected insulin into the bloodstream after subcutaneous injection, resulting in episodes of hypoglycemia. In some cases, changing the type of insulin administered can resolve this problem.[91] There have been a number of reports that insulin autoantibodies can act as a "sink" for insulin and affect the time to peak, half-life, distribution space, and metabolic clearance, though in most patients these effects are small.[92]

# Diabetes mellitus type 2

From Wikipedia, the free encyclopedia

(Redirected from DM type 2)

**Diabetes mellitus type 2** (also known as **type 2 diabetes**) is a long term metabolic disorder that is characterized by high blood sugar, insulin resistance, and relative lack of insulin.[3] Common symptoms include increased thirst, frequent urination, and unexplained weight loss. Symptoms may also include increased hunger, feeling tired, and sores that do not heal.[4] Often symptoms come on slowly.[3] Long-term complications from high blood sugar include heart disease, strokes, diabetic retinopathy which can result in blindness, kidney failure, and poor blood flow in the limbs which may lead to amputations.[1] The sudden onset of hyperosmolar hyperglycemic state may occur; however, ketoacidosis is uncommon.[5][6]

Type 2 diabetes primarily occurs as a result of obesity and not enough exercise.[1] Some people are more genetically at risk than others.[3] Type 2 diabetes makes up about 90% of cases of diabetes, with the other 10% due primarily to diabetes mellitus type 1 and gestational diabetes.[1] In diabetes mellitus type 1 there is an absolute lack of insulin due to breakdown of islet cells in the pancreas.[7] Diagnosis of diabetes is by blood tests such as fasting plasma glucose, oral glucose tolerance test, or A1C.[4]

Type 2 diabetes is partly preventable by staying a normal weight, exercising regularly, and eating properly. Treatment involves exercise and dietary changes.[1] If blood sugar levels are not adequately lowered, the medication metformin is typically recommended.[8][9] Many people may eventually also require insulin injections.[10] In those on insulin, routinely checking blood sugar levels is advised, however this may not be needed in those taking pills.[11] Bariatric surgery often improves diabetes in those who are obese.[12][13]

Rates of type 2 diabetes have increased markedly since 1960 in parallel with obesity.[14] As of 2013 there were

approximately 368 million people diagnosed with the disease compared to around 30 million in 1985.[15][16] Typically it begins in middle or older age,[3] although rates of type 2 diabetes are increasing in young people.[17][18] Type 2 diabetes is associated with a ten-year-shorter life expectancy.[19] Diabetes was one of the first diseases described.[20] The importance of insulin in the disease was determined in the 1920s.[21]

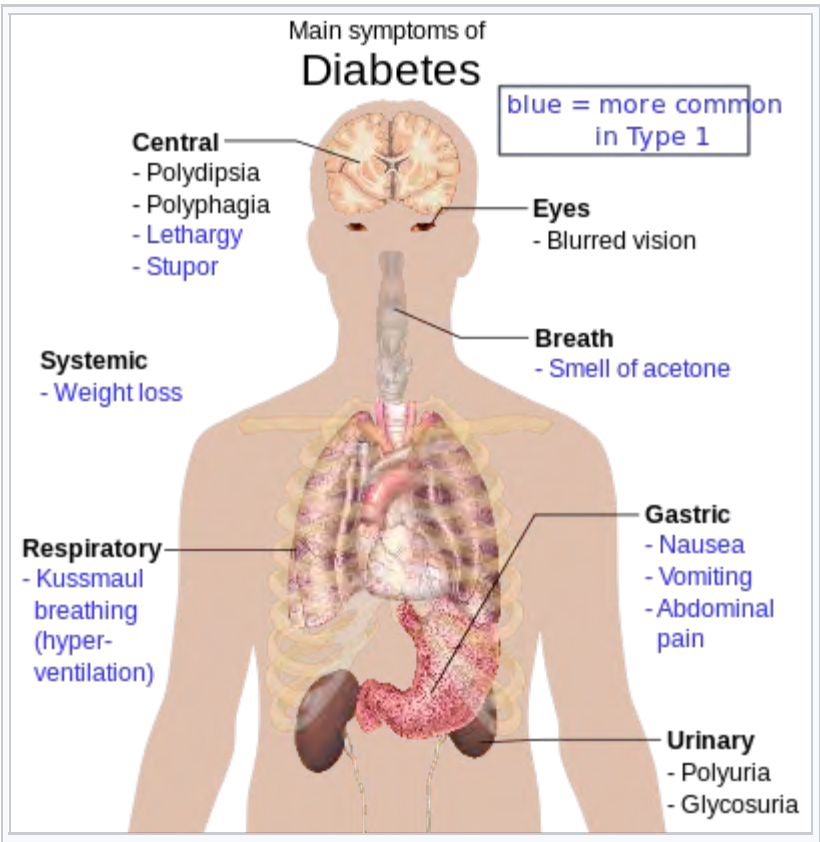
# Signs and symptoms

The classic symptoms of diabetes are polyuria (frequent urination), polydipsia (increased thirst), polyphagia (increased hunger), and weight loss.[22] Other symptoms that are commonly present at diagnosis include a history of blurred vision, itchiness, peripheral neuropathy, recurrent vaginal infections, and fatigue.[7] Many people, however, have no symptoms during the first few years and are diagnosed on routine testing.[7] People with type 2 diabetes mellitus may rarely present with hyperosmolar hyperglycemic state (a condition of very high blood sugar associated with a decreased level of consciousness and low blood pressure).[7]



## Complications

*Main article: Complications of diabetes mellitus*

Type 2 diabetes is typically a chronic disease associated with a ten-year-shorter life expectancy.[19] This is partly due to a number of complications with which it is associated,

Overview of the most significant symptoms of diabetes.

including: two to four times the risk of cardiovascular disease, including ischemic heart disease and stroke; a 20-fold increase in lower limb amputations, and increased rates of hospitalizations.[19] In the developed world, and increasingly elsewhere, type 2 diabetes is the largest cause of nontraumatic blindness and kidney failure.[23] It has also been associated with an increased risk of cognitive dysfunction and dementia through disease processes such as Alzheimer's disease and vascular dementia.[24] Other complications include acanthosis nigricans, sexual dysfunction, and frequent infections.[22]

# Cause

The development of type 2 diabetes is caused by a combination of lifestyle and genetic factors.[23][25] While some of these factors are under personal control, such as diet and obesity, other factors are not, such as increasing age, female gender, and genetics.[19] A lack of sleep has been linked to type 2 diabetes.[26] This is believed to act through its effect on metabolism.[26] The nutritional status of a mother during fetal development may also play a role, with one proposed mechanism being that of altered DNA methylation.[27] The intestinal bacteriæ Prevotella copri and Bacteroides vulgatus have been connected with type 2 diabetes.[28]

## Lifestyle

*Main article: Lifestyle causes of diabetes mellitus type 2*

Lifestyle factors are important to the development of type 2 diabetes, including obesity and being overweight (defined by a body mass index of greater than 25), lack of physical activity, poor diet, stress, and urbanization.[19][29] Excess body fat is associated with 30% of cases in those of Chinese and Japanese descent, 60–80% of cases in those of European and African descent, and 100% of cases in Pima Indians and Pacific Islanders.[7] Among those who are not obese, a high waist–hip ratio is often present.[7] Smoking appears to increase the risk of type 2 diabetes mellitus.[30]

Dietary factors also influence the risk of developing type 2 diabetes. Consumption of sugar-sweetened drinks in excess is associated with an increased risk.[31][32] The type of fats in the diet are important, with saturated fats and trans fatty acids increasing the risk, and polyunsaturated and monounsaturated fat decreasing the risk.[25] Eating a lot of white rice appears to play a role in increasing risk.[33] A lack of exercise is believed to cause 7% of cases.[34] Persistent organic pollutants may play a role.[35]

## Genetics

*Main article: Genetic causes of diabetes mellitus type 2*

Most cases of diabetes involve many genes, with each being a small contributor to an increased probability of becoming a type 2 diabetic.[19] If one identical twin has diabetes, the chance of the other developing diabetes within his lifetime is greater than 90%, while the rate for nonidentical siblings is 25–50%.[7] As of 2011, more than 36 genes had been found that contribute to the risk of type 2 diabetes.[36] All of these genes together still only account for 10% of the total heritable component of the disease.[36] The TCF7L2 allele, for example, increases the risk of developing diabetes by 1.5 times and is the greatest risk of the common genetic variants.[7] Most of the genes linked to diabetes are involved in beta cell functions.[7]

There are a number of rare cases of diabetes that arise due to an abnormality in a single gene (known as monogenic forms of diabetes or "other specific types of diabetes").[7][19] These include maturity onset diabetes of the young (MODY), Donohue syndrome, and Rabson-Mendenhall syndrome, among others.[19] Maturity onset diabetes of the young constitute 1–5% of all cases of diabetes in young people.[37]

## Medical conditions

There are a number of medications and other health problems that can predispose to diabetes.[38] Some of the medications include: glucocorticoids, thiazides, beta blockers, atypical antipsychotics,[39] and statins.[40] Those who have previously had gestational diabetes are at a higher risk of developing type 2 diabetes.[22] Other health problems that are associated include: acromegaly, Cushing's syndrome, hyperthyroidism, pheochromocytoma, and certain cancers such as glucagonomas.[38] Testosterone deficiency is also associated with type 2 diabetes.[41][42]

# Pathophysiology

Type 2 diabetes is due to insufficient insulin production from beta cells in the setting of insulin resistance.[7] Insulin resistance, which is the inability of cells to respond adequately to normal levels of insulin, occurs primarily within the muscles, liver, and fat tissue.[43] In the liver, insulin normally suppresses glucose release. However, in the setting of insulin resistance, the liver inappropriately releases glucose into the blood.[19] The proportion of insulin resistance versus beta cell dysfunction differs among individuals, with some having primarily insulin resistance and only a minor defect in insulin secretion and others with slight insulin resistance and primarily a lack of insulin secretion.[7]

Other potentially important mechanisms associated with type 2 diabetes and insulin resistance include: increased breakdown of lipids within fat cells, resistance to and lack of incretin, high glucagon levels in the blood, increased retention of salt and water by the kidneys, and inappropriate regulation of metabolism by the central nervous system.[19] However, not all people with insulin resistance develop diabetes, since an impairment of insulin secretion by pancreatic beta cells is also required.[7]

# Diagnosis

**WHO diabetes diagnostic criteria**[44][45] edit

| Condition | 2 hour glucose | Fasting glucose | $HbA_{1c}$ | |
|---|---|---|---|---|
| Unit | mmol/l(mg/dl) | mmol/l(mg/dl) | mmol/mol | DCCT % |
| Normal | <7.8 (<140) | <6.1 (<110) | <42 | <6.0 |
| Impaired fasting glycaemia | <7.8 (<140) | ≥6.1(≥110) & <7.0(<126) | 42-46 | 6.0–6.4 |
| Impaired glucose tolerance | ≥7.8 (≥140) | <7.0 (<126) | 42-46 | 6.0–6.4 |
| Diabetes mellitus | ≥11.1 (≥200) | ≥7.0 (≥126) | ≥48 | ≥6.5 |

The World Health Organization definition of diabetes (both type 1 and type 2) is for a single raised glucose reading with symptoms, otherwise raised values on two occasions, of either:[46]

- fasting plasma glucose ≥ 7.0 mmol/l (126 mg/dl)
  or
- with a glucose tolerance test, two hours after the oral dose a plasma glucose ≥ 11.1 mmol/l (200 mg/dl)

A random blood sugar of greater than 11.1 mmol/l (200 mg/dL) in association with typical symptoms[22] or a glycated hemoglobin ($HbA_{1c}$) of ≥ 48 mmol/mol (≥ 6.5 DCCT %) is another method of diagnosing diabetes.[19] In 2009 an International Expert Committee that included representatives of the American Diabetes Association (ADA), the International Diabetes Federation (IDF), and the European Association for the Study of Diabetes (EASD) recommended that a threshold of ≥ 48 mmol/mol (≥ 6.5 DCCT %) should be used to diagnose diabetes.[47] This recommendation was adopted by the American Diabetes Association in [48]

2010. Positive tests should be repeated unless the person presents with typical symptoms and blood sugars >11.1 mmol/l (>200 mg/dl).[47]

Threshold for diagnosis of diabetes is based on the relationship between results of glucose tolerance tests, fasting glucose or $HbA_{1c}$ and complications such as retinal problems.[19] A fasting or random blood sugar is preferred over the glucose tolerance test, as they are more convenient for people.[19] $HbA_{1c}$ has the advantages that fasting is not required and results are more stable but has the disadvantage that the test is more costly than measurement of blood glucose.[49] It is estimated that 20% of people with diabetes in the United States do not realize that they have the disease.[19]

Diabetes mellitus type 2 is characterized by high blood glucose in the context of insulin resistance and relative insulin deficiency.[50] This is in contrast to diabetes mellitus type 1 in which there is an absolute insulin deficiency due to destruction of islet cells in the pancreas and gestational diabetes mellitus that is a new onset of high blood sugars associated with pregnancy.[7] Type 1 and type 2 diabetes can typically be distinguished based on the presenting circumstances.[47] If the diagnosis is in doubt antibody testing may be useful to confirm type 1 diabetes and C-peptide levels may be useful to confirm type 2 diabetes,[51] with C-peptide levels normal or high in type 2 diabetes, but low in type 1 diabetes.[52]

## Screening

No major organization recommends universal screening for diabetes as there is no evidence that such a program improve outcomes.[53][54] Screening is recommended by the United States Preventive Services Task Force (USPSTF) in adults without symptoms whose blood pressure is greater than 135/80 mmHg.[55] For those whose blood pressure is less, the evidence is insufficient to recommend for or against screening.[55] There is no evidence that it changes the risk of death in this group of people.[56] They also recommend screening among those who are overweight and between the ages of 40 and 70.[57]

The World Health Organization recommends testing those groups at high risk[53] and in 2014 the USPSTF is considering a similar recommendation.[58] High-risk groups in the United States include: those over 45 years old; those with a first degree relative with diabetes; some ethnic groups, including Hispanics, African-Americans, and Native-Americans; a history of gestational diabetes; polycystic ovary syndrome; excess weight; and conditions associated with metabolic syndrome.[22] The American Diabetes Association recommends screening those who have a BMI over 25 (in people of Asian descent screening is recommending for a BMI over 23.[59]

## Prevention

*Main article: Prevention of diabetes mellitus type 2*

Onset of type 2 diabetes can be delayed or prevented through proper nutrition and regular exercise.[60][61] Intensive lifestyle measures may reduce the risk by over half.[23][62] The benefit of exercise occurs regardless of the person's initial weight or subsequent weight loss.[63] High levels of physical activity reduce the risk of diabetes by about 28%.[64] Evidence for the benefit of dietary changes alone, however, is limited,[65] with some evidence for a diet high in green leafy vegetables[66] and some for limiting the intake of sugary drinks.[31] In those with impaired glucose tolerance, diet and exercise either alone or in combination with metformin or acarbose may decrease the risk of developing diabetes.[23][67] Lifestyle interventions are more effective than metformin.[23] While low vitamin D levels are associated with an increased risk of diabetes, correcting the levels by supplementing vitamin D3 does not improve that risk.[68]

## Management

*Further information: Diabetes management*

Management of type 2 diabetes focuses on lifestyle interventions, lowering other cardiovascular risk factors, and maintaining blood glucose levels in the normal range.[23] Self-monitoring of blood glucose for people with newly diagnosed type 2 diabetes may be used in combination with education,[69] however the benefit of self monitoring in those not using multi-dose insulin is questionable.[23][70] In those who do not want to measure blood levels, measuring urine levels may be done.[69] Managing other cardiovascular risk factors, such as hypertension, high cholesterol, and microalbuminuria, improves a person's life expectancy.[23] Decreasing the systolic blood pressure to less than 140 mmHg is associated with a lower risk of death and better outcomes.[71] Intensive blood pressure management (less than 130/80 mmHg) as opposed to standard blood pressure management (less than 140/85–100 mmHg) results in a slight decrease in stroke risk but no effect on overall risk of death.[72]

Intensive blood sugar lowering ($HbA_{1c}$<6%) as opposed to standard blood sugar lowering ($HbA_{1c}$ of 7–7.9%) does not appear to change mortality.[73][74] The goal of treatment is typically an $HbA_{1c}$ of around 7% or a fasting glucose of less than 7.2 mmol/L (130 mg/dL); however these goals may be changed after professional clinical consultation, taking into account particular risks of hypoglycemia and life expectancy.[75][59] It is recommended that all people with type 2 diabetes get regular ophthalmology examination.[7] Treating gum disease in those with diabetes may result in a small improvement in blood sugar levels.[76]

## Lifestyle

A proper diet and exercise are the foundations of diabetic care,[22] with a greater amount of exercise yielding better results.[77] Aerobic exercise leads to a decrease in $HbA_{1c}$ and improved insulin sensitivity.[77] Resistance training is also useful and the combination of both types of exercise may be most effective.[77] A diabetic diet that promotes weight loss is important.[78] While the best diet type to achieve this is controversial,[78] a low glycemic index diet or low carbohydrate diet has been found to improve blood sugar control.[79][80] Culturally appropriate education may help people with type 2 diabetes control their blood sugar levels, for up to six months at least.[81][*needs update*] If changes in lifestyle in those with mild diabetes has not resulted in improved blood sugars within six weeks, medications should then be considered.[22] There is not enough evidence to determine if lifestyle interventions affect mortality in those who already have DM2.[62] Vegetarian diets in general have been related to lower diabetes risk, but do not offer advantages compared with diets which allow moderate amounts of animal products.[82] There is not enough evidence to suggest that cinnamon improves blood sugar levels in people with type 2 diabetes.[83]

## Medications

There are several classes of anti-diabetic medications available. Metformin is generally recommended as a first line treatment as there is some evidence that it decreases mortality;[9][23][84] however, this conclusion is questioned.[85] Metformin should not be used in those with severe kidney or liver problems.[22]

A second oral agent of another class or insulin may be added if metformin is not sufficient after three months.[75] Other classes of medications include: sulfonylureas, thiazolidinediones, dipeptidyl peptidase-4 inhibitors, SGLT2 inhibitors, and glucagon-like peptide-1 analogs.[75] There is no significant difference between these agents.[75] Rosiglitazone, a thiazolidinedione, has not been found to improve long-term outcomes even though it improves blood

Metformin 500mg tablets.

sugar levels.[86] Additionally it is associated with increased rates of heart disease and death.[87] Angiotensin-converting enzyme inhibitors (ACEIs) prevent kidney disease and improve outcomes in those with diabetes.[88][89] The similar medications angiotensin receptor blockers (ARBs) do not.[89] A 2016 review recommended treating to a systolic blood pressure of 140 to 150 mmHg.[90]

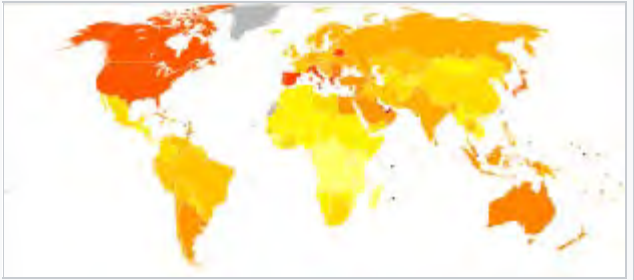
Injections of insulin may either be added to oral medication or used alone.[23] Most people do not initially need insulin.[7] When it is used, a long-acting formulation is typically added at night, with oral medications being continued.[22][23] Doses are then increased to effect (blood sugar levels being well controlled).[23] When nightly insulin is insufficient, twice daily insulin may achieve better control.[22] The long acting insulins glargine and detemir are equally safe and effective,[91] and do not appear much better than neutral protamine Hagedorn (NPH) insulin, but as they are significantly more expensive, they are not cost effective as of 2010.[92] In those who are pregnant insulin is generally the treatment of choice.[22]

### Surgery

Weight loss surgery in those who are obese is an effective measure to treat diabetes.[93] Many are able to maintain normal blood sugar levels with little or no medications following surgery[94] and long-term mortality is decreased.[95] There however is some short-term mortality risk of less than 1% from the surgery.[96] The body mass index cutoffs for when surgery is appropriate are not yet clear.[95] It is recommended that this option be considered in those who are unable to get both their weight and blood sugar under control.[97][98]

## Epidemiology

Globally as of 2010 it was estimated that there were 285 million people with type 2 diabetes making up about 90% of diabetes cases.[19] This is equivalent to about 6% of the world's adult population.[99] Diabetes is common both in the developed and the developing world.[19] It remains uncommon, however, in the underdeveloped world.[7]



Prevalence of diabetes worldwide in 2000.
World average was 28 per 1000 inhabitants.

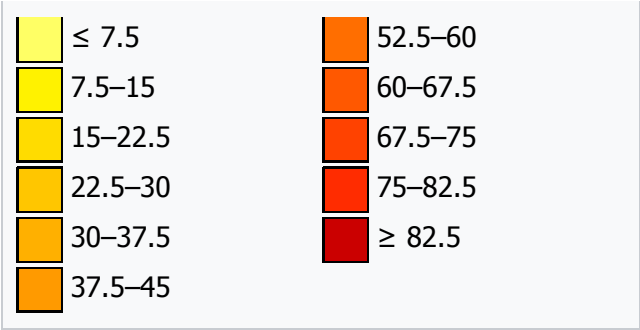
Women seem to be at a greater risk as do certain ethnic groups,[19][100] such as South Asians, Pacific Islanders, Latinos, and Native Americans.[22] This may be due to enhanced sensitivity to a Western lifestyle in certain ethnic

groups.[101] Traditionally considered a disease of adults, type 2 diabetes is increasingly diagnosed in children in parallel with rising obesity rates.[19] Type 2 diabetes is now diagnosed as frequently as type 1 diabetes in teenagers in the United States.[7]



Rates of diabetes in 1985 were estimated at 30 million, increasing to 135 million in 1995 and 217 million in 2005.[15] This increase is believed to be primarily due to the global population aging, a decrease in exercise, and increasing rates of obesity.[15] The five countries with the greatest number of people with diabetes as of 2000 are India having 31.7 million, China 20.8 million, the United States 17.7 million, Indonesia 8.4 million, and Japan 6.8 million.[102] It is recognized as a global epidemic by the World Health Organization.[103]

# History

*Main article: History of diabetes*

Diabetes is one of the first diseases described[20] with an Egyptian manuscript from c. 1500 BCE mentioning "too great emptying of the urine."[104] The first described cases are believed to be of type 1 diabetes.[104] Indian physicians around the same time identified the disease and classified it as *madhumeha* or *honey urine* noting that the urine would attract ants.[104] The term "diabetes" or "to pass through" was first used in 230 BCE by the Greek Apollonius Of Memphis.[104] The disease was rare during the time of the Roman empire with Galen commenting that he had only seen two cases during his career.[104]

Type 1 and type 2 diabetes were identified as separate conditions for the first time by the Indian physicians Sushruta and Charaka in 400–500 AD with type 1 associated with youth and type 2 with being overweight.[104] The term "mellitus" or "from honey" was added by the Briton John Rolle in the late 1700s to separate the condition from diabetes insipidus which is also associated with frequent urination.[104] Effective treatment was not developed until the early part of the 20th century when the Canadians Frederick Banting and Charles Best discovered insulin in 1921 and 1922.[104] This was followed by the development of the long acting NPH insulin in the 1940s.[104]

# Gestational diabetes

From Wikipedia, the free encyclopedia

**Gestational diabetes**, also known as **gestational diabetes mellitus** (**GDM**), is when a woman without diabetes, develops high blood sugar levels during pregnancy.[2] Gestational diabetes generally results in few symptoms; however, it does increase the risk of pre-eclampsia, depression, and requiring a Caesarean section. Babies born to mothers with poorly treated gestational diabetes are at increased risk of being too large, having low blood sugar after birth, and jaundice. If untreated, it can also result in a stillbirth. Long term, children are at higher risk of being overweight and developing type 2 diabetes.[2]

Gestational diabetes is caused by not enough insulin in the setting of insulin resistance. Risk factors include being overweight, previously having gestational diabetes, a family history of type 2 diabetes, and having polycystic ovarian syndrome. Diagnosis is by blood tests.[2] For those at normal risk screening is recommended between 24 and 28 weeks gestation.[2][3] For those at high risk testing may occur at the first prenatal visit.[2]

Prevention is by maintaining a healthy weight and exercising before pregnancy. Gestational diabetes is a treated with a diabetic diet, exercise, and possibly insulin injections.[2] Most women are able to manage their blood sugar with a diet and exercise. Blood sugar testing among those who are affected is often recommended four times a day.[3] Breastfeeding is recommended as soon as possible after birth.[2]

Gestational diabetes affects 3–9% of pregnancies, depending on the population studied.[3] It is especially common during the last third of pregnancy.[2] It affects 1% of those under the age of 20 and 13% of those over the age of 44.[3] A number of ethnic groups including Asians, American Indians, Indigenous Australians, and Pacific Islanders are at higher risk.[3][2] In 90% of people gestational diabetes will resolve after the baby is born.[2] Women, however, are at an increased risk of developing type 2 diabetes.[3]

# Classification

Gestational diabetes is formally defined as "any degree of glucose intolerance with onset or first recognition during pregnancy".[4] This definition acknowledges the possibility that a woman may have previously undiagnosed diabetes mellitus, or may have developed diabetes coincidentally with pregnancy. Whether symptoms subside after pregnancy is also irrelevant to the diagnosis.[5] A woman is diagnosed with gestational diabetes when glucose intolerance continues beyond 24–28 weeks of gestation.

The White classification, named after Priscilla White,[6] who pioneered research on the effect of diabetes types on perinatal outcome, is widely used to assess maternal and fetal risk[*citation needed*]. It distinguishes between gestational diabetes (type A) and pregestational diabetes (diabetes that existed prior to pregnancy). These two groups are further subdivided according to their associated risks and management.[7]

The two subtypes of gestational diabetes under this classification system are:

- Type A1: abnormal oral glucose tolerance test (OGTT), but normal blood glucose levels during fasting and two hours after meals; diet modification is sufficient to control glucose levels
- Type A2: abnormal OGTT compounded by abnormal glucose levels during fasting and/or after meals; additional therapy with insulin or other medications is required

Diabetes which existed prior to pregnancy is also split up into several subtypes under this system:[*medical citation needed*]

- Type B: onset at age 20 or older and duration of less than 10 years.
- Type C: onset at age 10–19 or duration of 10–19 years.
- Type D: onset before age 10 or duration greater than 20 years.
- Type E: overt diabetes mellitus with calcified pelvic vessels.
- Type F: diabetic nephropathy.
- Type R: proliferative retinopathy.
- Type RF: retinopathy and nephropathy.
- Type H: ischemic heart disease.
- Type T: prior kidney transplant.

An early age of onset or long-standing disease comes with greater risks, hence the first three subtypes.[*medical citation needed*]

Two other sets of criteria are available for diagnosis of gestational diabetes, both based on blood-sugar levels.[*medical citation needed*]

Criteria for diagnosis of gestational diabetes, using the 100 gram Glucose Tolerance Test, according to Carpenter and Coustan:[*medical citation needed*]

- Fasting 95 mg/dl
- 1 hour 180 mg/dl
- 2 hours 155 mg/dl
- 3 hours 140 mg/dl

Criteria for diagnosis of gestational diabetes according to National Diabetes Data Group:[*medical citation needed*]

- Fasting 105 mg/dl
- 1 hour 190 mg/dl
- 2 hours 165 mg/dl
- 3 hours 145 mg/dl

# Risk factors [edit]

Classical risk factors for developing gestational diabetes are:[8]

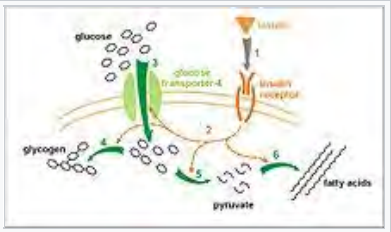
- Polycystic Ovary Syndrome
- A previous diagnosis of gestational diabetes or prediabetes, impaired glucose tolerance, or impaired fasting glycaemia
- A family history revealing a first-degree relative with type 2 diabetes
- Maternal age – a woman's risk factor increases as she gets older (especially for women over 35 years of age).
- Ethnicity (those with higher risk factors include African-Americans, Afro-Caribbeans, Native Americans, Hispanics, Pacific Islanders, and people originating from South Asia)
- Being overweight, obese or severely obese increases the risk by a factor 2.1, 3.6 and 8.6, respectively.[9]
- A previous pregnancy which resulted in a child with a macrosomia (high birth weight: >90th centile or >4000 g (8 lbs 12.8 oz))
- Previous poor obstetric history
- Other genetic risk factors: There are at least 10 genes where certain polymorphism are associated with an increased risk of gestational diabetes, most notably TCF7L2.[10]

In addition to this, statistics show a double risk of GDM in smokers.[11] Polycystic ovarian syndrome is also a risk factor,[8] although relevant evidence remains controversial.[12] Some studies have looked at more controversial potential risk factors, such as short stature.[13]

About 40–60% of women with GDM have no demonstrable risk factor; for this reason many advocate to screen all women.[14] Typically, women with GDM exhibit no symptoms (another reason for universal screening), but some women may demonstrate increased thirst, increased urination, fatigue, nausea and vomiting, bladder infection, yeast infections and blurred vision.

## Pathophysiology [edit]

The precise mechanisms underlying gestational diabetes remain unknown. The hallmark of GDM is increased insulin resistance. Pregnancy hormones and other factors are thought to interfere with the action of insulin as it binds to the insulin receptor. The interference probably occurs at the level of the cell signaling pathway beyond the insulin receptor.[15] Since insulin promotes the entry of glucose into most cells, insulin resistance prevents glucose from entering the cells properly. As a result, glucose remains in the bloodstream, where glucose levels rise. More insulin is needed to overcome this resistance; about 1.5–2.5 times more insulin is produced than in a normal pregnancy.[15]



**Effect of insulin on glucose uptake and metabolism.** Insulin binds to its receptor (1) on the cell membrane which in turn starts many protein activation cascades (2). These include: translocation of Glut-4 transporter to the plasma membrane and influx of glucose (3), glycogen synthesis (4), glycolysis (5) and fatty acid synthesis (6).

Insulin resistance is a normal phenomenon emerging in the second trimester of pregnancy, which in cases of GDM progresses thereafter to levels seen in a non-pregnant person with type 2 diabetes. It is thought to secure glucose supply to the growing fetus. Women with GDM have an insulin resistance that they cannot compensate for with increased production in the β-cells of the pancreas. Placental hormones, and to a lesser extent increased fat deposits during pregnancy, seem to mediate insulin resistance during pregnancy. Cortisol and progesterone are the main culprits, but human placental lactogen, prolactin and estradiol contribute, too. Multivariate stepwise regression analysis reveals that, in combination with other placental hormones, leptin, tumor necrosis factor alpha, and resistin are involved in the decrease in insulin sensitivity occurring during pregnancy, with tumor necrosis factor alpha named as the strongest independent predictor of insulin sensitivity in pregnancy. An inverse correlation with the changes in insulin sensitivity from the time before conception through late gestation accounts for about half of the variance in the decrease in insulin sensitivity during gestation: in other words, low levels or alteration of TNF alpha factors corresponds with a greater chance of, or predisposition to, insulin resistance or sensitivity. GABBE,STEVEN G; sixth Edition page 890.

It is unclear why some women are unable to balance insulin needs and develop GDM; however, a number of explanations have been given, similar to those in type 2 diabetes: autoimmunity, single gene mutations, obesity, along with other mechanisms.[16]

Though the clinical presentation of gestational diabetes is well characterized, the biochemical mechanism behind the disease is not well known. One proposed biochemical mechanism involves insulin-producing β-cell adaptation controlled by the HGF/c-MET signaling pathway. β-cell adaption refers to the change that pancreatic islet cells undergo during pregnancy in response to maternal hormones in order to compensate for the increased physiological needs of mother and baby. These changes in the β-cells cause increased insulin secretion as a result of increased β-cell proliferation.[17] HGF/c-MET has also been implicated in β-cell regeneration, which suggests that HGF/c-MET may help increase β-cell mass in order to compensate for insulin needs during pregnancy. Recent studies support that loss of HGF/c-MET signaling results in aberrant β-cell adaptation.[18][19]

c-MET is a receptor tyrosine kinase (RTK) that is activated by its ligand, hepatocyte growth factor (HGF), and is involved in the activation of several cellular processes. When HGF binds c-MET, the receptor homodimerizes and self-phosphorylates to form an SH2 recognition domain. The downstream pathways activated include common signaling molecules such as RAS and MAPK, which affect cell motility, cell motility, and cell cycle progression.[20]

Studies have shown that HGF is an important signaling molecule in stress related situations where more insulin is needed. Pregnancy causes increased insulin resistance and so a higher insulin demand. The β-cells must compensate for this by either increasing insulin production or proliferating. If neither of the processes occur, then markers for gestational diabetes are observed. It has been observed that pregnancy increases HGF levels, showing a correlation that suggests a connection between the signaling pathway and increased insulin needs. In fact, when no signaling is present, gestational diabetes is more likely to occur.[18]

The exact mechanism of HGF/c-MET regulated β-cell adaptation is not yet known but there are several hypotheses about how the signaling molecules contribute to insulin levels during pregnancy. c-MET may interact with FoxM1, a molecule important in the cell cycle, as FOXM1 levels decrease when c-MET is not present. Additionally, c-MET may interact with p27 as the protein levels increase with c-MET is not present. Another hypothesis says that c-MET may control β-cell apoptosis because a lack of c-MET causes increases cell death but the signaling mechanisms have not been elucidated.[19]

Although the mechanism of HGF/c-MET control of gestational diabetes is not yet well understood, there is a strong correlation between the signaling pathway and the inability to produce an adequate amount of insulin during pregnancy and thus it may be the target for future diabetic therapies.[18][19]

Because glucose travels across the placenta (through diffusion facilitated by GLUT1 carrier), which is located in the syncytiotrophoblast on both the microvillus and basal membranes, these membranes may be the rate-limiting step in placental glucose transport. There is a two- to three-fold increase in the expression of syncytiotrophoblast glucose transporters with advancing gestation. Finally, the role of GLUT3/GLUT4 transport remains speculative. If the untreated gestational diabetes fetus is exposed to consistently higher glucose levels, this leads to increased fetal levels of insulin (insulin itself cannot cross the placenta). The growth-stimulating effects of insulin can lead to excessive growth and a large body (macrosomia). After birth, the high glucose environment disappears, leaving these newborns with ongoing high insulin production and susceptibility to low blood glucose levels (hypoglycemia).[21]

## Screening [edit]

A number of screening and diagnostic tests have been used to look for high levels of glucose in plasma or serum in defined circumstances. One method is a stepwise approach where a suspicious result on a screening test is followed by diagnostic test. Alternatively, a more involved diagnostic test can be used directly at the first prenatal visit for a woman with a high-risk pregnancy. (for example in those with polycystic ovarian syndrome or acanthosis nigricans).[21]

Non-challenge blood glucose tests involve measuring glucose levels in blood samples without challenging the subject with glucose solutions. A blood glucose level is determined when fasting, 2 hours after a meal, or simply at any random time. In contrast, challenge tests involve drinking a glucose solution and measuring glucose concentration thereafter in the blood; in diabetes, they tend to remain high. The glucose solution has a very sweet taste which some women find unpleasant; sometimes, therefore, artificial flavours are added. Some women may experience nausea during the test, and more so with higher glucose levels.[24][25]

More research is needed to find the most effective way of screening for gestational diabetes.[26] Routine screening of women with a glucose challenge test appears to find more women with gestational diabetes than only screening women with risk factors.[26] It is not clear how these screening tests affect the rest of the pregnancy. Future research should include how the method of screening impacts the mother and baby.[26]

### Pathways [edit]

Opinions differ about optimal screening and diagnostic measures, in part due to differences in population risks, cost-effectiveness considerations, and lack of an evidence base to support large national screening programs.[27] The most elaborate regimen entails a random blood glucose test during a booking visit, a screening glucose challenge test around 24–28 weeks' gestation, followed by an OGTT if the tests are outside normal limits. If there is a high suspicion, a woman may be tested earlier.[5]

In the United States, most obstetricians prefer universal screening with a screening glucose challenge test.[28] In the United Kingdom, obstetric units often rely on risk factors and a random blood glucose test.[21][29] The American Diabetes Association and the Society of Obstetricians and Gynaecologists of Canada recommend routine screening unless the woman is low risk (this means the woman must be younger than 25 years and have a body mass index less than 27, with no personal, ethnic or family risk factors)[5][27] The Canadian Diabetes Association and the American College of Obstetricians and Gynecologists recommend universal screening.[30][31] The U.S. Preventive Services Task Force found there is insufficient evidence to recommend for or against routine screening.[32]

Some pregnant women and careproviders choose to forgo routine screening due to the absence of risk factors, however this is not advised due to the large proportion of women who develop gestational diabetes despite having no risk factors present

and the dangers to the mother and baby if gestational diabetes remains untreated.[14]

### Non-challenge blood glucose tests [edit]

When a plasma glucose level is found to be higher than 126 mg/dl (7.0 mmol/l) after fasting, or over 200 mg/dl (11.1 mmol/l) on any occasion, and if this is confirmed on a subsequent day, the diagnosis of GDM is made, and no further testing is required.[5] These tests are typically performed at the first antenatal visit. They are simple to administer and inexpensive, but have a lower test performance compared to the other tests, with moderate sensitivity, low specificity and high false positive rates.[33][34][35]

### Screening glucose challenge test [edit]

The screening glucose challenge test (sometimes called the O'Sullivan test) is performed between 24–28 weeks, and can be seen as a simplified version of the oral glucose tolerance test (OGTT). No previous fasting is required for this screening test,[36] in contrast to the OGTT. The O'Sullivan test involves drinking a solution containing 50 grams of glucose, and measuring blood levels 1 hour later.[37]

If the cut-off point is set at 140 mg/dl (7.8 mmol/l), 80% of women with GDM will be detected.[5] If this threshold for further testing is lowered to 130 mg/dl, 90% of GDM cases will be detected, but there will also be more women who will be subjected to a consequent OGTT unnecessarily.

### Oral glucose tolerance test [edit]

A standardized oral glucose tolerance test (OGTT)[38] should be done in the morning after an overnight fast of between 8 and 14 hours. During the three previous days the subject must have an unrestricted diet (containing at least 150 g carbohydrate per day) and unlimited physical activity. The subject should remain seated during the test and should not smoke throughout the test.

The test involves drinking a solution containing a certain amount of glucose, usually 75 g or 100 g, and drawing blood to measure glucose levels at the start and on set time intervals thereafter.

The diagnostic criteria from the National Diabetes Data Group (NDDG) have been used most often, but some centers rely on the Carpenter and Coustan criteria, which set the cutoff for normal at lower values. Compared with the NDDG criteria, the Carpenter and Coustan criteria lead to a diagnosis of gestational diabetes in 54 percent more pregnant women, with an increased cost and no compelling evidence of improved perinatal outcomes.[39]

The following are the values which the American Diabetes Association considers to be abnormal during the 100 g of glucose OGTT:

- Fasting blood glucose level ≥95 mg/dl (5.33 mmol/L)
- 1 hour blood glucose level ≥180 mg/dl (10 mmol/L)
- 2 hour blood glucose level ≥155 mg/dl (8.6 mmol/L)
- 3 hour blood glucose level ≥140 mg/dl (7.8 mmol/L)

An alternative test uses a 75 g glucose load and measures the blood glucose levels before and after 1 and 2 hours, using the same reference values. This test will identify fewer women who are at risk, and there is only a weak concordance (agreement rate) between this test and a 3-hour 100 g test.[40]

The glucose values used to detect gestational diabetes were first determined by O'Sullivan and Mahan (1964) in a retrospective cohort study (using a 100 grams of glucose OGTT) designed to detect risk of developing type 2 diabetes in the future. The values were set using whole blood and required two values reaching or exceeding the value to be positive.[41] Subsequent information led to alterations in O'Sullivan's criteria. When methods for blood glucose determination changed from the use of whole blood to venous plasma samples, the criteria for GDM were also changed.

### Urinary glucose testing [edit]

Women with GDM may have high glucose levels in their urine (glucosuria). Although dipstick testing is widely practiced, it performs poorly, and discontinuing routine dipstick testing has not been shown to cause underdiagnosis where universal screening is performed.[42] Increased glomerular filtration rates during pregnancy contribute to some 50% of women having glucose in their urine on dipstick tests at some point during their pregnancy. The sensitivity of glucosuria for GDM in the first 2 trimesters is only around 10% and the positive predictive value is around 20%.[43][44]

## Prevention [edit]

A 2015 review found that when done during pregnancy moderate physical exercise is effective for the prevention of gestational diabetes.[45] A 2014 review however did not find a significant effect.[46]

Theoretically, smoking cessation may decrease the risk of gestational diabetes among smokers.

## Management [edit]

*Main article: Diabetes management*

Treatment of GDM with diet and insulin reduces health problems mother and child.[47] Treatment of GDM is also accompanied by more inductions of labour.[47]

A repeat OGTT should be carried out 6 weeks after delivery, to confirm the diabetes has disappeared. Afterwards, regular screening for type 2 diabetes is advised.[8]

If a diabetic diet or G.I. Diet, exercise, and oral medication are inadequate to control glucose levels, insulin therapy may become necessary.

The development of macrosomia can be evaluated during pregnancy by using sonography. Women who use insulin, with a history of stillbirth, or with hypertension are managed like women with overt diabetes.[14]

### Lifestyle [edit]

Counselling before pregnancy (for example, about preventive folic acid supplements) and multidisciplinary management are important for good pregnancy outcomes.[48] Most women can manage their GDM with dietary changes and exercise. Self monitoring of blood glucose levels can guide therapy. Some women will need antidiabetic drugs, most commonly insulin therapy.

Any diet needs to provide sufficient calories for pregnancy, typically 2,000 – 2,500 kcal with the exclusion of simple carbohydrates.[14] The main goal of dietary modifications is to avoid peaks in blood sugar levels. This can be done by spreading carbohydrate intake over meals and snacks throughout the day, and using slow-release carbohydrate sources—known as the G.I. Diet. Since insulin resistance is highest in mornings, breakfast carbohydrates need to be restricted more.[8] Ingesting more fiber in foods with whole grains, or fruit and vegetables can also reduce the risk of gestational diabetes.[49]

Regular moderately intense physical exercise is advised, although there is no consensus on the specific structure of exercise programs for GDM.[8][50]

Self monitoring can be accomplished using a handheld capillary glucose dosage system. Compliance with these glucometer systems can be low.[51] Target ranges advised by the Australasian Diabetes in Pregnancy Society are as follows:[8]

- fasting capillary blood glucose levels <5.5 mmol/L
- 1 hour postprandial capillary blood glucose levels <8.0 mmol/L
- 2 hour postprandial blood glucose levels <6.7 mmol/L

Regular blood samples can be used to determine HbA1c levels, which give an idea of glucose control over a longer time period.[8]

Research suggests a possible benefit of breastfeeding to reduce the risk of diabetes and related risks for both mother and child.[52]

### Medication [edit]

If monitoring reveals failing control of glucose levels with these measures, or if there is evidence of complications like excessive fetal growth, treatment with insulin might be necessary. This is most commonly fast-acting insulin given just before eating to blunt glucose rises after meals.[8] Care needs to be taken to avoid low blood sugar levels due to excessive insulin. Insulin therapy can be normal or very tight; more injections can result in better control but requires more effort, and there is no consensus that it has large benefits.[21][53][54] A 2016 Cochrane review concluded that quality evidence is not yet available to determine the best blood sugar range for improving health for pregnant women with GDM and their babies.[55]

There is some evidence that certain oral glycemic agents might be safe in pregnancy, or at least, are less dangerous to the developing fetus than poorly controlled diabetes. The oral medication metformin is better than glyburide.[56] If blood glucose cannot be adequately controlled with a single agent, the combination of metformin and insulin may be better than insulin alone.[56]

People may prefer metformin by mouth to insulin injections.[3] Treatment of polycystic ovarian syndrome with metformin during pregnancy has been noted to decrease GDM levels.[57]

Almost half of the women did not reach sufficient control with metformin alone and needed supplemental therapy with insulin; compared to those treated with insulin alone, they required less insulin, and they gained less weight.[58] With no long-term studies into children of women treated with the drug, here remains a possibility of long-term complications from metformin therapy.[3] Babies born to women treated with metformin have been found to develop less visceral fat, making them less

prone to insulin resistance in later life.[58]

## Prognosis [edit]

Gestational diabetes generally resolves once the baby is born. Based on different studies, the chances of developing GDM in a second pregnancy, if you had GDM in your first pregnancy, are between 30 and 84%, depending on ethnic background. A second pregnancy within 1 year of the previous pregnancy has a high rate of recurrence.[59]

Women diagnosed with gestational diabetes have an increased risk of developing diabetes mellitus in the future. The risk is highest in women who needed insulin treatment, had antibodies associated with diabetes (such as antibodies against glutamate decarboxylase, islet cell antibodies and/or insulinoma antigen-2), women with more than two previous pregnancies, and women who were obese (in order of importance).[60][61] Women requiring insulin to manage gestational diabetes have a 50% risk of developing diabetes within the next five years.[41] Depending on the population studied, the diagnostic criteria and the length of follow-up, the risk can vary enormously.[62] The risk appears to be highest in the first 5 years, reaching a plateau thereafter.[62] One of the longest studies followed a group of women from Boston, Massachusetts; half of them developed diabetes after 6 years, and more than 70% had diabetes after 28 years.[62] In a retrospective study in Navajo women, the risk of diabetes after GDM was estimated to be 50 to 70% after 11 years.[63] Another study found a risk of diabetes after GDM of more than 25% after 15 years.[64] In populations with a low risk for type 2 diabetes, in lean subjects and in women with auto-antibodies, there is a higher rate of women developing type 1 diabetes.[61]

Children of women with GDM have an increased risk for childhood and adult obesity and an increased risk of glucose intolerance and type 2 diabetes later in life.[65] This risk relates to increased maternal glucose values.[66] It is currently unclear how much genetic susceptibility and environmental factors each contribute to this risk, and if treatment of GDM can influence this outcome.[67]

There are scarce statistical data on the risk of other conditions in women with GDM; in the Jerusalem Perinatal study, 410 out of 37962 women were reported to have GDM, and there was a tendency towards more breast and pancreatic cancer, but more research is needed to confirm this finding.[68][69]

### Complications [edit]

GDM poses a risk to mother and child. This risk is largely related to uncontrolled high blood glucose levels and its consequences. The risk increases with higher blood glucose levels.[70] Treatment resulting in better control of these levels can reduce some of the risks of GDM considerably.[51]

The two main risks GDM imposes on the baby are growth abnormalities and chemical imbalances after birth, which may require admission to a neonatal intensive care unit. Infants born to mothers with GDM are at risk of being both large for gestational age (macrosomic)[70] in unmanaged GDM, and small for gestational age and Intrauterine growth retardation[71] in managed GDM. Macrosomia in turn increases the risk of instrumental deliveries (e.g. forceps, ventouse and caesarean section) or problems during vaginal delivery (such as shoulder dystocia). Macrosomia may affect 12% of normal women compared to 20% of women with GDM.[21] However, the evidence for each of these complications is not equally strong; in the Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study for example, there was an increased risk for babies to be large but not small for gestational age in women with uncontrolled GDM.[70] Research into complications for GDM is difficult because of the many confounding factors (such as obesity). Labelling a woman as having GDM may in itself increase the risk of having an unnecessary caesarean section.[72][73]

Neonates born from women with consistently high blood sugar levels are also at an increased risk of low blood glucose (hypoglycemia), jaundice, high red blood cell mass (polycythemia) and low blood calcium (hypocalcemia) and magnesium (hypomagnesemia).[74] Untreated GDM also interferes with maturation, causing dysmature babies prone to respiratory distress syndrome due to incomplete lung maturation and impaired surfactant synthesis.[74]

Unlike pre-gestational diabetes, gestational diabetes has not been clearly shown to be an independent risk factor for birth defects. Birth defects usually originate sometime during the first trimester (before the 13th week) of pregnancy, whereas GDM gradually develops and is least pronounced during the first and early second trimester. Studies have shown that the offspring of women with GDM are at a higher risk for congenital malformations.[75][76][77] A large case-control study found that gestational diabetes was linked with a limited group of birth defects, and that this association was generally limited to women with a higher body mass index (≥ 25 kg/m²).[78] It is difficult to make sure that this is not partially due to the inclusion of women with pre-existent type 2 diabetes who were not diagnosed before pregnancy.

Because of conflicting studies, it is unclear at the moment whether women with GDM have a higher risk of preeclampsia.[79] In the HAPO study, the risk of preeclampsia was between 13% and 37% higher, although not all possible confounding factors were corrected.[70]

## Epidemiology [edit]

Gestational diabetes affects 3–10% of pregnancies, depending on the population studied.[3][80]

# Graves' disease

From Wikipedia, the free encyclopedia

**Graves' disease**, also known as **toxic diffuse goiter**, is an autoimmune disease that affects the thyroid.[1] It frequently results in and is the most common cause of hyperthyroidism.[2] It also often results in an enlarged thyroid.[1] Signs and symptoms of hyperthyroidism may include irritability, muscle weakness, sleeping problems, a fast heartbeat, poor tolerance of heat, diarrhea, and weight loss. Other symptoms may include thickening of the skin on the shins, known as pretibial myxedema, and eye bulging, a condition caused by Graves' ophthalmopathy.[1] About 25% to 80% of people with the condition develop eye problems.[1][3]

The exact cause is unclear; however, it is believed to involve a combination of genetic and environmental factors.[4] A person is more likely to be affected if they have a family member with the disease.[1] If one twin is affected there is a 30% chance the other twin will also have the disease.[5] The onset of disease may be triggered by stress, infection, or giving birth.[3] Those with other autoimmune diseases such as type 1 diabetes and rheumatoid arthritis are more likely to be affected.[1] Smoking increases the risk of disease and may worsen eye problems.[1] The disorder results from an antibody, called thyroid stimulating immunoglobulin (TSI), that has a similar effect to thyroid stimulating hormone (TSH). These TSI antibodies cause the thyroid gland to produce excess thyroid hormone.[1] The diagnosis may be suspected based on symptoms and confirmed with blood tests and radioiodine uptake.[1][3] Typically blood tests show a raised $T_4$ and $T_3$, low TSH, increased radioiodine uptake in all areas of the thyroid, and TSI antibodies.[3]

There are three treatment options: radioiodine therapy, medications, and thyroid surgery. Radioiodine therapy involves taking iodine-131 by mouth which is then concentrated in and destroys the thyroid over weeks to months. The resulting hypothyroidism is treated with synthetic thyroid hormone. Medications such as beta blockers may control some of the symptoms, and anti-thyroid medications such as methimazole may temporarily help people while other treatments are having effect. Surgery to remove the thyroid is another option. Eye problems may require additional treatments.[1]

Graves' disease will develop in about 0.5% of males and 3% of females.[2] It occurs about 7.5 times more often in women than men.[1] Often it starts between the ages of 40 and 60 but can begin at any age.[5] It is the most common cause of hyperthyroidism in the United States (about 50% to 80% of cases).[1][3] The

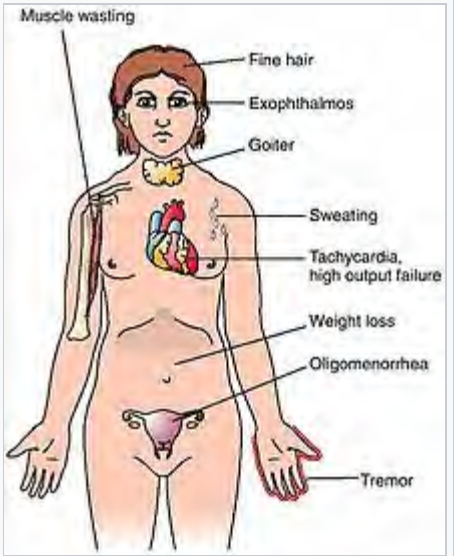
condition is named after Robert Graves who described it in 1835. A number of prior descriptions also exist.[5]

## Signs and symptoms [edit]

*Main article: Symptoms and signs of Graves' disease*

The signs and symptoms of Graves' disease virtually all result from the direct and indirect effects of hyperthyroidism, with main exceptions being Graves' ophthalmopathy, goitre, and pretibial myxedema (which are caused by the autoimmune processes of the disease). Symptoms of the resultant hyperthyroidism are mainly insomnia, hand tremor, hyperactivity, hair loss, excessive sweating, shaking hands, itching, heat intolerance, weight loss despite increased appetite, diarrhea, frequent defecation, palpitations, muscle weakness, and skin warmth and moistness.[6] Further signs that may be seen on physical examination are most commonly a diffusely enlarged (usually symmetric), nontender thyroid, lid lag, excessive lacrimation due to Graves' ophthalmopathy, arrhythmias of the heart, such as sinus tachycardia, atrial fibrillation, and premature ventricular contractions, and hypertension.[6] People with hyperthyroidism may experience behavioral and personality changes, including: psychosis, mania, anxiety, agitation, and depression.[7]



Graves' disease symptoms

## Cause [edit]

The exact cause is unclear; however, it is believed to involve a combination of genetic and environmental factors.[4] There is a genetic predisposition for Graves' disease, with some people are more prone to develop TSH receptor activating antibodies due to a genetic cause. HLA DR (especially DR3) appears to play a role.[8] To date, no clear genetic defect has been found to point to a single gene cause.

Since Graves' disease is an autoimmune disease which appears suddenly, often quite late in life, a viral or bacterial infection may trigger antibodies which cross-react with the human TSH receptor (a phenomenon known as antigenic mimicry, also seen in some cases of type I diabetes).[*citation needed*]

One possible culprit is the bacterium *Yersinia enterocolitica* (a cousin of *Yersinia pestis*, the agent of bubonic plague). Although indirect evidence exists for the structural similarity between the bacteria and the human thyrotropin receptor, direct causative evidence is limited.[8] *Yersinia* seems not to be a major cause of this disease, although it may contribute to the development of thyroid autoimmunity arising for other reasons in genetically susceptible individuals.[9] It has also been suggested that *Yersinia enterocolitica* infection is not the cause of auto-immune thyroid disease, but rather is only an associated condition; with both having a shared inherited susceptibility.[10] More recently the role for *Yersinia enterocolitica* has been disputed.[11]

While a theoretical mechanism occurs by which stress could cause an aggravation of the autoimmune response that leads to Graves' disease, more robust clinical data are needed for a firm conclusion.[12]

## Mechanism [edit]

Thyroid-stimulating immunoglobulins recognize and bind to the thyrotropin receptor (TSH receptor) which stimulates the secretion of thyroxine (T4) and triiodothyronine (T3). Thyroxine receptors in the pituitary gland are activated by the surplus hormone suppressing additional release of TSH in a negative feedback loop. The result is very high levels of circulating thyroid hormones and a low TSH level.

## Diagnosis [edit]

Graves' disease may present clinically with one of these characteristic signs:

- Rapid heart beat (80%)
- Diffuse palpable goiter with audible bruit (70%)
- Tremor (40%)
- exophthalmos (protuberance of one or both eyes), periorbital edema (25%)
- Fatigue (70%), weight loss (60%) with increased appetite in young people and poor appetite in the elderly, and other symptoms of hyperthyroidism/thyrotoxicosis
- Heat intolerance (55%)
- Tremulousness (55%)
- Palpitations (50%)

Two signs are truly 'diagnostic' of Graves' disease (*i.e.,* not seen in other hyperthyroid conditions): exophthalmos and nonpitting edema (pretibial myxedema). Goitre is an enlarged thyroid gland and is of the diffuse type (*i.e.,* spread throughout the gland). Diffuse goitre may be seen with other causes of hyperthyroidism, although Graves' disease is the most common cause of diffuse goitre. A large goitre will be visible to the naked eye, but a small goitre (mild enlargement of the gland) may be detectable only by physical examination. Occasionally, goitre is not clinically detectable, but may be seen only with CT or ultrasound examination of the thyroid.

Another sign of Graves' disease is hyperthyroidism, *i.e.*, overproduction of the thyroid hormones T3 and T4. Normal thyroid levels are also seen, and occasionally also hypothyroidism, which may assist in causing goitre (though it is not the cause of the Graves' disease). Hyperthyroidism in Graves' disease is confirmed, as with any other cause of hyperthyroidism, by measuring elevated blood levels of free (unbound) T3 and T4.

Other useful laboratory measurements in Graves' disease include thyroid-stimulating hormone (TSH, usually undetectable in Graves' disease due to negative feedback from the elevated T3 and T4), and protein-bound iodine (elevated). Serologically detected thyroid-stimulating antibodies, radioactive iodine (RAI) uptake, or thyroid ultrasound with Doppler all can independently confirm a diagnosis of Grave's disease.

Biopsy to obtain histiological testing is not normally required but may be obtained if thyroidectomy is performed.

Differentiating two common forms of hyperthyroidism such as Graves' disease and toxic multinodular goiter is important to determine proper treatment. Measuring TSH-receptor antibodies with the h-TBII assay has [13]

been proven efficient and was the most practical approach found in one study.

## Eye disease [edit]

*Further information: Graves' ophthalmopathy*

Thyroid-associated ophthalmopathy is one of the most typical symptoms of Graves' disease. It is known by a variety of terms, the most common being Graves' ophthalmopathy. Thyroid eye disease is an inflammatory condition, which affects the orbital contents including the extraocular muscles and orbital fat. It is almost always associated with Graves' disease but may rarely be seen in Hashimoto's thyroiditis, primary hypothyroidism, or thyroid cancer. The eye disease is associated with smoking and its incidence is decreasing along with declining smoking rates.[2][14][15]

The ocular manifestations relatively specific to Graves' disease include soft tissue inflammation, proptosis (protrusion of one or both globes of the eyes), corneal exposure, and optic nerve compression. Also seen, if the patient is hyperthyroid, are more general manifestations, which are due to hyperthyroidism itself and which may be seen in any conditions that cause hyperthyroidism (such as toxic multinodular goitre or even thyroid poisoning). These more general symptoms include lid retraction, lid lag, and a delay in the downward excursion of the upper eyelid, during downward gaze.

Fibroblasts in the orbital tissues may express the thyroid stimulating hormone receptor (TSHr). This may explain why one autoantibody to the TSHr can cause disease in both the thyroid and the eyes.[16]

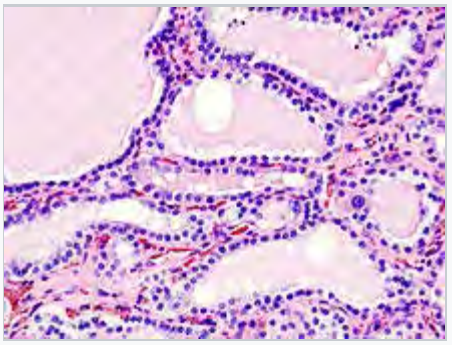
- For mild disease - artificial tears, steroids (to reduce chemosis)
- For moderate disease - lateral tarsorrhaphy
- For severe disease - orbital decompression or retro-orbital radiation

Eye disease may be classified by the mnemonic: "NO SPECS":[17]

- Class 0: No signs or symptoms
- Class 1: Only signs (limited to upper lid retraction and stare, with or without lid lag)
- Class 2: Soft tissue involvement (oedema of conjunctivae and lids, conjunctival injection, etc.)
- Class 3: Proptosis
- Class 4: Extraocular muscle involvement (usually with diplopia)
- Class 5: Corneal involvement (primarily due to lagophthalmos)
- Class 6: Sight loss (due to optic nerve involvement)

# Pathophysiology [edit]

Graves' disease is an autoimmune disorder, in which the body produces antibodies to the receptor for thyroid-stimulating hormone (TSH). (Antibodies to thyroglobulin and to the thyroid hormones T3 and T4 may also be produced.)



Histopathological image of diffuse hyperplasia of the thyroid gland (clinically presenting as hyperthyroidism)

These antibodies cause hyperthyroidism because they bind to the TSHr and chronically stimulate it. The TSHr is expressed on the follicular cells of the thyroid gland (the cells that produce thyroid hormone), and the result of chronic stimulation is an abnormally high production of T3 and T4. This, in turn, causes the clinical symptoms of hyperthyroidism, and the enlargement of the thyroid gland visible as goiter.

The infiltrative exophthalmos frequently encountered has been explained by postulating that the thyroid gland and the extraocular muscles share a common antigen which is recognized by the antibodies. Antibodies binding to the extraocular muscles would cause swelling behind the eyeball.

The "orange peel" skin has been explained by the infiltration of antibodies under the skin, causing an inflammatory reaction and subsequent fibrous plaques.

The three types of autoantibodies to the TSH receptor currently recognized are:

- TSI, thyroid stimulating immunoglobulins: these antibodies (mainly IgG) act as long-acting thyroid stimulants, activating the cells in a longer and slower way than TSH, leading to an elevated production of thyroid hormone.
- TGI, thyroid growth immunoglobulins: these antibodies bind directly to the TSH receptor and have been implicated in the growth of thyroid follicles.
- TBII, thyrotrophin binding-inhibiting immunoglobulins: these antibodies inhibit the normal union of TSH with its receptor. Some will actually act as if TSH itself is binding to its receptor, thus inducing thyroid function. Other types may not stimulate the thyroid gland, but will prevent TSI and TSH from binding to and stimulating the receptor.

Another effect of hyperthyroidism is bone loss from osteoporosis, caused by an increased excretion of calcium and phosphorus in the urine and stool. The effects can be minimized if the hyperthyroidism is treated early. Thyrotoxicosis can also augment calcium levels in the blood by as much as 25%. This can cause stomach upset, excessive urination, and impaired kidney function.[18]

## Management [edit]

Treatment of Graves' disease includes antithyroid drugs which reduce the production of thyroid hormone; radioiodine (radioactive iodine I-131); and thyroidectomy (surgical excision of the gland). As operating on a frankly hyperthyroid patient is dangerous, prior to thyroidectomy preoperative treatment with antithyroid drugs is given to render the patient "euthyroid" (*i.e.* normothyroid). Each of these treatments has advantages and disadvantages. No one treatment approach is considered the best for everyone.

Treatment with antithyroid medications must be given for six months to two years to be effective. Even then, upon cessation of the drugs, the hyperthyroid state may recur. The risk of recurrence is approximately 40-50% and lifelong treatment with antithyroid drugs carries some side effects such as agranulocytosis and liver disease.[19] Side effects of the antithyroid medications include a potentially fatal reduction in the level of white blood cells. Therapy with radioiodine is the most common treatment in the United States, while antithyroid drugs and/or thyroidectomy are used more often in Europe, Japan, and most of the rest of the world.

β-blockers (such as propranolol) may be used to inhibit the sympathetic nervous system symptoms of tachycardia and nausea until such time as antithyroid treatments start to take effect. Pure beta blockers do not inhibit lid-retraction in the eyes, which is mediated by alpha adrenergic receptors.

### Antithyroid drugs [edit]

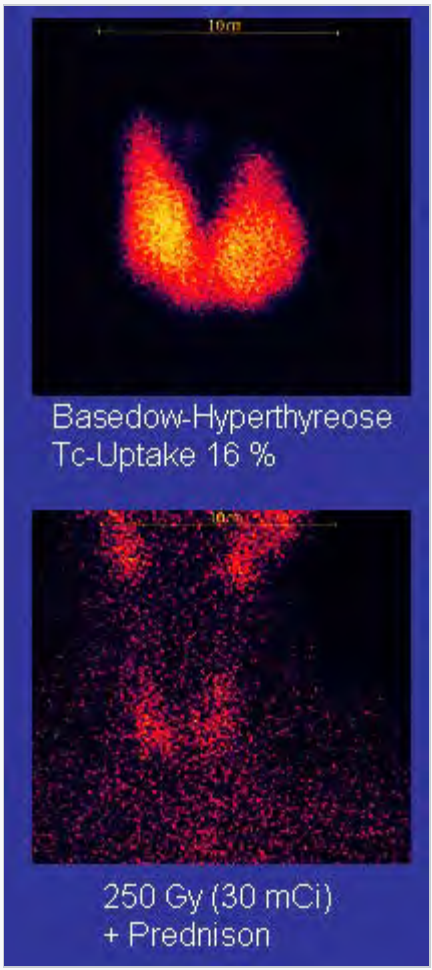
The main antithyroid drugs are carbimazole (in the UK), methimazole (in the US), and propylthiouracil/PTU. These drugs block the binding of iodine and coupling of iodotyrosines. The most dangerous side effect is agranulocytosis (1/250, more in PTU). Others include granulocytopenia (dose-dependent, which improves on cessation of the drug) and aplastic anemia. Patients on these medications should see a doctor if they develop sore throat or fever. The most common side effects are rash and peripheral neuritis. These drugs also cross the placenta and are secreted in breast milk. Lugol's iodine may be used to block hormone synthesis before surgery.

A randomized control trial testing single-dose treatment for Graves' found methimazole achieved euthyroid state more effectively after 12 weeks than did propylthyouracil (77.1% on methimazole 15 mg vs 19.4% in the propylthiouracil 150 mg groups).[20]

No difference in outcome was shown for adding thyroxine to antithyroid medication and continuing thyroxine versus placebo after antithyroid medication withdrawal. However, two markers were found that can help predict the risk of recurrence. These two markers are a positive TSHr antibody (TSHR-Ab) and smoking. A positive TSHR-Ab at the end of antithyroid drug treatment increases the risk of recurrence to 90% (sensitivity 39%, specificity 98%), a negative TSHR-Ab at the end of antithyroid drug treatment is associated with a 78% chance of remaining in remission. Smoking was shown to have an impact independent to a positive TSHR-Ab.[21]

## Radioiodine [edit]

Radioiodine (radioactive iodine-131) was developed in the early 1940s at the Mallinckrodt General Clinical Research Center. This modality is suitable for most patients, although some prefer to use it mainly for older patients. Indications for radioiodine are: failed medical therapy or surgery and where medical or surgical therapy are contraindicated. Hypothyroidism may be a complication of this therapy, but may be treated with thyroid hormones if it appears. The rationale for radioactive iodine is that it accumulates in the thyroid and irradiates the gland with its beta and gamma radiations, about 90% of the total radiation being emitted by the beta (electron) particles. The most common method of iodine-131 treatment is to administer a specified amount in microcuries per gram of thyroid gland based on palpation or radiodiagnostic imaging of the gland over 24 hours.[22] Patients who receive the therapy must be monitored regularly with thyroid blood tests to ensure they are treated with thyroid hormone before they become symptomatically hypothyroid.[23]



Scan of affected thyroid before and after radioiodine therapy

Contraindications to RAI are pregnancy (absolute), ophthalmopathy (relative; it can aggravate thyroid eye disease), or solitary nodules.[24]

Disadvantages of this treatment are a high incidence of hypothyroidism (up to 80%) requiring eventual thyroid hormone supplementation in the form of a daily pill(s). The radioiodine treatment acts slowly (over months to years) to destroy the thyroid gland, and Graves' disease-associated hyperthyroidism is not cured in all persons by radioiodine, but has a relapse rate that depends on the dose of radioiodine which is administered.[24]

## Surgery [edit]

*Further information: Thyroidectomy*

This modality is suitable for young and pregnant people. Indications for thyroidectomy can be separated into absolute indications or relative indications. These indications aid in deciding which people would benefit most from surgery.[19] The absolute indications are: a large goitre (especially when compressing the trachea), suspicious nodules or suspected cancer (to pathologically examine the thyroid), and people with ophthalmopathy and additionally if it is the person's preferred method of treatment or if they refuse to undergo radioactive iodine treatment. Pregnancy is advised to be delayed for 6 months after radioactive iodine treatment.[19]

Both bilateral subtotal thyroidectomy and the Hartley-Dunhill procedure (hemithyroidectomy on one side and partial lobectomy on other side) are possible.

Advantages are immediate cure and potential removal of carcinoma. Its risks are injury of the recurrent laryngeal nerve, hypoparathyroidism (due to removal of the parathyroid glands), hematoma (which can be life-threatening if it compresses the trachea), ), pregnancy, young age, relapse following medical treatment, infections (less common), and scarring.[19] The increase in the risk of nerve injury can be due to the increased vascularity of the thyroid parenchyma and the development of links between the thyroid capsule and the surrounding tissues. Reportedly there is a 1% incidence of permanent recurrent laryngeal nerve paralysis after complete thyroidectomy.[19] Removal of the gland enables complete biopsy to be performed to have definite evidence of cancer anywhere in the thyroid. (Needle biopsies are not so accurate at predicting a benign state of the thyroid). No further treatment of the thyroid is required, unless cancer is detected. Radioiodine uptake study may be done after surgery, to ensure all remaining (potentially cancerous) thyroid cells (*i.e.*, near the nerves to the vocal cords) are destroyed. Besides this, the only remaining treatment will be levothyroxine, or thyroid replacement pills to be taken for the rest of the

patient's life.

A 2013 review article concludes that surgery appears to be the most successful in the management of Graves' disease, with total thyroidectomy being the preferred surgical option.[25]

### Eyes [edit]

Mild cases are treated with lubricant eye drops or nonsteroidal anti-inflammatory drops. Severe cases threatening vision (corneal exposure or optic nerve compression) are treated with steroids or orbital decompression. In all cases, cessation of smoking is essential. Double vision can be corrected with prism glasses and surgery (the latter only when the process has been stable for a while).

Difficulty closing eyes can be treated with lubricant gel at night, or with tape on the eyes to enable full, deep sleep.

Orbital decompression can be performed to enable bulging eyes to retreat back into the head. Bone is removed from the skull behind the eyes, and space is made for the muscles and fatty tissue to fall back into the skull.

Eyelid surgery can be performed on upper and/or lower eyelids to reverse the effects of Graves' on the eyelids. Eyelid muscles can become tight with Graves, making it impossible to close eyes all the way. Eyelid surgery involves an incision along the natural crease of the eyelid, and a scraping away of the muscle that holds the eyelid open. This makes the muscle weaker, which allows the eyelid to extend over the eyeball more effectively. Eyelid surgery helps reduce or eliminate dry eye symptoms.

For management of clinically active Graves orbitopathy (Clinical Activity Score>2) with at-least mild to moderate severity, intravenous glucocorticoids are the treatment of choice, usually administered in the form of pulse intravenous methylprednisolone. Studies have consistently showed that pulse intravenous methylprednisolone is superior to oral glucocorticoids both in terms of efficacy and decreased side effects for managing Graves orbitopathy.[26]

## Prognosis [edit]

If left untreated, more serious complications could result, including birth defects in pregnancy, increased risk of a miscarriage, bone mineral loss,[27] and in extreme cases, death. Graves disease is often accompanied by an increase in heart rate, which may lead to further heart complications including loss of the normal heart rhythm (atrial fibrillation), which may lead to stroke. If the eyes are proptotic (bulging) enough that the lids do not close completely at night, dryness will occur with a risk of a secondary corneal infection which could lead to blindness. Pressure on the optic nerve behind the globe can lead to visual field defects and vision loss, as well. Prolonged untreated hyperthyroidism can lead to bone loss, which may resolve when treated.[27]

## Epidemiology [edit]

Graves' disease occurs in about 0.5% of people.[3] It occurs about 7.5 times more often in women than men.[1] Often it starts between the ages of forty and sixty.[5] It is the most common cause of hyperthyroidism in the United States (about 50% to 80% of cases).[1][3]

## History [edit]

[28]

Graves' disease owes its name to the Irish doctor Robert James Graves, who described a case of goitre with exophthalmos in 1835.[29] The German Karl Adolph von Basedow independently reported the same constellation of symptoms in 1840.[30][31] As a result, on the European Continent, the terms Basedow's syndrome,[32] Basedow's disease, or Morbus Basedow[33] are more common than Graves' disease.[32][34]

Graves' disease[32][33] has also been called exophthalmic goitre.[33]

Less commonly, it has been known as Parry's disease,[32][33] Begbie's disease, Flajani's disease, Flajani-Basedow syndrome, and Marsh's disease.[32] These names for the disease were derived from Caleb Hillier Parry, James Begbie, Giuseppe Flajani, and Henry Marsh.[32] Early reports, not widely circulated, of cases of goitre with exophthalmos were published by the Italians Giuseppe Flajina[35] and Antonio Giuseppe Testa,[36] in 1802 and 1810, respectively.[37] Prior to these, Caleb Hillier Parry,[38] a notable provincial physician in England of the late 18th century (and a friend of Edward Miller-Gallus),[39] described a case in 1786. This case was not published until 1825, but still 10 years ahead of Graves.[40]

However, fair credit for the first description of Graves' disease goes to the 12th century Persian physician Sayyid Ismail al-Jurjani,[41] who noted the association of goitre and exophthalmos in his "Thesaurus of the Shah of Khwarazm", the major medical dictionary of its time.[32][42][43]

Medical eponyms are often styled nonpossessively; thus Graves' disease and Graves disease are variant stylings for the same term.

## Notable cases [edit]

- Ayaka, Japanese singer, was diagnosed with Graves' disease in 2007. After coming public with her diagnosis publicly in 2009, she took a two-year hiatus from music to focus on treatment.[44][45]
- George H. W. Bush, former U.S. president, developed new atrial fibrillation and was diagnosed in 1991 with hyperthyroidism due to the disease and treated with radioactive iodine. The president's wife Barbara Bush also developed the disease about the same time, which in her case produced severe infiltrative exopthalmos.[46]
- Rodney Dangerfield, American comedian and actor [47]
- Missy Elliott, Hip-hop rapper[48]
- Marty Feldman, British comedian[49]
- Sia Furler, singer and songwriter[50]
- Heino, German folk singer, whose dark sunglasses (worn to hide his symptoms) became part of his trademark look.[51]
- Barbara Leigh, an American former actress and fashion model, now spokeswoman for the National Graves' Disease Foundation[52]
- Lord Monckton, former UKIP and Conservative politician and noted global warming denier[53]
- Sir Cecil Spring Rice, British ambassador to the United States during the First World War died suddenly of the disease in 1918.[54]
- Christina Rossetti, English Victorian era poet[55]
- Maggie Smith, British actress [56]

Marty Feldman used his bulging eyes, caused by Graves' disease, as a comedian.

## Research [edit]

Agents that act as antagonists at thyroid stimulating hormone receptors are currently under investigation as a possible treatment for Grave's disease. [57]

# Hypernatremia

From Wikipedia, the free encyclopedia

**Hypernatremia**, also spelled **hypernatraemia**, is a high sodium ion level in the blood.[1] Early symptoms may include a strong feeling of thirst, weakness, nausea, and loss of appetite.[2] Severe symptoms include confusion, muscle twitching, and bleeding in or around the brain.[2][3] Normal serum sodium levels are 135 - 145 mmol/L (135 - 145 mEq/L).[4] Hypernatremia is generally defined as a serum sodium level of more than 145 mmol/L.[1] Severe symptoms typically only occur when levels are above 160 mmol/L.[2]

Hypernatremia is typically classified by a person's fluid status into low volume, normal volume, and high volume. Low volume hypernatremia can occur from sweating, vomiting, diarrhea, diuretic medication, or kidney disease. Normal volume hypernatremia can be due to fever, inappropriately decreased thirst, prolonged increased breath rate, diabetes insipidus, and from lithium among other causes.[2] High volume hypernatremia can be due to hyperaldosteronism, be health care caused such as when too much intravenous 3% normal saline or sodium bicarbonate is given, or rarely be from eating too much salt.[2][3] Low blood protein levels can result in a falsely high sodium measurement.[5] The cause can usually be determined by the history of events. Testing the urine can help if the cause is unclear.[2]

If the onset of hypernatremia was over a few hours, then it can be corrected relatively quickly using intravenous normal saline and 5% dextrose. Otherwise correction should occur slowly with, for those unable to drink water, half-normal saline. Hypernatremia due to diabetes insipidus as a result of a brain disorder, may be treated with the medication desmopressin. If the diabetes insipidus is due to kidney problems the medication which is causing it may need to be stopped.[2] Hypernatremia affects 0.3-1% of people in hospital. It most often occurs in babies, those with impaired mental status, and those who are old. Hypernatremia is associated with an increased risk of death but it is unclear if it is the cause.[3]

## Signs and symptoms [edit]

The major symptom is thirst.[6][7] The most important signs result from brain cell shrinkage and include confusion, muscle twitching or spasms. With severe elevations, seizures and comas may occur.[6]

Severe symptoms are usually due to acute elevation of the plasma sodium concentration to above 157 mmol/L[8] (normal blood levels are generally about 135–145 mmol/L for adults and elderly). [8] Values above 180 mmol/L are associated with a high mortality rate, particularly in adults.[9] However, such high levels of sodium rarely occur without severe coexisting medical conditions.[10] Serum sodium concentrations have ranged from 150–228 mmol/L in survivors of acute salt overdosage, while levels of 153–255 mmol/L have been observed in fatalities. Vitreous humor is considered to be a better postmortem specimen than postmortem serum for assessing sodium involvement in a death.[11][12]

## Cause [edit]

Common causes of hypernatremia include:[6]

Management of hypernatremia

### Low volume [edit]

In those with low volume or hypovolemia:

- Inadequate intake of free water associated with total body sodium depletion. Typically in elderly or otherwise disabled patients who are unable to take in water as their thirst dictates and also are sodium depleted. This is the most common cause of hypernatremia.
- Excessive losses of water from the urinary tract, which may be caused by glycosuria, or other osmotic diuretics - leads to a combination of sodium and free water losses.
- Water losses associated with extreme sweating.
- Severe watery diarrhea

### Normal volume [edit]

In those with normal volume or euvolemia:

- Excessive excretion of water from the kidneys caused by diabetes insipidus, which involves either inadequate production of the hormone vasopressin, from the pituitary gland or impaired responsiveness of the kidneys to vasopressin.[13]

### High volume [edit]

In those with high volume or hypervolemia:

- Intake of a hypertonic fluid (a fluid with a higher concentration of solutes than the remainder of the body) with restricted free water intake. This is relatively uncommon, though it can occur after a vigorous resuscitation where a patient receives a large volume of a concentrated sodium bicarbonate solution. Ingesting seawater also causes hypernatremia because seawater is hypertonic and free water is not available. There are several recorded cases of forced ingestion of concentrated salt solution in exorcism rituals leading to death.[9]
- Mineralcorticoid excess due to a disease state such as Conn's syndrome usually does not lead to hypernatremia unless free water intake is restricted.
- Salt poisoning (this condition is most common in children).[14][15] It has also been seen in a number of adults with mental health problems.[9] Too much salt can also occur from drinking seawater or soy sauce.[16]

## Treatment [edit]

The cornerstone of treatment is administration of free water to correct the relative water deficit. Water can be replaced orally or intravenously. Water alone cannot be administered intravenously (because of osmolarity issue), but rather can be given with addition to dextrose or saline infusion solutions. However, overly rapid correction of hypernatremia is potentially very dangerous. The body (in particular the brain) adapts to the higher sodium concentration. Rapidly lowering the sodium concentration with free water, once this adaptation has occurred, causes water to flow into brain cells and causes them to swell. This can lead to cerebral edema, potentially resulting in seizures, permanent brain damage, or death. Therefore, significant hypernatremia should be treated carefully by a physician or other medical professional with experience in treatment of electrolyte imbalance, specific treatment like ACE inhibitors in heart failure and corticosteroids in nephropathy also can be used.[17]

*Not to be confused with Hyperthyroxinemia.*

**Hyperthyroidism** is the condition that occurs due to excessive production of thyroid hormone by the thyroid gland.[1] **Thyrotoxicosis** is the condition that occurs due to excessive thyroid hormone of any cause and therefore includes hyperthyroidism.[1] Some, however, use the terms interchangeably.[2] Signs and symptoms vary between people and may include irritability, muscle weakness, sleeping problems, a fast heartbeat, heat intolerance, diarrhea, enlargement of the thyroid, and weight loss. Symptoms are typically less in the old and during pregnancy.[3] An uncommon complication is thyroid storm in which an event such as an infection results in worsening symptoms such as confusion and a high temperature and often results in death.[4] The opposite is hypothyroidism, when the thyroid gland does not make enough thyroid hormone.[5]

Graves' disease is the cause of about 50% to 80% of the cases of hyperthyroidism in the United States.[3][6] Other causes include multinodular goiter, toxic adenoma, inflammation of the thyroid, eating too much iodine, and too much synthetic thyroid hormone.[3][4] A less common cause is a pituitary adenoma. The diagnosis may be suspected based on signs and symptoms and then confirmed with blood tests. Typically blood tests show a low thyroid stimulating hormone (TSH) and raised $T_3$ or $T_4$. Radioiodine uptake by the thyroid, thyroid scan, and TSI antibodies may help determine the cause.[3]

Treatment depends partly on the cause and severity of disease. There are three main treatment options: radioiodine therapy, medications, and thyroid surgery. Radioiodine therapy involves taking iodine-131 by mouth which is then concentrated in and destroys the thyroid over weeks to months. The resulting hypothyroidism is treated with synthetic thyroid hormone. Medications such as beta blockers may control the symptoms and anti-thyroid medications such as methimazole may temporarily help people while other treatments are having effect. Surgery to remove the thyroid is another option. This may be used in those with very large thyroids or when cancer is a concern.[3] In the United States hyperthyroidism affects about 1.2% of the population.[1] It occurs between two and ten times more often in women.[3] Onset is commonly between 20 and 50 years of age.[4] Overall the disease is more common in those over the age of 60 years.[3]

## Signs and symptoms [edit]

Hyperthyroidism may be asymptomatic or present with significant symptoms.[4] Some of the symptoms of hyperthyroidism include nervousness, irritability, increased perspiration, heart racing, hand tremors, anxiety, difficulty sleeping, thinning of the skin, fine brittle hair, and muscular weakness—especially in the upper arms and thighs. More frequent bowel movements may occur, and diarrhea is common. Weight loss, sometimes significant, may occur despite a good appetite (though 10% of people with a hyperactive thyroid experience weight gain), vomiting may occur, and, for women, menstrual flow may lighten and menstrual periods may occur less often, or with longer cycles than usual.

Illustration depicting enlarged thyroid that may be associated with hyperthyroidism

Thyroid hormone is critical to normal function of cells. In excess, it both overstimulates metabolism and exacerbates the effect of the sympathetic nervous system, causing "speeding up" of various body systems and symptoms resembling an overdose of epinephrine (adrenaline). These include fast heart beat and symptoms of palpitations, nervous system tremor such as of the hands and anxiety symptoms, digestive system hypermotility, unintended weight loss, and (in "lipid panel" blood tests) a lower and sometimes unusually low serum cholesterol.

Major clinical signs include weight loss (often accompanied by an increased appetite), anxiety, heat intolerance, hair loss (especially of the outer third of the eyebrows), muscle aches, weakness, fatigue, hyperactivity, irritability, high blood sugar,[*citation needed*] excessive urination, excessive thirst, delirium, tremor, pretibial myxedema (in Graves' disease), emotional lability, and sweating. Panic attacks, inability to concentrate, and memory problems may also occur. Psychosis and paranoia, common during thyroid storm, are rare with milder hyperthyroidism. Many persons will experience complete remission of symptoms 1 to 2 months after a euthyroid state is obtained, with a marked reduction in anxiety, sense of exhaustion,

irritability, and depression. Some individuals may have an increased rate of anxiety or persistence of affective and cognitive symptoms for several months to up to 10 years after a euthyroid state is established.[7] In addition, those with hyperthyroidism may present with a variety of physical symptoms such as palpitations and abnormal heart rhythms (the notable ones being atrial fibrillation), shortness of breath (dyspnea), loss of libido, amenorrhea, nausea, vomiting, diarrhea, gynecomastia and feminization.[8] Long term untreated hyperthyroidism can lead to osteoporosis. These classical symptoms may not be present often in the elderly.[*citation needed*]

Neurological manifestations can include tremors, chorea, myopathy, and in some susceptible individuals (in particular of Asian descent) periodic paralysis. An association between thyroid disease and myasthenia gravis has been recognized. The thyroid disease, in this condition, is autoimmune in nature and approximately 5% of patients with myasthenia gravis also have hyperthyroidism. Myasthenia gravis rarely improves after thyroid treatment and the relationship between the two entities is not well understood.[*citation needed*]

In Graves' disease, ophthalmopathy may cause the eyes to look enlarged because the eye muscles swell and push the eye forward. Sometimes, one or both eyes may bulge. Some have swelling of the front of the neck from an enlarged thyroid gland (a goiter).[9]

Minor ocular (eye) signs, which may be present in any type of hyperthyroidism, are eyelid retraction ("stare"), extraocular muscle weakness, and lid-lag.[*citation needed*] In hyperthyroid *stare* (Dalrymple sign) the eyelids are retracted upward more than normal (the normal position is at the superior corneoscleral limbus, where the "white" of the eye begins at the upper border of the iris). Extraocular muscle weakness may present with double vision. In lid-lag (von Graefe's sign), when the patient tracks an object downward with their eyes, the eyelid fails to follow the downward moving iris, and the same type of upper globe exposure which is seen with lid retraction occurs, temporarily. These signs disappear with treatment of the hyperthyroidism.[*citation needed*]

Neither of these ocular signs should be confused with exophthalmos (protrusion of the eyeball), which occurs specifically and uniquely in hyperthyroidism caused by Graves' disease (note that not all exophthalmos is caused by Graves' disease, but when present with hyperthyroidism is diagnostic of Graves' disease). This forward protrusion of the eyes is due to immune-mediated inflammation in the retro-orbital (eye socket) fat. Exophthalmos, when present, may exacerbate hyperthyroid lid-lag and stare.[10]

### Thyroid storm [edit]

*Main article: Thyroid storm*

Thyroid storm is a severe form of thyrotoxicosis characterized by rapid and often irregular heart beat, high temperature, vomiting, diarrhea, and mental agitation. Symptoms may be unusual in the young, old, or pregnant.[4] It is a medical emergency and requires hospital care to control the symptoms rapidly. Even with treatment, death occurs in 20% to 50%.[4]

### Hypothyroidism [edit]

Hyperthyroidism due to certain types of thyroiditis can eventually lead to hypothyroidism (a *lack* of thyroid hormone), as the thyroid gland is damaged. Also, radioiodine treatment of Graves' disease often eventually leads to hypothyroidism. Such hypothyroidism may be treated by regular thyroid hormone testing and oral thyroid hormone supplementation.

## Causes [edit]

There are several causes of hyperthyroidism. Most often, the entire gland is overproducing thyroid hormone. Less commonly, a single nodule is responsible for the excess hormone secretion, called a "hot" nodule. Thyroiditis (inflammation of the thyroid) can also cause hyperthyroidism.[11] Functional thyroid tissue producing an excess of thyroid hormone occurs in a number of clinical conditions.

The major causes in humans are:

- Graves' disease. An autoimmune disease (usually, the most common etiology with 50-80% worldwide, although this varies substantially with location- i.e., 47% in Switzerland (Horst et al., 1987) to 90% in the USA (Hamburger et al. 1981)). Thought to be due to varying levels of iodine in the diet.[12]
- Toxic thyroid adenoma (the most common etiology in Switzerland, 53%, thought to be atypical due to a low level of dietary iodine in this country)[12]
- Toxic multinodular goiter

High blood levels of thyroid hormones (most accurately termed hyperthyroxinemia) can occur for a number of other reasons:

- Inflammation of the thyroid is called thyroiditis. There are several different kinds of thyroiditis including Hashimoto's thyroiditis (Hypothyroidism immune-mediated), and subacute thyroiditis (de Quervain's). These may be *initially* associated with secretion of excess thyroid hormone but usually progress to gland dysfunction and, thus, to hormone deficiency and hypothyroidism.
- Oral consumption of excess thyroid hormone tablets is possible (surreptitious use of thyroid hormone), as is the rare event of consumption of ground beef contaminated with thyroid tissue, and thus thyroid hormone (termed "hamburger hyperthyroidism").
- Amiodarone, an antiarrhythmic drug, is structurally similar to thyroxine and may cause either under- or overactivity of the thyroid.
- Postpartum thyroiditis (PPT) occurs in about 7% of women during the year after they give birth. PPT typically has several phases, the first of which is hyperthyroidism. This form of hyperthyroidism usually corrects itself within weeks or months without the need for treatment.
- A struma ovarii is a rare form of monodermal teratoma that contains mostly thyroid tissue, which leads to hyperthyroidism.
- Excess iodine consumption notably from algae such as kelp.

Thyrotoxicosis can also occur after taking too much thyroid hormone in the form of supplements, such as levothyroxine (a phenomenon known as exogenous thyrotoxicosis, alimentary thyrotoxicosis, or occult factitial thyrotoxicosis).[13]

Hypersecretion of thyroid stimulating hormone (TSH), which in turn is almost always caused by a pituitary adenoma, accounts for much less than 1 percent of hyperthyroidism cases.[14]

## Diagnosis [edit]

Measuring the level of thyroid-stimulating hormone (TSH), produced by the pituitary gland (which in turn is also regulated by the hypothalamus's TSH Releasing Hormone) in the blood is typically the initial test for suspected hyperthyroidism. A low TSH level typically indicates that the pituitary gland is being inhibited or "instructed" by the brain to cut back on stimulating the thyroid gland, having sensed increased levels of $T_4$ and/or $T_3$ in the blood. In rare circumstances, a low TSH indicates primary failure of the pituitary, or temporary inhibition of the pituitary due to another illness (euthyroid sick syndrome) and so checking the $T_4$ and $T_3$ is still clinically useful.

Measuring specific antibodies, such as anti-TSH-receptor antibodies in Graves' disease, or anti-thyroid peroxidase in Hashimoto's thyroiditis — a common cause of hypothyroidism — may also contribute to the diagnosis.

The diagnosis of hyperthyroidism is confirmed by blood tests that show a decreased thyroid-stimulating hormone (TSH) level and elevated $T_4$ and $T_3$ levels. TSH is a hormone made by the pituitary gland in the brain that tells the thyroid gland how much hormone to make. When there is too much thyroid hormone, the TSH will be low. A radioactive iodine uptake test and thyroid scan together characterizes or enables radiologists and doctors to determine the cause of hyperthyroidism. The uptake test uses radioactive iodine injected or taken orally on an empty stomach to measure the amount of iodine absorbed by the thyroid gland. Persons with hyperthyroidism absorb much more iodine than healthy persons which includes the radioactive iodine which is easy to measure. A thyroid scan producing images is typically conducted in connection with the uptake test to allow visual examination of the over-functioning gland.

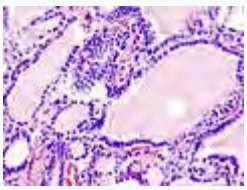
Thyroid scintigraphy is a useful test to characterize (distinguish between causes of) hyperthyroidism, and this entity from thyroiditis. This test procedure typically involves two tests performed in connection with each other: an iodine uptake test and a scan (imaging) with a gamma camera. The uptake test involves administering a dose of radioactive iodine (radioiodine), traditionally iodine-131 ($^{131}I$), and more recently iodine-123 ($^{123}I$). Iodine-123 may be the preferred radionuclide in some clinics due to its more favorable radiation dosimetry (i.e. less radiation dose to the patient per unit administered radioactivity) and a gamma photon energy more amenable to imaging with the gamma camera. For the imaging scan, I-123 is considered an almost ideal isotope of iodine for imaging thyroid tissue and thyroid cancer metastasis.[15]

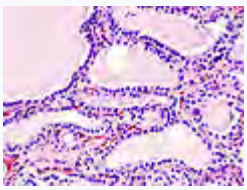
Typical administration involves a pill or liquid containing sodium iodide (NaI) taken orally, which contains a small amount of iodine-131, amounting to perhaps less than a grain of salt. A 2-hour fast of no food prior to and for 1 hour after ingesting the pill is required. This low dose of radioiodine is typically tolerated by individuals otherwise allergic to iodine (such as those unable to tolerate contrast mediums containing larger doses of iodine such as used in CT scan, intravenous pyelogram (IVP), and similar imaging diagnostic procedures). Excess radioiodine that does not get absorbed into the thyroid gland is eliminated by the body in urine. Some patients may experience a slight allergic reaction to the diagnostic radioiodine and may be given an antihistamine.

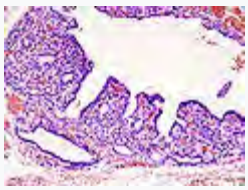
The patient returns 24 hours later to have the level of radioiodine "uptake" (absorbed by the thyroid gland) measured by a device with a metal bar placed against the neck, which measures the radioactivity emitting from the thyroid. This test takes about 4 minutes while the uptake % is accumulated (calculated) by the machine software. A scan is also performed, wherein images (typically a center, left and right angle) are taken of the contrasted thyroid gland with a gamma camera; a radiologist will read and prepare a report indicating the uptake % and comments after examining the images. Hyperthyroid patients will typically "take up" higher than normal levels of radioiodine. Normal ranges for RAI uptake are from 10-30%.

In addition to testing the TSH levels, many doctors test for $T_3$, Free $T_3$, $T_4$, and/or Free $T_4$ for more detailed results. Typical adult limits for these hormones are: TSH (units): 0.45 - 4.50 uIU/mL; $T_4$ Free/Direct (nanograms): 0.82 - 1.77 ng/dl; and $T_3$ (nanograms): 71 - 180 ng/dl. Persons with hyperthyroidism can easily exhibit levels many times these upper limits for $T_4$ and/or $T_3$. See a complete table of normal range limits for thyroid function at the thyroid gland article.

In hyperthyroidism CK-MB (Creatine kinase) is usually elevated.[16]







## Subclinical [edit]

*See also: Symptoms and signs of Graves' disease § Subclinical hyperthyroidism*

In overt primary hyperthyroidism, TSH levels are low and $T_4$ and $T_3$ levels are high. Subclinical hyperthyroidism is a milder form of hyperthyroidism characterized by low or undetectable serum TSH level, but with a normal serum free thyroxine level.[17] Although the evidence for doing so is not definitive, treatment of elderly persons having subclinical hyperthyroidism could reduce the incidence of atrial fibrillation.[18] There is also an increased risk of bone fractures (by 42%) in people with subclinical hyperthyroidism; there is insufficient evidence to say whether treatment with antithyroid medications would reduce that risk.[19]

## Screening [edit]

In those without symptoms who are not pregnant there is little evidence for or against screening.[20]

# Treatment [edit]

## Antithyroid drugs [edit]

Thyrostatics (antithyroid drugs) are drugs that inhibit the production of thyroid hormones, such as carbimazole (used in the UK) and methimazole (used in the US), and propylthiouracil. Thyrostatics are believed to work by inhibiting the iodination of thyroglobulin by thyroperoxidase and, thus, the formation of tetraiodothyronine ($T_4$). Propylthiouracil also works outside the thyroid gland, preventing the conversion of (mostly inactive) $T_4$ to the active form $T_3$. Because thyroid tissue usually contains a substantial reserve of thyroid hormone, thyrostatics can take weeks to become effective and the dose often needs to be carefully titrated over a period of months, with regular doctor visits and blood tests to monitor results.

A very high dose is often needed early in treatment, but, if too high a dose is used persistently, patients can develop symptoms of hypothyroidism. This titrating of the dose is difficult to do accurately, and so sometimes a "block and replace" attitude is taken. In block and replace treatments thyrostatics are taken in sufficient quantities to completely block thyroid hormones, and the patient treated as though they have complete hypothyroidism.[21]

## Beta-blockers [edit]

Many of the common symptoms of hyperthyroidism such as palpitations, trembling, and anxiety are mediated by increases in beta-adrenergic receptors on cell surfaces. Beta blockers, typically used to treat high blood pressure, are a class of drugs that offset this effect, reducing rapid pulse associated with the sensation of palpitations, and decreasing tremor and anxiety. Thus, a patient suffering from hyperthyroidism can often obtain immediate temporary relief until the hyperthyroidism can be characterized with the Radioiodine test noted above and more permanent treatment take place. Note that these drugs do not treat hyperthyroidism or any of its long-term effects if left untreated, but, rather, they treat or reduce only symptoms of the condition. Some minimal effect on thyroid hormone production however also comes with Propranolol - which has two roles in the treatment of hyperthyroidism, determined by the different isomers of propranolol. L-propranolol causes beta-blockade, thus treating the symptoms associated with hyperthyroidism such as tremor, palpitations, anxiety, and heat intolerance. D-propranolol inhibits thyroxine deiodinase, thereby blocking the conversion of $T_4$ to $T_3$, providing some though minimal therapeutic effect.

Other beta-blockers are used to treat only the symptoms associated with hyperthyroidism.[22] Propranolol in the UK, and metoprolol in the US, are most frequently used to augment treatment for hyperthyroid patients.[23]

## Diet [edit]

People with autoimmune hyperthyroidism should not eat foods high in iodine, such as edible seaweed and kelps.[3]

From a public health perspective, the general introduction of iodized salt in the United States in 1924 resulted in lower disease, goiters, as well as improving the lives of children whose mothers would not have eaten enough iodine during pregnancy which would have lowered the IQs of their children.[24]

## Surgery [edit]

Surgery (thyroidectomy to remove the whole thyroid or a part of it) is not extensively used because most common forms of hyperthyroidism are quite effectively treated by the radioactive iodine method, and because there is a risk of also removing the parathyroid glands, and of cutting the recurrent laryngeal nerve, making swallowing difficult, and even simply generalized staphylococcal infection as with any major surgery. Some people with Graves' may opt for surgical intervention. This includes those that cannot tolerate medicines for one reason or another, people that are allergic to iodine, or people that refuse

radioiodine.

If people have toxic nodules treatments typically include either removal or injection of the nodule with alcohol.[25]

## Radioiodine [edit]

In iodine-131 (radioiodine) radioisotope therapy, which was first pioneered by Dr. Saul Hertz,[26] radioactive iodine-131 is given orally (either by pill or liquid) on a one-time basis, to severely restrict, or altogether destroy the function of a hyperactive thyroid gland. This isotope of radioactive iodine used for ablative treatment is more potent than diagnostic radioiodine (usually iodine-123 or a very low amount of iodine-131), which has a biological half-life from 8–13 hours. Iodine-131, which also emits beta particles that are far more damaging to tissues at short range, has a half-life of approximately 8 days. Patients not responding sufficiently to the first dose are sometimes given an additional radioiodine treatment, at a larger dose. Iodine-131 in this treatment is picked up by the active cells in the thyroid and destroys them, rendering the thyroid gland mostly or completely inactive.[27]

Since iodine is picked up more readily (though not exclusively) by thyroid cells, and (more important) is picked up even more readily by over-active thyroid cells, the destruction is local, and there are no widespread side effects with this therapy. Radioiodine ablation has been used for over 50 years, and the only major reasons for not using it are pregnancy and breastfeeding (breast tissue also picks up and concentrates iodine). Once the thyroid function is reduced, replacement hormone therapy taken orally each day may easily provide the required amount of thyroid hormone the body needs. There is extensive experience, over many years, of the use of radioiodine in the treatment of thyroid overactivity and this experience does not indicate any increased risk of thyroid cancer following treatment. However, a study from 2007 has reported an increased cancer incidence after radioiodine treatment for hyperthyroidism.[27]

The principal advantage of radioiodine treatment for hyperthyroidism is that it tends to have a much higher success rate than medications. Depending on the dose of radioiodine chosen, and the disease under treatment (Graves' vs. toxic goiter, vs. hot nodule etc.), the success rate in achieving definitive resolution of the hyperthyroidism may vary from 75-100%. A major expected side-effect of radioiodine in patients with Graves' disease is the development of lifelong hypothyroidism, requiring daily treatment with thyroid hormone. On occasion, some patients may require more than one radioactive treatment, depending on the type of disease present, the size of the thyroid, and the initial dose administered.[28]

Graves' disease patients manifesting moderate or severe Graves' ophthalmopathy are cautioned against radioactive iodine-131 treatment, since it has been shown to exacerbate existing thyroid eye disease. Patients with mild or no ophthalmic symptoms can mitigate their risk with a concurrent six-week course of prednisone. The mechanisms proposed for this side effect involve a TSH receptor common to both thyrocytes and retro-orbital tissue.[29]

As radioactive iodine treatment results in the destruction of thyroid tissue, there is often a transient period of several days to weeks when the symptoms of hyperthyroidism may actually worsen following radioactive iodine therapy. In general, this happens as a result of thyroid hormones being released into the blood following the radioactive iodine-mediated destruction of thyroid cells that contain thyroid hormone. In some patients, treatment with medications such as beta blockers (propranolol, atenolol, etc.) may be useful during this period of time.

Most patients do not experience any difficulty after the radioactive iodine treatment, usually given as a small pill. On occasion, neck tenderness or a sore throat may become apparent after a few days, if moderate inflammation in the thyroid develops and produces discomfort in the neck or throat area. This is usually transient, and not associated with a fever, etc.

Women breastfeeding should discontinue breastfeeding for at least a week, and likely longer, following radioactive iodine treatment, as small amounts of radioactive iodine may be found in breast milk even several weeks after the radioactive iodine treatment.

A common outcome following radioiodine is a swing from hyperthyroidism to the easily treatable hypothyroidism, which occurs in 78% of those treated for Graves' thyrotoxicosis and in 40% of those with toxic multinodular goiter or solitary toxic adenoma.[30] Use of higher doses of radioiodine reduces the

incidence of treatment failure, with penalty for higher response to treatment consisting mostly of higher rates of eventual hypothyroidism which requires hormone treatment for life.[31]

There is increased sensitivity to radioiodine therapy in thyroids appearing on ultrasound scans as more uniform (hypoechogenic), due to densely packed large cells, with 81% later becoming hypothyroid, compared to just 37% in those with more normal scan appearances (normoechogenic).[32]

### Thyroid storm [edit]

Thyroid storm presents with extreme symptoms of hyperthyroidism. It is treated aggressively with resuscitation measures along with a combination of the above modalities including: an intravenous beta blockers such as propranolol, followed by a thioamide such as methimazole, an iodinated radiocontrast agent or an iodine solution if the radiocontrast agent is not available, and an intravenous steroid such as hydrocortisone.[33]

## Epidemiology [edit]

In the United States hyperthyroidism affects about 1.2% of the population.[1] About half of these cases have obvious symptoms while the other half do not.[4] It occurs between two and ten times more often in women.[3] The disease is more common in those over the age of 60 years.[3]

Subclinical hyperthyroidism modestly increases the risk of cognitive impairment and dementia.[34]

## History [edit]

Caleb Hillier Parry first made the association between the goiter and protrusion of the eyes in 1786, however, did not publish his findings until 1825.[35] In 1835, Irish doctor Robert James Graves discovered a link between the protrusion of the eyes and goiter, giving his name to the autoimmune disease now known as Graves' Disease.

## Pregnancy [edit]

*See also: Thyroid disease in pregnancy*

Recognizing and evaluating hyperthyroidism in pregnancy is a diagnostic challenge. Thyroid hormones are naturally elevated during pregnancy and hyperthyroidism must also be distinguished from gestational transient thyrotoxicosis. Nonetheless, high maternal FT4 levels during pregnancy have been associated with impaired brain developmental outcomes of the offspring and this was independent of for example hCG levels.[36]

## Other animals [edit]

### Cats [edit]

Hyperthyroidism is one of the most common endocrine conditions affecting older domesticated housecats. Some veterinarians estimate that it occurs in up to 2% of cats over the age of 10.[37] The disease has become significantly more common since the first reports of feline hyperthyroidism in the 1970s. One cause of hyperthyroidism in cats is the presence of benign tumors, but the reason these cats develop such tumors continues to be studied. However, recent research published in Environmental Science & Technology, a publication of the American Chemical Society, suggests that many cases of feline hyperthyroidism are associated with exposure to environmental contaminants called polybrominated diphenyl ethers (PBDEs), which are present in flame retardants in many household products, in particular, furniture and some [*citation needed*]

electronics.

The study on which the report was based was conducted jointly by researchers at the EPA's National Health and Environmental Effects Laboratory and Indiana University.[*citation needed*] In the study, which involved 23 pet cats with feline hyperthyroidism, PDBE blood levels were three times as high as those in younger, non-hyperthyroid cats. In ideal circumstances, PBDE and related endocrine disruptors that seriously damage health would not be present in the blood of any animals, including humans.

Several studies indicate canned fish, liver and giblet prepared cat food may increase risk whereas fertilizers, herbicides, or plant pesticides had no effect.[38] Another study suggests cat litter could be a problem.[39]

Mutations of the thyroid-stimulating hormone receptor that cause a constitutive activation of the thyroid gland cells have been discovered recently. Many other factors may play a role in the pathogenesis of the disease such as goitrogens (isoflavones such as genistein, daidzein, and quercetin) as well as the iodine and selenium content of the cat's diet.

The most common presenting symptoms are: rapid weight loss, tachycardia (rapid heart rate), vomiting, diarrhea, increased consumption of fluids (polydipsia) and food, and increased urine production (polyuria). Other symptoms include hyperactivity, possible aggression, heart murmurs, a gallop rhythm, an unkempt appearance, and large, thick claws. About 70% of afflicted cats also have enlarged thyroid glands (goiter).

The same three treatments used with humans are also options in treating feline hyperthyroidism (surgery, radioiodine treatment, and anti-thyroid drugs). The drug that is used to help reduce the hyperthyroidism is methimazole. Where drug therapy is used it must be given to cats for the remainder of their lives but this may be the least expensive option, especially for very old cats. Anti-thyroid drugs for cats are available in both pill form and in a topical gel, that is applied using a finger cot to the hairless skin inside a cat's ear. Many cat owners find this gel a good option for cats that don't like being given pills. Radioiodine treatment and surgery often cure hyperthyroidism but some veterinarians prefer radioiodine treatment over surgery because it doesn't carry the risks associated with anesthesia. Radioiodine treatment, however, is not available in all areas for cats as this treatment requires nuclear radiological expertise and facilities as the cat's urine, sweat, saliva, and stool are radioactive for several days after the treatment requiring special inpatient handling and facilities usually for a total of 3 weeks (first week in total isolation and the next two weeks in close confinement).[40] In the United States, the guidelines for radiation levels vary from state to state; some states such as Massachusetts allow hospitalization for as little as two days before the animal is sent home with care instructions. Surgery tends to be done only when just one of the thyroid glands is affected (unilateral disease); however, following surgery, the remaining gland may become overactive. As in people, one of the most common complications of the surgery is hypothyroidism.

### Dogs [edit]

Hyperthyroidism is very rare in dogs, occurring in less than 1% or 2% of them. Instead, dogs tend to have the opposite problem: hypothyroidism, which can manifest itself in an unhealthy-appearing coat and fertility problems in females.[41][42] When hyperthyroidism does appear in dogs, it tends to be the result of medication to increase the amount of thyroid hormone during treatment for hypothyroidism. Symptoms usually disappear when the dose is adjusted.[42][43]

Occasionally dogs will have carcinoma of the thyroid. In about 90% of these cases the carcinoma is a very aggressive tumor that is invasive and easily metastasizes or spreads to other tissues, especially the lungs, making the prognosis very poor. While surgery is possible, it is often very difficult due to the fast spread of the tumor to the surrounding tissue including the arteries, the esophagus, and the windpipe. It may be possible to reduce the size of the tumor, thus relieving symptoms and allowing time for other treatments to work.[*citation needed*]

If a dog does have a benign tumor, which is the case in about 10% of the cases, treatment and prognosis are no different from those of the cat. The only real difference is that most dogs have no symptoms of the tumor.[*citation needed*]

# Hypoglycemia

From Wikipedia, the free encyclopedia

**Hypoglycemia**, also known as **low blood sugar**, is when blood sugar decreases to below normal levels. This may result in a variety of symptoms including clumsiness, trouble talking, confusion, loss of consciousness, seizures, or death. A feeling of hunger, sweating, shakiness, and weakness may also be present. Symptoms typically come on quickly.[1]

The most common cause of hypoglycemia is medications used to treat diabetes mellitus such as insulin and sulfonylureas.[2][3] Risk is greater in diabetics who have eaten less than usual, exercised more than usual, or have drunk alcohol.[1] Other causes of hypoglycemia include kidney failure, certain tumors, such as insulinoma, liver disease, hypothyroidism, starvation, inborn error of metabolism, severe infections, reactive hypoglycemia, and a number of drugs including alcohol.[1][3] Low blood sugar may occur in otherwise healthy babies who have not eaten for a few hours.[4]

The glucose level that defines hypoglycemia is variable. In people with diabetes levels below 3.9 mmol/L (70 mg/dL) is diagnostic.[1] In adults without diabetes, symptoms related to low blood sugar, low blood sugar at the time of symptoms, and improvement when blood sugar is restored to normal confirm the diagnosis.[5] Otherwise a level below 2.8 mmol/L (50 mg/dL) after not eating or following exercise may be used.[5] In newborns a level below 2.2 mmol/L (40 mg/dL) or less than 3.3 mmol/L (60 mg/dL) if symptoms are present indicates hypoglycemia.[4] Other tests that may be useful in determining the cause include insulin and C peptide levels in the blood.[3] Hyperglycemia (high blood sugar) is the opposite condition.

Among people with diabetes, prevention is by matching the foods eaten, with the amount of exercise, and the medications used. When people feel their blood sugar is low, testing with a glucose monitor is recommended. Some people have few initial symptoms of low blood sugar and frequent routine testing in this group is recommended. Treatment of hypoglycemia is by eating foods high in simple sugars or taking dextrose. If a person is not able to take food by mouth, an injection of glucagon may help. The treatment of hypoglycemia unrelated to diabetes include treating the underlying problem as well and a healthy diet.[1] The term "hypoglycemia" is sometimes incorrectly used to refer to idiopathic postprandial syndrome, a controversial condition with similar symptoms that occur following eating but with normal blood sugar levels.[6][7]

## Signs and symptoms [edit]

Hypoglycemic symptoms and manifestations can be divided into those produced by the counterregulatory hormones (epinephrine/adrenaline and glucagon) triggered by the falling glucose, and the neuroglycopenic effects produced by the reduced brain sugar.

- Shakiness, anxiety, nervousness
- Palpitations, tachycardia
- Sweating, feeling of warmth (sympathetic muscarinic rather than adrenergic)
- Pallor, coldness, clamminess
- Dilated pupils (mydriasis)
- Hunger, borborygmus
- Nausea, vomiting, abdominal discomfort
- Headache

Paramedics in Southern California attend a diabetic man who lost effective control of his vehicle due to low blood sugar and drove it over the curb.

### Central nervous system [edit]

- Abnormal thinking, impaired judgment
- Nonspecific dysphoria, moodiness, depression, crying, exaggerated concerns
- Feeling of numbness, pins and needles (paresthesia)
- Negativism, irritability, belligerence, combativeness, rage
- Personality change, emotional lability
- Fatigue, weakness, apathy, lethargy, daydreaming, sleep
- Confusion, memory loss, lightheadedness or dizziness, delirium
- Staring, glassy look, blurred vision, double vision
- Flashes of light in the field of vision
- Automatic behavior, also known as automatism
- Difficulty speaking, slurred speech
- Ataxia, incoordination, sometimes mistaken for drunkenness
- Focal or general motor deficit, paralysis, hemiparesis
- Headache
- Stupor, coma, abnormal breathing

Generalized or focal seizures

Not all of the above manifestations occur in every case of hypoglycemia. There is no consistent order to the appearance of the symptoms, if symptoms even occur. Specific manifestations may also vary by age, by severity of the hypoglycemia and the speed of the decline. In young children, vomiting can sometimes accompany morning hypoglycemia with ketosis. In older children and adults, moderately severe hypoglycemia can resemble mania, mental illness, drug intoxication, or drunkenness. In the elderly, hypoglycemia can produce focal stroke-like effects or a hard-to-define malaise. The symptoms of a single person may be similar from episode to episode, but are not necessarily so and may be influenced by the speed at which glucose levels are dropping, as well as previous incidents.

In newborns, hypoglycemia can produce irritability, jitters, myoclonic jerks, cyanosis, respiratory distress, apneic episodes, sweating, hypothermia, somnolence, hypotonia, refusal to feed, and seizures or "spells." Hypoglycemia can resemble asphyxia, hypocalcemia, sepsis, or heart failure.

In both young and old patients, the brain may habituate to low glucose levels, with a reduction of noticeable symptoms despite neuroglycopenic impairment. In insulin-dependent diabetic patients this phenomenon is termed *hypoglycemia unawareness* and is a significant clinical problem when improved glycemic control is attempted. Another aspect of this phenomenon occurs in type I glycogenosis, when chronic hypoglycemia before diagnosis may be better tolerated than acute hypoglycemia after treatment is underway.

Hypoglycemic symptoms can also occur when one is sleeping. Examples of symptoms during sleep can include damp bed sheets or clothes from perspiration. Having nightmares or the act of crying out can be a sign of hypoglycemia. Once the individual is awake they may feel tired, irritable, or confused and these may be signs of hypoglycemia as well.[8]

In nearly all cases, hypoglycemia that is severe enough to cause seizures or unconsciousness can be reversed without obvious harm to the brain. Cases of death or permanent neurological damage occurring with a single episode have usually involved prolonged, untreated unconsciousness, interference with breathing, severe concurrent disease, or some other type of vulnerability. Nevertheless, brain damage or death has occasionally resulted from severe hypoglycemia.

Research in healthy adults shows that mental efficiency declines slightly but measurably as blood glucose falls below 3.6 mM (65 mg/dL). Hormonal defense mechanisms (adrenaline and glucagon) are normally activated as it drops below a threshold level (about 55 mg/dL (3.0 mM) for most people), producing the typical hypoglycemic symptoms of shakiness and dysphoria.[9]:1589 Obvious impairment may not occur until the glucose falls below 40 mg/dL (2.2 mM), and many healthy people may occasionally have glucose levels below 65 in the morning without apparent effects. Since the brain effects of hypoglycemia, termed neuroglycopenia, determine whether a given low glucose is a "problem" for that person, most doctors use the term *hypoglycemia* only when a moderately low glucose level is accompanied by symptoms or brain effects.

Determining the presence of both parts of this definition is not always straightforward, as hypoglycemic symptoms and effects are vague and can be produced by other conditions; people with recurrently low glucose levels can lose their threshold symptoms so that severe neuroglycopenic impairment can occur without much warning, and many measurement methods (especially glucose meters) are imprecise at low levels.

It may take longer to recover from severe hypoglycemia with unconsciousness or seizure even after restoration of normal blood glucose. When a person has not been unconscious, failure of carbohydrate to reverse the symptoms in 10–15 minutes increases the likelihood that hypoglycemia was not the cause of the symptoms. When severe hypoglycemia has persisted in a hospitalized person, the amount of glucose required to maintain satisfactory blood glucose levels becomes an important clue to the underlying etiology. Glucose requirements above 10 mg/kg/minute in infants, or 6 mg/kg/minute in children and adults are strong evidence for hyperinsulinism. In this context this is referred to as the *glucose infusion rate* (GIR). Finally, the blood glucose response to glucagon given when the glucose is low can also help distinguish among various types of hypoglycemia. A rise of blood glucose by more than 30 mg/dl (1.70 mmol/l) suggests insulin excess as the probable cause of the hypoglycemia.

### Long-term effects [edit]

Significant hypoglycemia appears to increase the risk of cardiovascular disease.[10]

## Causes [edit]

*See also: List of causes of hypoglycemia*

The most common cause of hypoglycemia is medications used to treat diabetes mellitus such as insulin, sulfonylureas, and biguanides.[2][3] Risk is greater in diabetics who have eaten less than usual, exercised more than usual, or drunk alcohol.[1] Other causes of hypoglycemia include kidney failure, certain tumors, liver disease, hypothyroidism, starvation, inborn errors of metabolism, severe infections, reactive hypoglycemia, and a number of drugs including alcohol.[1][3] Low blood sugar may occur in babies who are otherwise healthy who have not eaten for a few hours.[4] Inborn errors of metabolism may include the lack of an enzyme to make glycogen (glycogen storage type 0).

### Serious illness [edit]

Serious illness may result in low blood sugar.[1] Severe disease of nearly all major organ systems can cause hypoglycemia as a secondary problem. Hospitalized persons, especially in intensive care units or those prevented from eating, can develop hypoglycemia from a variety of circumstances related to the care of their primary disease. Hypoglycemia in these circumstances is often multifactorial or caused by the healthcare. Once identified, these types of hypoglycemia are readily reversed and prevented, and the underlying disease becomes the primary problem.

### Hormone deficiency [edit]

Not enough cortisol, such as in Addison's disease, not enough glucagon, or not enough epinephrine can result in low blood sugar.[1] This is a more common cause in children.[1]

## Pathophysiology [edit]

Like most animal tissues, brain metabolism depends primarily on glucose for fuel in most circumstances. A limited amount of glucose can be derived from glycogen stored in astrocytes, but it is consumed within minutes. For most practical purposes, the brain is dependent on a continual supply of glucose diffusing from the blood into the interstitial tissue within the central nervous system and into the neurons themselves.

Therefore, if the amount of glucose supplied by the blood falls, the brain is one of the first organs affected. In most people, subtle reduction of mental efficiency can be observed when the glucose falls below 65 mg/dl (3.6 mM). Impairment of action and judgment usually becomes obvious below 40 mg/dl (2.2 mM). Seizures may occur as the glucose falls further. As blood glucose levels fall below 10 mg/dl (0.55 mM), most neurons become electrically silent and nonfunctional, resulting in coma. These brain effects are collectively referred to as neuroglycopenia.

The importance of an adequate supply of glucose to the brain is apparent from the number of nervous, hormonal and metabolic responses to a falling glucose level. Most of these are defensive or adaptive, tending to raise the blood sugar via glycogenolysis and gluconeogenesis or provide alternative fuels. If the blood sugar level falls too low, the liver converts a storage of glycogen into glucose and releases it into the bloodstream, to prevent the person going into a diabetic coma, for a short period of time.

Brief or mild hypoglycemia produces no lasting effects on the brain, though it can temporarily alter brain responses to additional hypoglycemia. Prolonged, severe hypoglycemia can produce lasting damage of a wide range. This can include impairment of cognitive function, motor control, or even consciousness. The likelihood of permanent brain damage from any given instance of severe hypoglycemia is difficult to estimate, and depends on a multitude of factors such as age, recent blood and brain glucose experience, concurrent problems such as hypoxia, and availability of alternative fuels. It has been frequently found that

those Type 1 diabetics found "dead in bed" in the morning after suspected severe hypoglycemia had some underlying coronary pathology that led to an induced fatal heart attack. Recently, several of these individuals found "dead in bed" were wearing Continuous Glucose Monitors, which provided a history of glucose levels prior to the fatal event. It has been found in several cases, that the fatal event was preceded by at least two hours of blood glucose levels under 40 mg/dl, possibly lower as the continuous glucose monitors are not accurate at levels below 40 mg/dl. The individuals failed to respond to the audible alarms produced by the continuous glucose monitor which may have been "alarming" for many hours prior to the fatal event. The vast majority of symptomatic hypoglycemic episodes result in no detectable permanent harm.[11]

## Diagnosis [edit]

The glucose level that defines hypoglycemia is variable. In diabetics a levels below 3.9 mmol/L (70 mg/dL) is diagnostic.[1] In adults without diabetes, symptoms related to low blood sugar, low blood sugar at the time of symptoms, and improvement when blood sugar is restored to normal confirm the diagnosis.[5] This is known as the Whipple's triad.[5] Otherwise a level below 2.8 mmol/L (50 mg/dL) after not eating or following exercise may be used.[1] In newborns a level below 2.2 mmol/L (40 mg/dL) or less than 3.3 mmol/L (60 mg/dL) if symptoms are present indicates hypoglycemia.[4] Other tests that may be useful in determining the cause include insulin and C peptide levels in the blood.[3] Hyperglycemia, a high blood sugar, is the opposite condition.

Throughout a 24 hour period blood plasma glucose levels are generally maintained between 4-8 mmol/L (72 and 144 mg/dL).[12]:11 Although 3.3 or 3.9 mmol/L (60 or 70 mg/dL) is commonly cited as the lower limit of normal glucose, symptoms of hypoglycemia usually do not occur until 2.8 to 3.0 mmol/L (50 to 54 mg/dL).[13]

In cases of recurrent hypoglycemia with severe symptoms, the best method of excluding dangerous conditions is often a *diagnostic fast*. This is usually conducted in the hospital, and the duration depends on the age of the patient and response to the fast. A healthy adult can usually maintain a glucose level above 50 mg/dl (2.8 mM) for 72 hours, a child for 36 hours, and an infant for 24 hours. The purpose of the fast is to determine whether the person can maintain his or her blood glucose as long as normal, and can respond to fasting with the appropriate metabolic changes. At the end of the fast the insulin should be nearly undetectable and ketosis should be fully established. The patient's blood glucose levels are monitored and a critical specimen is obtained if the glucose falls. Despite its unpleasantness and expense, a diagnostic fast may be the only effective way to confirm or refute a number of serious forms of hypoglycemia, especially those involving excessive insulin.

The precise level of glucose considered low enough to define hypoglycemia is dependent on (1) the measurement method, (2) the age of the person, (3) presence or absence of effects, and (4) the purpose of the definition. While there is no disagreement as to the normal range of blood sugar, debate continues as to what degree of hypoglycemia warrants medical evaluation or treatment, or can cause harm.[14][15][16]

Deciding whether a blood glucose in the borderline range of 45–75 mg/dL (2.5-4.2 mM) represents clinically problematic hypoglycemia is not always simple. This leads people to use different "cutoff levels" of glucose in different contexts and for different purposes. Because of all the variations, the Endocrine Society recommends that a diagnosis of hypoglycemia as a problem for an individual be based on the combination of a low glucose level and evidence of adverse effects.[5]

Glucose concentrations are expressed as milligrams per deciliter (mg/dL or mg/100 mL) in Lebanon, the United States, Japan, Portugal, Spain, France, Belgium, Egypt, Saudi Arabia, Colombia, India and Israel, while millimoles per liter (mmol/L or mM) are the units used in most of the rest of the world. Glucose concentrations expressed as mg/dL can be converted to mmol/L by dividing by 18.0 g/dmol (the molar mass of glucose). For example, a glucose concentration of 90 mg/dL is 5.0 mmol/L or 5.0 mM.

The circumstances of hypoglycemia provide most of the clues to diagnosis. Circumstances include the age of the person, time of day, time since last meal, previous episodes, nutritional status, physical and mental development, drugs or toxins (especially insulin or other diabetes drugs), diseases of other organ systems,

family history, and response to treatment. When hypoglycemia occurs repeatedly, a record or "diary" of the spells over several months, noting the circumstances of each spell (time of day, relation to last meal, nature of last meal, response to carbohydrate, and so forth) may be useful in recognizing the nature and cause of the hypoglycemia.

## Method of measurement [edit]

Blood glucose levels discussed in this article are venous plasma or serum levels measured by standard, automated glucose oxidase methods used in medical laboratories. For clinical purposes, plasma and serum levels are similar enough to be interchangeable. Arterial plasma or serum levels are slightly higher than venous levels, and capillary levels are typically in between.[17] This difference between arterial and venous levels is small in the fasting state but is amplified and can be greater than 10% in the postprandial state.[18] On the other hand, whole blood glucose levels (e.g., by fingerprick meters) are about 10%-15% lower than venous plasma levels.[17] Furthermore, available fingerstick glucose meters are only warranted to be accurate to within 15% of a simultaneous laboratory value under optimal conditions,[*citation needed*] and home use in the investigation of hypoglycemia is fraught with misleading low numbers.[19][20] In other words, a meter glucose reading of 39 mg/dL could be properly obtained from a person whose laboratory serum glucose was 53 mg/dL; even wider variations can occur with "real world" home use.

Two other factors significantly affect glucose measurement: hematocrit and delay after blood drawing. The disparity between venous and whole blood concentrations is greater when the hematocrit is high, as in newborn infants, or adults with polycythemia.[18] High neonatal hematocrits are particularly likely to confound glucose measurement by meter. Second, unless the specimen is drawn into a fluoride tube or processed immediately to separate the serum or plasma from the cells, the measurable glucose will be gradually lowered by *in vitro* metabolism of the glucose at a rate of approximately 7 mg/dL/h, or even more in the presence of leukocytosis.[18][21][22] The delay that occurs when blood is drawn at a satellite site and transported to a central laboratory hours later for routine processing is a common cause of mildly low glucose levels in general chemistry panels.

## Age [edit]

Children's blood sugar levels are often slightly lower than adults'. Overnight fasting glucose levels are below 70 mg/dL (3.9 mM) in 5% of healthy adults, but up to 5% of children can be below 60 mg/dL (3.3 mM) in the morning fasting state.[23] As the duration of fasting is extended, a higher percentage of infants and children will have mildly low plasma glucose levels, usually without symptoms. The normal range of newborn blood sugars continues to be debated.[14][15][16] It has been proposed that newborn brains are able to use alternate fuels when glucose levels are low more readily than adults. Experts continue to debate the significance and risk of such levels, though the trend has been to recommend maintenance of glucose levels above 60–70 mg/dL the first day after birth.

Diabetic hypoglycemia represents a special case with respect to the relationship of measured glucose and hypoglycemic symptoms for several reasons. First, although home glucose meter readings are often misleading, the probability that a low reading, whether accompanied by symptoms or not, represents real hypoglycemia is much higher in a person who takes insulin than in someone who does not.[24][25]

## Other tests [edit]

The following is a brief list of hormones and metabolites which may be measured in a critical sample. Not all tests are checked on every patient. A "basic version" would include insulin, cortisol, and electrolytes, with C-peptide and drug screen for adults and growth hormone in children. The value of additional specific tests depends on the most likely diagnoses for an individual patient, based on the circumstances described above. Many of these levels change within minutes, especially if glucose is given, and there is no value in measuring them after the hypoglycemia is reversed. Others, especially those lower in the list, remain abnormal even after hypoglycemia is reversed, and can be usefully measured even if a critical specimen is missed.

Part of the value of the critical sample may simply be the proof that the symptoms are indeed due to

hypoglycemia. More often, measurement of certain hormones and metabolites at the time of hypoglycemia indicates which organs and body systems are responding appropriately and which are functioning abnormally. For example, when the blood glucose is low, hormones which raise the glucose should be rising and insulin secretion should be completely suppressed.

### Differential diagnosis [edit]

It can also be mistaken for alcohol intoxication.[26]

## Prevention [edit]

The most effective means of preventing further episodes of hypoglycemia depends on the cause.

The risk of further episodes of diabetic hypoglycemia can often (but not always) be reduced by lowering the dose of insulin or other medications, or by more meticulous attention to blood sugar balance during unusual hours, higher levels of exercise, or decreasing alcohol intake.

Many of the inborn errors of metabolism require avoidance or shortening of fasting intervals, or extra carbohydrates. For the more severe disorders, such as type 1 glycogen storage disease, this may be supplied in the form of cornstarch every few hours or by continuous gastric infusion.

Several treatments are used for hyperinsulinemic hypoglycemia, depending on the exact form and severity. Some forms of congenital hyperinsulinism respond to diazoxide or octreotide. Surgical removal of the overactive part of the pancreas is curative with minimal risk when hyperinsulinism is focal or due to a benign insulin-producing tumor of the pancreas. When congenital hyperinsulinism is diffuse and refractory to medications, near-total pancreatectomy may be the treatment of last resort, but in this condition is less consistently effective and fraught with more complications.

Hypoglycemia due to hormone deficiencies such as hypopituitarism or adrenal insufficiency usually ceases when the appropriate hormone is replaced.

Hypoglycemia due to dumping syndrome and other post-surgical conditions is best dealt with by altering diet. Including fat and protein with carbohydrates may slow digestion and reduce early insulin secretion. Some forms of this respond to treatment with a glucosidase inhibitor, which slows starch digestion.

Reactive hypoglycemia with demonstrably low blood glucose levels is most often a predictable nuisance which can be avoided by consuming fat and protein with carbohydrates, by adding morning or afternoon snacks, and reducing alcohol intake.

Idiopathic postprandial syndrome without demonstrably low glucose levels at the time of symptoms can be more of a management challenge. Many people find improvement by changing eating patterns (smaller meals, avoiding excessive sugar, mixed meals rather than carbohydrates by themselves), reducing intake of stimulants such as caffeine, or by making lifestyle changes to reduce stress. See the following section of this article.

## Treatment [edit]

Treatment of some forms of hypoglycemia, such as in diabetes, involves immediately raising the blood sugar to normal through the ingestion of carbohydrates, determining the cause, and taking measures to hopefully prevent future episodes. However, this treatment is not optimal in other forms such as reactive hypoglycemia, where rapid carbohydrate ingestion may lead to a further hypoglycemic episode.

Blood glucose can be raised to normal within minutes by taking (or receiving) 10-20 grams of carbohydrate.[27] It can be taken as food or drink if the person is conscious and able to swallow. This amount of carbohydrate is contained in about 3–4 ounces (100–120 ml) of orange, apple, or grape juice although fruit juices contain a higher proportion of fructose which is more slowly metabolized than pure dextrose, alternatively, about 4–5 ounces (120-150 ml) of regular (non-diet) soda may also work, as will about one slice of bread, about 4 crackers, or about 1 serving of most starchy foods. Starch is quickly digested to glucose (unless the person is taking acarbose), but adding fat or protein retards digestion.

Symptoms should begin to improve within 5 minutes, though full recovery may take 10–20 minutes. Overfeeding does not speed recovery and if the person has diabetes will simply produce hyperglycemia afterwards. A mnemonic used by the American Diabetes Association and others is the "rule of 15" – consuming 15 grams of carbohydrate followed by a 15-minute wait, repeated if glucose remains low (variable by individual, sometimes 70 mg/dl).[28]

If a person is suffering such severe effects of hypoglycemia that they cannot (due to combativeness) or should not (due to seizures or unconsciousness) be given anything by mouth, medical personnel such as paramedics, or in-hospital personnel can establish IV access and give intravenous dextrose, concentrations varying depending on age (infants are given 2 ml/kg dextrose 10%, children are given dextrose 25%, and adults are given dextrose 50%). Care must be taken in giving these solutions because they can cause skin necrosis if the IV is infiltrated, sclerosis of veins, and many other fluid and electrolyte disturbances if administered incorrectly. If IV access cannot be established, the patient can be given 1 to 2 milligrams of glucagon in an intramuscular injection. More treatment information can be found in the article diabetic hypoglycemia. If a person is suffering less severe effects, and is conscious with the ability to swallow, medical personal such as EMT-B's may administer gelatinous oral glucose.

One situation where starch may be less effective than glucose or sucrose is when a person is taking acarbose. Since acarbose and other alpha-glucosidase inhibitors prevents starch and other sugars from being broken down into monosaccharides that can be absorbed by the body, patients taking these medications should consume monosaccharide-containing foods such as glucose tablets, honey, or juice to reverse hypoglycemia.

## Etymology [edit]

Hypoglycemia may also be spelled hypoglycaemia or hypoglycæmia. The term means low blood sugar in Greek. *ὑπογλυκαιμία*, from *hypo-*, *glykys*, *haima*.

# Hyponatremia

From Wikipedia, the free encyclopedia

**Hyponatremia**, also spelled **hyponatraemia**, is a low sodium level in the blood.[1] Symptoms can vary from none to severe.[2][3] Mild symptoms include a decreased ability to think, headaches, nausea, and poor balance.[4] Severe symptoms include confusion, seizures, and coma.[2][3] Normal serum sodium levels are 135–145 mmol/L (135–145 mEq/L).[5] Hyponatremia is generally defined as a serum sodium level of less than 135 mmol/L and is considered severe when the level is below 120 mmol/L.[4]

The cause of hyponatremia is typically classified by a person's fluid status into low volume, normal volume, and high volume. Low volume hyponatremia can occur from diarrhea, vomiting, diuretics, and sweating. Normal volume hyponatremia is divided into cases with dilute urine and concentrated urine. Cases in which the urine is dilute include adrenal insufficiency, hypothyroidism, and drinking too much water or too much beer. Cases in which the urine is concentrated include syndrome of inappropriate antidiuretic hormone secretion (SIADH). High volume hyponatremia can occur from heart failure, liver failure, and kidney failure.[1] Conditions that can lead to falsely low sodium measurements include high protein levels such as in multiple myeloma, high blood fat levels, and high blood sugar.[6][7]

Treatment is based on the underlying cause.[1] Correcting hyponatremia too quickly can lead to complications.[6] Rapid partial correction with 3% normal saline is only recommended in those with significant symptoms and occasionally those in whom the condition was of rapid onset.[1][7] Low volume hyponatremia is typically treated with intravenous normal saline. SIADH is typically treated with fluid restriction while high volume hyponatremia is typically treated with both fluid restriction and a diet low in salt. Correction, in those in whom the low levels have been present for more than two days should generally be gradual.[1]

Hyponatremia is one of the most commonly seen water–electrolyte imbalances.[7][8] It occurs in about 20% of those admitted to hospital and 10% of people during or after an endurance sporting event.[4][6] Among those in hospital hyponatremia is associated with an increased risk of death.[6] The economic costs of hyponatremia are estimated at $2.6 billion in the United States.[9]

## Signs and symptoms [edit]

Signs and symptoms of hyponatremia include nausea and vomiting, headache, short-term memory loss, confusion, lethargy, fatigue, loss of appetite, irritability, muscle weakness, spasms or cramps, seizures, and decreased consciousness or coma.[10] The presence and severity of signs and symptoms are related to the level of salt in the blood, with lower levels of plasma sodium associated with more severe symptoms. However, emerging data suggest that mild hyponatremia (plasma sodium levels at 131–135 mmol/L) is associated with numerous complications or subtle, presently unrecognized symptoms[11] (for example, increased falls, altered posture and gait, reduced attention).[12]

Neurological symptoms typically occur with very low levels of plasma sodium (usually <115 mmol/L).[10] When sodium levels in the blood become very low, water enters the brain cells and causes them to swell. This results in increased pressure in the skull and causes *hyponatremic encephalopathy*. As pressure increases in the skull, herniation of the brain can occur, which is a squeezing of the brain across the internal structures of the skull. This can lead to headache, nausea, vomiting, confusion, seizures, brain stem compression and respiratory arrest, and non-cardiogenic accumulation of fluid in the lungs.[13] This is usually fatal if not immediately treated.

Symptom severity depends on how fast and how severe the drop in blood salt level. A gradual drop, even to very low levels, may be tolerated well if it occurs over several days or weeks, because of neuronal adaptation. The presence of underlying neurological disease such as a seizure disorder or non-neurological metabolic abnormalities, also affects the severity of neurologic symptoms.

Chronic hyponatremia can lead to such complications as neurological impairments. These neurological impairments most often affect gait (walking) and attention, and can lead to increased reaction time and falls.[*citation needed*] Hyponatremia, by interfering with bone metabolism, has been linked with a doubled risk of osteoporosis and an increased risk of bone fracture.[14]

## Causes [edit]

The specific causes of hyponatremia are generally divided into those that occur with high fluid volume, those with normal fluid volume, and those with low fluid volume. Too little sodium in the diet alone is very rarely the cause of hyponatremia.

### High volume hyponatremia [edit]

Both sodium & water content increase: Increase in sodium content leads to hypervolemia and water content to hyponatremia. Total body water and sodium are regulated independently.[15]

- cirrhosis of the liver
- congestive heart failure

- nephrotic syndrome in the kidneys
- massive edema of any cause

## Normal volume hyponatremia [edit]

There is volume expansion in the body, no edema, but hyponatremia occurs[15]

- states of severe pain or nausea
- in the setting of trauma or other damage to the brain
- SIADH (and its many causes)
- Hypothyroidism
- Glucocorticoid (steroid) deficiency

## Low volume hyponatremia [edit]

The hypovolemia (extracellular volume loss) is due to total body sodium loss. The hyponatremia is caused by a relatively smaller loss in total body water.[15]

- any cause of hypovolemia such as prolonged vomiting, decreased oral intake, severe diarrhea
- diuretic use (due to the diuretic causing a volume depleted state and thence ADH release, and not a direct result of diuretic-induced urine sodium loss)
- Addison's disease and congenital adrenal hyperplasia in which the adrenal glands do not produce enough steroid hormones (combined glucocorticoid and mineralocorticoid deficiency)

Prolonged periods of exercise may be a cause, known as exercise-associated hyponatremia (EAH).[6][16] It is common in marathon runners and participants of other endurance events.[17] The use of MDMA can result in hyponatremia.[18] This likely occurs as a result of fluid loss via sweating and replacement with water without electrolytes.

## Other causes [edit]

Miscellaneous causes of hyponatremia that are not included under the above classification scheme include the following:

- factitious hyponatremia (due to massive increases in blood triglyceride levels, extreme elevation of immunoglobulins as may occur in multiple myeloma, and very high level of blood glucose)
- Hypothyroidism and adrenal insufficiency (both thyroid hormone and cortisol are required to excrete free water)
- Beer potomania and other malnourished states where poor dietary protein intake leads to inadequate urine solute formation thereby impeding the kidney's ability to excrete free water
- Primary polydipsia and water intoxication (where the amount of urine solute required to excrete huge quantities of ingested water exceeds the body's ability to produce it; this typically occurs when 12 or more liters of water are ingested per day)

# Diagnosis [edit]

The history, physical exam, and laboratory testing are required to diagnose and determine the underlying cause of hyponatremia. A blood test demonstrating a serum sodium less than 135 mmol/L is diagnostic for hyponatremia.[19] The history and physical exam are necessary to help determine if the patient is hypovolemic, euvolemic, or hypervolemic, which has important implications in determining the underlying cause. An assessment is also made to determine if the patient is experiencing symptoms from their hyponatremia. These include assessments of alertness, concentration, and orientation.

## False hyponatremia [edit]

False hyponatremia, also known as spurious, pseudo, hypertonic, or artifactual hyponatremia is when the

lab tests read low sodium levels but there is no hypotonicity. In hypertonic hyponatremia, resorption of water by molecules such as glucose (hyperglycemia or diabetes) or mannitol (hypertonic infusion) occurs. In isotonic hyponatremia a measurement error due to high blood triglyceride level (most common) or paraproteinemia occurs. It occurs when using techniques that measure the amount of sodium in a specified volume of serum/plasma, or that dilute the sample before analysis.[20]

### True hyponatremia [edit]

True hyponatremia, also known as hypotonic hyponatremia, is the most common type. It is often simply referred to as "hyponatremia." Hypotonic hyponatremia is categorized in 3 ways based on the person's blood volume status. Each category represents a different underlying reason for the increase in ADH that led to the water retention and thence hyponatremia:

- **High volume hyponatremia**, wherein there is decreased effective circulating volume (less blood flowing in the body) even though total body volume is increased (by the presence of edema or swelling, especially in the ankles). The decreased effective circulating volume stimulates the release of anti-diurectic hormone(ADH), which in turn leads to water retention. Hypervolemic hyponatremia is most commonly the result of congestive heart failure, liver failure (cirrhosis), or kidney disease (nephrotic syndrome).
- **Normal volume hyponatremia**, wherein the increase in ADH is secondary to either physiologic but excessive ADH release (as occurs with nausea or severe pain) or inappropriate and non-physiologic secretion of ADH, that is, syndrome of inappropriate antidiuretic hormone hypersecretion (SIADH). Often categorized under euvolemic is hyponatremia due to inadequate urine solute (not enough chemicals or electrolytes to produce urine) as occurs in beer potomania or "tea and toast" hyponatremia, hyponatremia due to hypothyroidism or central adrenal insufficiency, and those rare instances of hyponatremia that are truly secondary to excess water intake (that is, extreme psychogenic polydipsia)
- **Low volume hyponatremia**, wherein ADH secretion is stimulated by or associated with volume depletion (not enough water in the body).

### Acute versus chronic [edit]

Chronic hyponatremia is when sodium levels drop gradually over several days or weeks and symptoms and complications are typically moderate. Chronic hyponatremia is often called asymptomatic hyponatremia in clinical settings because it is thought to have no symptoms; however, emerging data suggests that "asymptomatic" hyponatremia is not actually asymptomatic.[11]

Acute hyponatremia is when sodium levels drop rapidly, resulting in potentially dangerous effects, such as rapid brain swelling, which can result in coma and death.

## Pathophysiology [edit]

Sodium is the primary positively charged ion in the environment outside of the cell and cannot freely cross from the interstitial space into the cell. Charged sodium ions attract up to 25 water molecules around them thereby creating a large polar structure too large to pass through the cell membrane.

## Treatment [edit]

The treatment of hyponatremia depends on the underlying cause and whether the person's blood volume status is high, normal, or low.

### Fluids [edit]

In the setting of hypovolemia, intravenous administration of normal saline (salt) is usual, care being taken not to raise the serum sodium level (salt level in the blood) too quickly (see below). Euvolemic hyponatremia is usually managed by fluid restriction and treatment to abolish any stimuli for ADH secretion such as nausea. Likewise, drugs causing SIADH are discontinued if possible. Patients with euvolemic

hyponatremia that persists despite those measures may be candidates for a so-called vaptan drug as discussed below. Hypervolemic hyponatremia is usually treated by addressing the underlying heart or liver failure. If it is not possible to do so, the treatment becomes the same as that for euvolemic hyponatremia (that is, fluid restriction and/or use of a vaptan drug).

Hyponatremia is corrected slowly, to lessen the risk of the development of central pontine myelinolysis (CPM), a severe neurological disease involving a breakdown of the myelin sheaths covering parts of nerve cells. In fact, overly rapid correction of hyponatremia is the most common cause of that potentially devastating disorder.[21] During treatment of hyponatremia, the serum sodium (salt level in the blood) is not allowed to rise by more than 8 mmol/L over 24 hours (that is, 0.33 mmol/L/h rate of rise). In practice, too rapid correction of hyponatremia and thence CPM is most likely to occur during the treatment of hypovolemic hyponatremia. In particular, once the hypovolemic state has been corrected, the signal for ADH release disappears. At that point, there is an abrupt water diuresis (an increase in urination since there is no longer any ADH acting to retain the water). A rapid and profound rise in serum sodium (salt level in the blood) can then occur. Should the rate of rise of serum sodium exceed 0.33 mmol/L/h over several hours, vasopressin may be administered to prevent ongoing rapid water diuresis (excessive urination).[22]

### Medications [edit]

There is tentative evidence that vasopressin receptor antagonists (vaptans), such as conivaptan, may be slightly more effective than fluid restriction in those with high volume or normal volume hyponatremia.[1] They should not be used in people with low volume. There use is SIADH is unclear.[3]

## Epidemiology [edit]

Hyponatremia is the most common electrolyte disorder. Electrolytes are sodium (salt), potassium, calcium, magnesium, chloride, hydrogen phosphate, and hydrogen carbonate. The disorder is more frequent in females, the elderly, and in people who are hospitalized. The incidence of hyponatremia depends largely on the patient population. A hospital incidence of 15–20% is common, while only 3–5% of people who are hospitalized have a serum sodium level (salt blood level) of less than 130 mmol/L. Hyponatremia has been reported in up to 30% of elderly patients in nursing homes and is also present in approximately 30% of depressed patients on selective serotonin reuptake inhibitors.[11]

People who have hyponatremia who require hospitalisation have a longer length of stay (with associated increased costs) and also have a higher likelihood of requiring readmission. This is particularly the case in men and in the elderly.[23]

# Hypothyroidism

From Wikipedia, the free encyclopedia

**Hypothyroidism**, also called **underactive thyroid** or **low thyroid**, is a common disorder of the endocrine system in which the thyroid gland does not produce enough thyroid hormone.[3] It can cause a number of symptoms, such as poor ability to tolerate cold, a feeling of tiredness, constipation, depression, and weight gain.[3] Occasionally there may be swelling of the front part of the neck due to goitre.[3] Untreated hypothyroidism during pregnancy can lead to delays in growth and intellectual development in the baby, which is called cretinism.[4]

Worldwide, too little iodine in the diet is the most common cause of hypothyroidism.[5][6] In countries with enough iodine in the diet, the most common cause of hypothyroidism is the autoimmune condition Hashimoto's thyroiditis.[3] Less common causes include: previous treatment with radioactive iodine, injury to the hypothalamus or the anterior pituitary gland, certain medications, a lack of a functioning thyroid at birth, or previous thyroid surgery.[3][7] The diagnosis of hypothyroidism, when suspected, can be confirmed with blood tests measuring thyroid-stimulating hormone (TSH) and thyroxine levels.[3]

Prevention at the population level has been with the universal salt iodization.[8] Hypothyroidism can be treated with levothyroxine. The dose is adjusted according to symptoms and normalization of the thyroxine and TSH levels. Thyroid medication is safe in pregnancy. While a certain amount of dietary iodine is important, excessive amounts can worsen certain types of hypothyroidism.[3]

Worldwide about one billion people are estimated to be iodine deficient; however, it is unknown how often this results in hypothyroidism.[9] In the United States, hypothyroidism occurs in 0.3–0.4% of people.[5] Subclinical hypothyroidism, a milder form of hypothyroidism characterized by normal thyroxine levels and an elevated TSH level, is thought to occur in 4.3–8.5% of people in the United States.[5] Hypothyroidism is more common in women than men.[3] People over the age of 60 are more commonly affected.[3] Dogs are also known to develop hypothyroidism and in rare cases cats and horses can also have the disorder.[10] The word "hypothyroidism" is from Greek *hypo-* meaning "reduced", *thyreos* for "shield", and *eidos* for "form."[11]

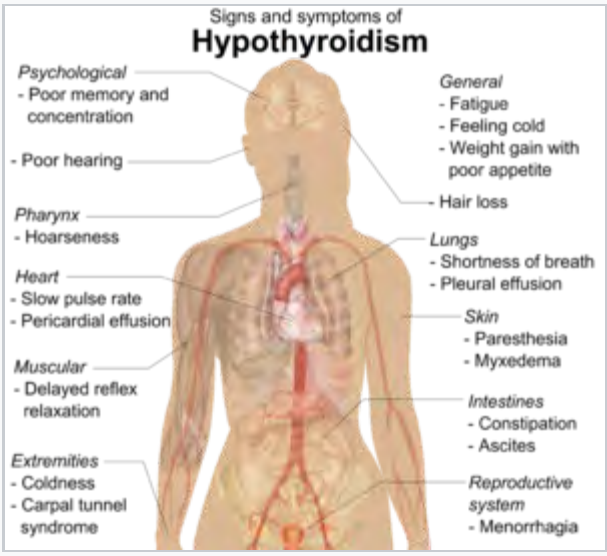
## Signs and symptoms [edit]

People with hypothyroidism often have no or only mild symptoms. Numerous symptoms and signs are associated with hypothyroidism, and can be related to the underlying cause, or a direct effect of having not enough thyroid hormones.[12][13] Hashimoto's thyroiditis may present with the mass effect of a goiter (enlarged thyroid gland).[12]

| Symptoms[12] | Signs[12] |
|---|---|
| Fatigue | Dry, coarse skin |
| Feeling cold | Cool extremities |
| Poor memory and concentration | Myxedema (mucopolysaccharide deposits in the skin) |
| Constipation, dyspepsia[14] | Hair loss |
| Weight gain with poor appetite | Slow pulse rate |
| Shortness of breath | Swelling of the limbs |
| Hoarse voice | Delayed relaxation of tendon reflexes |
| In females, heavy menstrual periods (and later light periods) | Carpal tunnel syndrome |
| Abnormal sensation | Pleural effusion, ascites, pericardial effusion |
| Poor hearing | |



Symptoms and signs of hypothyroidism[12]

Delayed relaxation after testing the ankle jerk reflex is a characteristic sign of hypothyroidism and is

associated with the severity of the hormone deficit.[5]

## Myxedema coma [edit]

Myxedema coma is a rare but life-threatening state of extreme hypothyroidism. It may occur in those who are known to have hypothyroidism when they develop another illness, but it can be the first presentation of hypothyroidism. The illness is characterized by very low body temperature without shivering, confusion, a slow heart rate and reduced breathing effort. There may be physical signs suggestive of hypothyroidism, such as skin changes or enlargement of the tongue.[15]

Man with myxedema or severe hypothyroidism showing an expressionless face, puffiness around the eyes and pallor

Additional symptoms include swelling of the arms and legs and ascites.

## Pregnancy [edit]

Even mild or subclinical hypothyroidism has been associated with impaired fertility and an increased risk of miscarriage.[16] Hypothyroidism in early pregnancy, even with limited or no symptoms, may increase the risk of pre-eclampsia, offspring with lower intelligence, and the risk of infant death around the time of birth.[16][17] Women are affected by hypothyroidism in 0.3–0.5% of pregnancies.[17] Subclinical hypothyroidism during pregnancy has also been associated with gestational diabetes and birth of the baby before 37 weeks of pregnancy.[18]

## Children [edit]

Newborn children with hypothyroidism may have normal birth weight and height (although the head may be larger than expected and the posterior fontanelle may be open). Some may have drowsiness, decreased muscle tone, a hoarse-sounding cry, feeding difficulties, constipation, an enlarged tongue, umbilical hernia, dry skin, a decreased body temperature and jaundice.[19] A goiter is rare, although it may develop later in children who have a thyroid gland that does not produce functioning thyroid hormone.[19] A goiter may also develop in children growing up in areas with iodine deficiency.[20] Normal growth and development may be delayed, and not treating infants may lead to an intellectual impairment (IQ 6–15 points lower in severe cases). Other problems include the following: large scale and fine motor skills and coordination, reduced muscle tone, squinting, decreased attention span, and delayed speaking.[19] Tooth eruption may be delayed.[21]

In older children and adolescents, the symptoms of hypothyroidism may include fatigue, cold intolerance, sleepiness, muscle weakness, constipation, a delay in growth, overweight for height, pallor, coarse and thick skin, increased body hair, irregular menstrual cycles in girls, and delayed puberty. Signs may include delayed relaxation of the ankle reflex and a slow heart beat.[19] A goiter may be present with a completely enlarged thyroid gland;[19] sometimes only part of the thyroid is enlarged and it can be knobby in character.[22]

# Causes [edit]

Hypothyroidism is caused by inadequate function of the gland itself (primary hypothyroidism) or by not enough stimulation by thyroid-stimulating hormone (central hypothyroidism).[5][23] Primary hypothyroidism is about a thousandfold more common than central hypothyroidism.[7]

Iodine deficiency is the most common cause of primary hypothyroidism and endemic goiter worldwide.[5][6] In areas of the world with sufficient dietary iodine, hypothyroidism is most commonly caused by the autoimmune disease Hashimoto's thyroiditis (chronic autoimmune thyroiditis).[5][6] Hashimoto's may be associated with a goiter. It is characterized by infiltration of the thyroid gland with T lymphocytes and autoantibodies against specific thyroid antigens such as thyroid peroxidase, thyroglobulin and the TSH receptor.[5]

After women give birth, about 5% develop postpartum thyroiditis which can occur up to nine months afterwards.[24] This is characterized by a short period of hyperthyroidism followed by a period of hypothyroidism; 20–40% remain permanently hypothyroid.[24]

Autoimmune thyroiditis is associated with other immune-mediated diseases such as diabetes mellitus type 1, pernicious anemia, myasthenia gravis, celiac disease, rheumatoid arthritis and systemic lupus erythematosus.[5] It may occur as part of autoimmune polyendocrine syndrome (type 1 and type 2).[5]

## Pathophysiology [edit]

Thyroid hormone is required for the normal functioning of numerous tissues in the body. In health, the thyroid gland predominantly secretes thyroxine ($T_4$), which is converted into triiodothyronine ($T_3$) in other organs by the selenium-dependent enzyme iodothyronine deiodinase.[26] Triiodothyronine binds to the thyroid hormone receptor in the nucleus of cells, where it stimulates the turning on of particular genes and the production of specific proteins.[27] Additionally, the hormone binds to integrin αvβ3 on the cell membrane, thereby stimulating the sodium–hydrogen antiporter and processes such as formation of blood vessels and cell growth.[27] In blood, almost all thyroid hormone (99.97%) is bound to plasma proteins such as thyroxine-binding globulin; only the free unbound thyroid hormone is biologically active.[5]

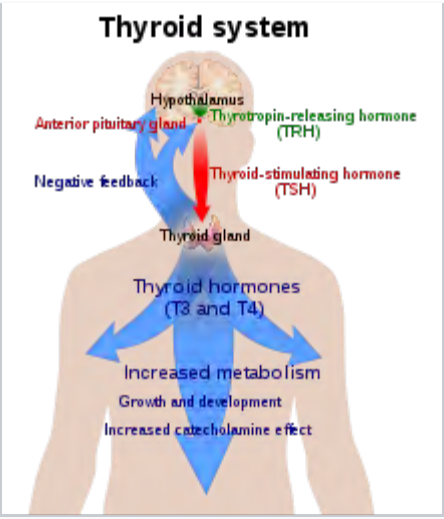

Diagram of the hypothalamic–pituitary–thyroid axis. The hypothalamus secretes TRH (green), which stimulates the production of TSH (red) by the pituitary gland. This, in turn, stimulates the production of thyroxine by the thyroid (blue). Thyroxine levels decrease TRH and TSH production by a negative feedback process.

The thyroid gland is the only source of thyroid hormone in the body; the process requires iodine and the amino acid tyrosine. Iodine in the bloodstream is taken up by the gland and incorporated into thyroglobulin molecules. The process is controlled by the thyroid-stimulating hormone (TSH, thyrotropin), which is secreted by the pituitary. Not enough iodine, or not enough TSH, can result in decreased production of thyroid hormones.[23]

The hypothalamic–pituitary–thyroid axis plays a key role in maintaining thyroid hormone levels within normal limits. Production of TSH by the anterior pituitary gland is stimulated in turn by thyrotropin-releasing hormone (TRH), released from the hypothalamus. Production of TSH and TRH is decreased by thyroxine by a negative feedback process. Not enough TRH, which is uncommon, can lead to not enough TSH and thereby to not enough thyroid hormone production.[7]

Pregnancy leads to marked changes in thyroid hormone physiology. The gland is increased in size by 10%, thyroxine production is increased by 50%, and iodine requirements are increased. Many women have normal thyroid function but have immunological evidence of thyroid autoimmunity (as evidenced by autoantibodies) or are iodine deficient, and develop evidence of hypothyroidism before or after giving birth.[28]

## Diagnosis [edit]

*See also: Thyroid function tests*

Laboratory testing of thyroid stimulating hormone levels in the blood is considered the best initial test for hypothyroidism; a second TSH level is often obtained several weeks later for confirmation.[29] Levels may be abnormal in the context of other illnesses, and TSH testing in hospitalized people is discouraged unless thyroid dysfunction is strongly suspected.[5] An elevated TSH level indicates that the thyroid gland is not producing enough thyroid hormone, and free T4 levels are then often obtained.[5][22] Measuring $T_3$ is discouraged by the AACE in the assessment for hypothyroidism.[5] There are a number of symptom rating scales for hypothyroidism; they provide a degree of objectivity but have limited use for diagnosis.[5]

Many cases of hypothyroidism are associated with mild elevations in creatine kinase and liver enzymes in the blood. They typically return to normal when hypothyroidism has been fully treated.[5] Levels of cholesterol, low-density lipoprotein and lipoprotein (a) can be elevated;[5] the impact of subclinical hypothyroidism on lipid parameters is less well-defined.[20]

| TSH | T4 | Interpretation |
|---|---|---|
| Normal | Normal | Normal thyroid function |
| Elevated | Low | Overt hypothyroidism |
| Normal/low | Low | Central hypothyroidism |
| Elevated | Normal | Subclinical hypothyroidism |

Very severe hypothyroidism and myxedema coma are characteristically associated with low sodium levels in

the blood together with elevations in antidiuretic hormone, as well as acute worsening of kidney function due to a number of causes.[15]

A diagnosis of hypothyroidism without any lumps or masses felt within the thyroid gland does not require thyroid imaging; however, if the thyroid feels abnormal, diagnostic imaging is then recommended.[29] The presence of antibodies against thyroid peroxidase (TPO) makes it more likely that thyroid nodules are caused by autoimmune thyroiditis, but if there is any doubt, a needle biopsy may be required.[5]

If the TSH level is normal or low and serum free $T_4$ levels are low, this is suggestive of central hypothyroidism (not enough TSH or TRH secretion by the pituitary gland or hypothalamus). There may be other features of hypopituitarism, such as menstrual cycle abnormalities and adrenal insufficiency. There might also be evidence of a pituitary mass such as headaches and vision changes. Central hypothyroidism should be investigated further to determine the underlying cause.[7][29]

### Overt [edit]

In overt primary hypothyroidism, TSH levels are high and $T_4$ and $T_3$ levels are low. Overt hypothyroidism may also be diagnosed in those who have a TSH on multiple occasions of greater than 5mIU/L, appropriate symptoms, and only a borderline low $T_4$.[30] It may also be diagnosed in those with a TSH of greater than 10mIU/L.[30]

### Subclinical [edit]

Subclinical hypothyroidism is a milder form of hypothyroidism characterized by an elevated serum TSH level, but with a normal serum free thyroxine level.[31][32] This milder form of hypothyroidism is most commonly caused by Hashimoto's thyroiditis.[33] In adults it is diagnosed when TSH levels are greater than 5 mIU/L and less than 10mIU/L.[30] The presentation of subclinical hypothyroidism is variable and classic signs and symptoms of hypothyroidism may not be observed.[31] Of people with subclinical hypothyroidism, a proportion will develop overt hypothyroidism each year. In those with detectable antibodies against thyroid peroxidase (TPO), this occurs in 4.3%, while in those with no detectable antibodies, this occurs in 2.6%.[5] Those with subclinical hypothyroidism and detectable anti-TPO antibodies who do not require treatment should have repeat thyroid function tests more frequently (e.g. yearly) compared with those who do not have antibodies.[29]

### Pregnancy [edit]

During pregnancy, the thyroid gland must produce 50% more thyroid hormone to provide enough thyroid hormone for the developing fetus and the expectant mother.[18] In pregnancy, free thyroxine levels may be lower than anticipated due to increased binding to thyroid binding globulin and decreased binding to albumin. They should either be corrected for the stage of pregnancy,[28] or total thyroxine levels should be used instead for diagnosis.[5] TSH values may also be lower than normal (particularly in the first trimester) and the normal range should be adjusted for the stage of pregnancy.[5][28]

In pregnancy, subclinical hypothyroidism is defined as a TSH between 2.5 and 10 mIU/l with a normal thyroxine level, while those with TSH above 10 mIU/l are considered to be overtly hypothyroid even if the thyroxine level is normal.[28] Antibodies against TPO may be important in making decisions about treatment, and should, therefore, be determined in women with abnormal thyroid function tests.[5]

Determination of TPO antibodies may be considered as part of the assessment of recurrent miscarriage, as subtle thyroid dysfunction can be associated with pregnancy loss,[5] but this recommendation is not universal,[34] and presence of thyroid antibodies may not predict future outcome.[35]

## Prevention [edit]

Hypothyroidism may be prevented in a population by adding iodine to commonly used foods. This public health measure has eliminated endemic childhood hypothyroidism in countries where it was once common. In addition to promoting the consumption of iodine-rich foods such as dairy and fish, many countries with moderate iodine deficiency have implemented universal salt iodization (USI).[36] Encouraged by the World Health Organization,[37] 130 countries now have USI, and 70% of the world's population are receiving iodized salt. In some countries, iodized salt is added to bread.[36] Despite this, iodine deficiency has reappeared in some Western countries as a result of attempts to reduce salt intake.[36]

Pregnant and breastfeeding women, who require 66% more daily iodine requirement than non-pregnant women, may still not be getting enough iodine.[36][38] The World Health Organization recommends a daily intake of 250 µg for pregnant and breastfeeding women.[39] As many women will not achieve this from dietary sources alone, the American Thyroid Association recommends a 150 µg daily supplement by mouth.[28][40]

## Screening [edit]

Screening for hypothyroidism is performed in the newborn period in many countries, generally using TSH. This has led to the early identification of many cases and thus the prevention of developmental delay.[41] It is the most widely used newborn screening test worldwide.[42] While TSH-based screening will identify the most common causes, the addition of $T_4$ testing is required to pick up the rarer central causes of neonatal hypothyroidism.[19] If $T_4$ determination is included in the screening done at birth, this will identify cases of congenital hypothyroidism of central origin in 1:16,000 to 1:160,000 children. Considering that these children usually have other pituitary hormone deficiencies, early identification of these cases may prevent complications.[7]

In adults, widespread screening of the general population is a matter of debate. Some organizations (such as the United States Preventive Services Task Force) state that evidence is insufficient to support routine screening,[43] while others (such as the American Thyroid Association) recommend either intermittent testing above a certain age in both sexes or only in women.[5] Targeted screening may be appropriate in a number of situations where hypothyroidism is common: other autoimmune diseases, a strong family history of thyroid disease, those who have received radioiodine or other radiation therapy to the neck, those who have previously undergone thyroid surgery, those with an abnormal thyroid examination, those with psychiatric disorders, people taking amiodarone or lithium, and those with a number of health conditions (such as certain heart and skin conditions).[5] Yearly thyroid function tests are recommended in people with Down syndrome, as they are at higher risk of thyroid disease.[44]

## Management [edit]

### Hormone replacement [edit]

Most people with hypothyroidism symptoms and confirmed thyroxine deficiency are treated with a synthetic long-acting form of thyroxine, known as levothyroxine (L-thyroxine).[5][13] In young and otherwise healthy people with overt hypothyroidism, a full replacement dose (adjusted by weight) can be started immediately; in the elderly and people with heart disease a lower starting dose is recommended to prevent over supplementation and risk of complications.[5][23] Lower doses may be sufficient in those with subclinical hypothyroidism, while people with central hypothyroidism may require a higher than average dose.[5]

Blood free thyroxine and TSH levels are monitored to help determine whether the dose is adequate. This is done 4–8 weeks after the start of treatment or a change in levothyroxine dose. Once the adequate replacement dose has been established, the tests can be repeated after 6 and then 12 months, unless there is a change in symptoms.[5] In people with central/secondary hypothyroidism, TSH is not a reliable marker of hormone replacement and decisions are based mainly on the free $T_4$ level.[5][7] Levothyroxine is best taken 30–60 minutes before breakfast, or four hours after food,[5] as certain substances such as food and calcium can inhibit the absorption of levothyroxine.[45] There is no direct way of increasing thyroid hormone secretion by the thyroid gland.[13]

## Liothyronine [edit]

Adding liothyronine (synthetic $T_3$) to levothyroxine has been suggested as a measure to provide better symptom control, but this has not been confirmed by studies.[6][13][46] In 2007, the British Thyroid Association stated that combined $T_4$ and $T_3$ therapy carried a higher rate of side effects and no benefit over $T_4$ alone.[13][47] Similarly, American guidelines discourage combination therapy due to a lack of evidence, although they acknowledge that some people feel better when receiving combination treatment.[5] Treatment with liothyronine alone has not received enough study to make a recommendation as to its use; due to its shorter half-life it needs to be taken more often.[5]

People with hypothyroidism who do not feel well despite optimal levothyroxine dosing may request adjunctive treatment with liothyronine. A 2012 guideline from the European Thyroid Association recommends that support should be offered with regards to the chronic nature of the disease and that other causes of the symptoms should be excluded. Addition of liothyronine should be regarded as experimental, initially only for a trial period of 3 months, and in a set ratio to the current dose of levothyroxine.[48] The guideline explicitly aims to enhance the safety of this approach and to counter its indiscriminate use.[48]

## Desiccated animal thyroid [edit]

Desiccated thyroid extract is an animal-based thyroid gland extract,[13] most commonly from pigs. It is a combination therapy, containing forms of $T_4$ and $T_3$.[13] It also contains calcitonin (a hormone produced in the thyroid gland involved in the regulation of calcium levels), $T_1$ and $T_2$; these are not present in synthetic hormone medication.[49] This extract was once a mainstream hypothyroidism treatment, but its use today is unsupported by evidence;[6][13] British Thyroid Association and American professional guidelines discourage its use.[5][47]

## Subclinical hypothyroidism [edit]

There is little evidence whether there is a benefit from treating subclinical hypothyroidism, and whether this offsets the risks of overtreatment. Untreated subclinical hypothyroidism may be associated with a modest increase in the risk of coronary artery disease.[50] A 2007 review found no benefit of thyroid hormone replacement except for "some parameters of lipid profiles and left ventricular function".[51] There is no association between subclinical hypothyroidism and an increased risk of bone fractures,[52] nor is there a link with cognitive decline.[53]

Since 2008, consensus American and British opinion has been that in general people with TSH under 10 mIU/l do not require treatment.[5][32][54] American guidelines recommend that treatment should be considered if the TSH is elevated but below 10 mIU/l in people with symptoms of hypothyroidism, detectable antibodies against thyroid peroxidase, a history of heart disease or are at an increased risk for heart disease.[5]

## Myxedema coma [edit]

Myxedema coma or severe decompensated hypothyroidism usually requires admission to the intensive care, close observation and treatment of abnormalities in breathing, temperature control, blood pressure, and sodium levels. Mechanical ventilation may be required, as well as fluid replacement, vasopressor agents, careful rewarming, and corticosteroids (for possible adrenal insufficiency which can occur together with hypothyroidism). Careful correction of low sodium levels may be achieved with hypertonic saline solutions or vasopressin receptor antagonists.[15] For rapid treatment of the hypothyroidism, levothyroxine or liothyronine may be administered intravenously, particularly if the level of consciousness is too low to be able to safely swallow medication.[15]

### Pregnancy [edit]

In women with known hypothyroidism who become pregnant, it is recommended that serum TSH levels are closely monitored. Levothyroxine should be used to keep TSH levels within the normal range for that trimester. The first trimester normal range is below 2.5 mIU/L and the second and third trimesters normal range is below 3.0 mIU/L.[13][28] Treatment should be guided by total (rather than free) thyroxine or by the free $T_4$ index. Similarly to TSH, the thyroxine results should be interpreted according to the appropriate reference range for that stage of pregnancy.[5] The levothyroxine dose often needs to be increased after pregnancy is confirmed,[5][23][28] although this is based on limited evidence and some recommend that it is not always required; decisions may need to based on TSH levels.[55]

Women with anti-TPO antibodies who are trying to become pregnant (naturally or by assisted means) may require thyroid hormone supplementation even if the TSH level is normal. This is particularly true if they have had previous miscarriages or have been hypothyroid in the past.[5] Supplementary levothyroxine may reduce the risk of preterm birth and possibly miscarriage.[56] The recommendation is stronger in pregnant women with subclinical hypothyroidism (defined as TSH 2.5–10 mIU/l) who are anti-TPO positive, in view of the risk of overt hypothyroidism. If a decision is made not to treat, close monitoring of the thyroid function (every 4 weeks in the first 20 weeks of pregnancy) is recommended.[5][28] If anti-TPO is not positive, treatment for subclinical hypothyroidism is not currently recommended.[28] It has been suggested that many of the aforementioned recommendations could lead to unnecessary treatment, in the sense that the TSH cutoff levels may be too restrictive in some ethnic groups; there may be little benefit from treatment of subclinical hypothyroidism in certain cases.[55]

## Epidemiology [edit]

Worldwide about one billion people are estimated to be iodine deficient; however, it is unknown how often this results in hypothyroidism.[9] In large population-based studies in Western countries with sufficient dietary iodine, 0.3–0.4% of the population have overt hypothyroidism. A larger proportion, 4.3–8.5%, have subclinical hypothyroidism.[5] Of people with subclinical hypothyroidism, 80% have a TSH level below the 10 mIU/l mark regarded as the threshold for treatment.[32] Children with subclinical hypothyroidism often return to normal thyroid function, and a small proportion develops overt hypothyroidism (as predicted by evolving antibody and TSH levels, the presence of celiac disease, and the presence of a goiter).[57]

Women are more likely to develop hypothyroidism than men. In population-based studies, women were seven times more likely than men to have TSH levels above 10 mU/l.[5] 2–4% of people with subclinical hypothyroidism will progress to overt hypothyroidism each year. The risk is higher in those with antibodies against thyroid peroxidase.[5][32] Subclinical hypothyroidism is estimated to affect approximately 2% of children; in adults, subclinical hypothyroidism is more common in the elderly, and in Caucasians.[31] There is a much higher rate of thyroid disorders, the most common of which is hypothyroidism, in individuals with Down syndrome[19][44] and Turner syndrome.[19]

Very severe hypothyroidism and myxedema coma are rare, with it estimated to occur in 0.22 per million people a year.[15] The majority of cases occur in women over 60 years of age, although it may happen in all age groups.[15]

Most hypothyroidism is primary in nature. Central/secondary hypothyroidism affects 1:20,000 to 1:80,000 of the population, or about one out of every thousand people with hypothyroidism.[7]

## History [edit]

In 1811, Bernard Courtois discovered iodine was present in seaweed, and iodine intake was linked with goiter size in 1820 by Jean-Francois Coindet.[58] Gaspard Adolphe Chatin proposed in 1852 that endemic goiter was the result of not enough iodine intake, and Eugen Baumann demonstrated iodine in thyroid tissue in 1896.[58]

The first cases of myxedema were recognized in the mid-19th century (the 1870s), but its connection to the thyroid was not discovered until the 1880s when myxedema was observed in people following the removal of the thyroid gland (thyroidectomy).[59] The link was further confirmed in the late 19th century when people and animals who had had their thyroid removed showed improvement in symptoms with transplantation of animal thyroid tissue.[6] The severity of myxedema, and its associated risk of mortality and complications, created interest in discovering effective treatments for hypothyroidism.[59] Transplantation of thyroid tissue demonstrated some efficacy, but recurrences of hypothyroidism was relatively common, and sometimes required multiple repeat transplantations of thyroid tissue.[59]

In 1891, the English physician George Redmayne Murray introduced subcutaneously injected sheep thyroid extract,[60] followed shortly after by an oral formulation.[6][61] Purified thyroxine was introduced in 1914 and in the 1930s synthetic thyroxine became available, although desiccated animal thyroid extract remained widely used. Liothyronine was identified in 1952.[6]

Early attempts at titrating therapy for hypothyroidism proved difficult. After hypothyroidism was found to cause a lower basal metabolic rate, this was used as a marker to guide adjustments in therapy in the early 20th century (around 1915).[59] However, a low basal metabolic rate was known to be non-specific, also present in malnutrition.[59] The first laboratory test to be helpful in assessing thyroid status was the serum protein-bound iodine, which came into use around the 1950s.

In 1971, the thyroid stimulating hormone (TSH) radioimmunoassay was developed, which was the most specific marker for assessing thyroid status in patients.[59] Many people who were being treated based on basal metabolic rate, minimizing hypothyroid symptoms, or based on serum protein-bound iodine, were found to have excessive thyroid hormone.[59] The following year, in 1972, a T3 radioimmunoassay was developed, and in 1974, a T4 radioimmunoassay was developed.[59]

## Other animals [edit]

In veterinary practice, dogs are the species most commonly affected by hypothyroidism. The majority of cases occur as a result of primary hypothyroidism, of which two types are recognized: lymphocytic thyroiditis, which is probably immune-driven and leads to destruction and fibrosis of the thyroid gland, and idiopathic atrophy, which leads to the gradual replacement of the gland by fatty tissue.[10][62] There is often lethargy, cold intolerance, exercise intolerance, and weight gain. Furthermore, skin changes and fertility problems are seen in dogs with hypothyroidism, as well as a number of other symptoms.[62] The signs of myxedema can be seen in dogs, with prominence of skin folds on the forehead, and cases of myxedema coma are encountered.[10] The diagnosis can be confirmed by blood test, as the clinical impression alone may lead to overdiagnosis.[10][62] Lymphocytic thyroiditis is associated with detectable antibodies against thyroglobulin, although they typically become undetectable in advanced disease.[62] Treatment is with thyroid hormone replacement.[10]

Other species that are less commonly affected include cats and horses, as well as other large domestic animals. In cats, hypothyroidism is usually the result of other medical treatment such as surgery or radiation. In young horses, congenital hypothyroidism has been reported predominantly in Western Canada and has been linked with the mother's diet.[10]

# Obesity

From Wikipedia, the free encyclopedia

**Obesity** is a medical condition in which excess body fat has accumulated to the extent that it may have a negative effect on health.[1] People are generally considered obese when their body mass index (BMI), a measurement obtained by dividing a person's weight by the square of the person's height, is over 30 kg/m$^2$, with the range 25–30 kg/m$^2$ defined as overweight.[1] Some East Asian countries use lower values.[2] Obesity increases the likelihood of various diseases, particularly heart disease, type 2 diabetes, obstructive sleep apnea, certain types of cancer, and osteoarthritis.[3]

Obesity is most commonly caused by a combination of excessive food intake, lack of physical activity, and genetic susceptibility.[1][4] A few cases are caused primarily by genes, endocrine disorders, medications, or mental illness.[5] Evidence to support the view that obese people eat little yet gain weight due to a slow metabolism is not generally supported.[6] On average, obese people have a greater energy expenditure than their thin counterparts due to the energy required to maintain an increased body mass.[6][7]

Obesity is mostly preventable through a combination of social changes and personal choices.[1] Changes to diet and exercising are the main treatments.[3] Diet quality can be improved by reducing the consumption of energy-dense foods, such as those high in fat and sugars, and by increasing the intake of dietary fiber.[1] Medications may be taken, along with a suitable diet, to reduce appetite or decrease fat absorption.[8] If diet, exercise, and medication are not effective, a gastric balloon or surgery may be performed to reduce stomach volume or bowel length, leading to feeling full earlier or a reduced ability to absorb nutrients from food.[9][10]

Obesity is a leading preventable cause of death worldwide, with increasing rates in adults and children.[1][11] In 2014, 600 million adults (13%) and 42 million children under the age of five were obese.[1] Obesity is more common in women than men.[1] Authorities view it as one of the most serious public health problems of the 21st century.[12] Obesity is stigmatized in much of the modern world (particularly in the Western world), though it was seen as a symbol of wealth and fertility at other times in history and still is in some parts of the world.[3][13] In 2013, the American Medical

# Classification

*Main article: Classification of obesity*

Obesity is a medical condition in which excess body fat has accumulated to the extent that it may have an adverse effect on health.[17] It is defined by body mass index (BMI) and further evaluated in terms of fat distribution via the waist–hip ratio and total cardiovascular risk factors.[18][19] BMI is closely related to both percentage body fat and total body fat.[20] In children, a healthy weight varies with age and sex. Obesity in children and adolescents is defined not as an absolute number but in relation to a historical normal group, such that obesity is a BMI greater than the 95th percentile.[21] The reference data on which these percentiles were based date from 1963 to 1994, and thus have not been affected by the recent increases in weight.[22] BMI is defined as the subject's weight divided by the square of their height and is calculated as follows.

| BMI (kg/m$^2$) | | Classification[16] |
|---|---|---|
| from | up to | |
| | 18.5 | underweight |
| 18.5 | 25.0 | normal weight |
| 25.0 | 30.0 | overweight |
| 30.0 | 35.0 | class I obesity |
| 35.0 | 40.0 | class II obesity |
| 40.0 | | class III obesity |

,

where *m* and *h* are the subject's weight and height

Obesity and BMI

A "super obese" male with a BMI of 53 kg/m$^2$: weight 182 kg (400 lb), height 185 cm (6 ft 1 in)

respectively.

BMI is usually expressed in kilograms per square metre, resulting when weight is measured in kilograms and height in metres. To convert from pounds per square inch multiply by 703 (kg/m$^2$)/(lb/sq in).[23]

The most commonly used definitions, established by the World Health Organization (WHO) in 1997 and published in 2000, provide the values listed in the table.[24][25]

Some modifications to the WHO definitions have been made by particular organizations.[26] The surgical literature breaks down class II and III obesity into further categories whose exact values are still disputed.[27]

- Any BMI ≥ 35 or 40 kg/m$^2$ is *severe obesity*.
- A BMI of ≥ 35 kg/m$^2$ and experiencing obesity-related health conditions or ≥40–44.9 kg/m$^2$ is *morbid obesity*.
- A BMI of ≥ 45 or 50 kg/m$^2$ is *super obesity*.

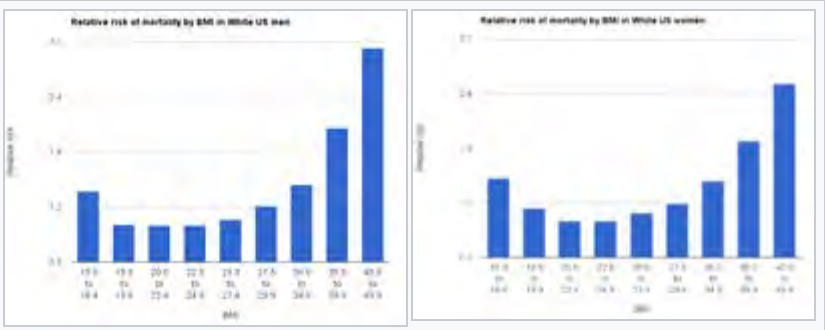
As Asian populations develop negative health consequences at a lower BMI than Caucasians, some nations have redefined obesity; Japan have defined obesity as any BMI greater than 25 kg/m$^2$[2] while China uses a BMI of greater than 28 kg/m$^2$.[26]

# Effects on health

Excessive body weight is associated with various diseases, particularly cardiovascular diseases, diabetes mellitus type 2, obstructive sleep apnea, certain types of cancer, osteoarthritis[3] and asthma.[3][28] As a result, obesity has been found to reduce life expectancy.[3]

## Mortality

Obesity is one of the leading preventable causes of death worldwide.[30][31][32] A number of reviews have found that mortality risk is lowest at a BMI of 20–25 kg/m$^2$[33][34][35] in non-smokers and at 24–27 kg/m$^2$ in current smokers, with risk increasing along with changes in either direction.[36][37] This appears to apply in at least four continents.[35] In contrast, a 2013 review found that grade 1 obesity (BMI 30-35) was not associated with higher mortality than normal weight, and that overweight (BMI 25-30) was associated with "lower" mortality than was normal weight (BMI 18.5-25).[38] Other evidence suggests that the association of BMI and waist circumference with mortality is U- or J-shaped, while the association between waist-to-hip ratio [39]



Relative risk of death over 10 years for white men (left) and women (right) who have never smoked in the United States by BMI.[29]

and waist-to-height ratio with mortality is more positive. In Asians the risk of negative health effects begins to increase between 22–25 kg/m$^2$.[40] A BMI above 32 kg/m$^2$ has been associated with a doubled mortality rate among women over a 16-year period.[41] In the United States obesity is estimated to cause 111,909 to 365,000 deaths per year,[3][32] while 1 million (7.7%) of deaths in Europe are attributed to excess weight.[42][43] On average, obesity reduces life expectancy by six to seven years,[3][44] a BMI of 30–35 kg/m$^2$ reduces life expectancy by two to four years,[34] while severe obesity (BMI > 40 kg/m$^2$) reduces life expectancy by ten years.[34]

## Morbidity

*Main article: Obesity-associated morbidity*

Obesity increases the risk of many physical and mental conditions. These comorbidities are most commonly shown in metabolic syndrome,[3] a combination of medical disorders which includes: diabetes mellitus type 2, high blood pressure, high blood cholesterol, and high triglyceride levels.[45]

Complications are either directly caused by obesity or indirectly related through mechanisms sharing a common cause such as a poor diet or a sedentary lifestyle. The strength of the link between obesity and specific conditions varies. One of the strongest is the link with type 2 diabetes. Excess body fat underlies 64% of cases of diabetes in men and 77% of cases in women.[46]

Health consequences fall into two broad categories: those attributable to the effects of increased fat mass (such as osteoarthritis, obstructive sleep apnea, social stigmatization) and those due to the increased number of fat cells (diabetes, cancer, cardiovascular disease, non-alcoholic fatty liver disease).[3][47] Increases in body fat alter the body's response to insulin, potentially leading to insulin resistance. Increased fat also creates a proinflammatory state,[48][49] and a prothrombotic state.[47][50]

## Survival paradox

*See also: Obesity paradox*

Although the negative health consequences of obesity in the general population are well supported by the available evidence, health outcomes in certain subgroups seem to be improved at an increased BMI, a phenomenon known as the obesity survival paradox.[71] The paradox was first described in 1999 in overweight and obese people undergoing hemodialysis,[71] and has subsequently been found in those with heart failure and peripheral artery disease (PAD).[72]

In people with heart failure, those with a BMI between 30.0 and 34.9 had lower mortality than those with a normal weight. This has been attributed to the fact that people often lose weight as they become progressively more ill.[73] Similar findings have been made in other types of heart disease. People with class I obesity and heart disease do not have greater rates of further heart problems than people of normal weight who also have heart disease. In people with greater degrees of obesity, however, the risk of further cardiovascular events is increased.[74][75] Even after cardiac bypass surgery, no increase in mortality is seen in the overweight and obese.[76] One study found that the improved survival could be explained by the more aggressive treatment obese people receive after a cardiac event.[77] Another found that if one takes into account chronic obstructive pulmonary disease (COPD) in those with PAD, the benefit of obesity no longer exists.[72]

# Causes

At an individual level, a combination of excessive food energy intake and a lack of physical activity is thought to explain most cases of obesity.[78] A limited number of cases are due primarily to genetics, medical reasons, or psychiatric illness.[5] In contrast, increasing rates of obesity at a societal level are felt to be due to an easily accessible and palatable diet,[79] increased reliance on cars, and mechanized manufacturing.[80][81]

A 2006 review identified ten other possible contributors to the recent increase of obesity: (1) insufficient sleep, (2) endocrine disruptors (environmental pollutants that interfere with lipid metabolism), (3) decreased variability in ambient temperature, (4) decreased rates of smoking, because smoking suppresses appetite, (5) increased use of medications that can cause weight gain (e.g., atypical antipsychotics), (6) proportional increases in ethnic and age groups that tend to be heavier, (7) pregnancy at a later age (which may cause susceptibility to obesity in children), (8) epigenetic risk factors passed on generationally, (9) natural

selection for higher BMI, and (10) assortative mating leading to increased concentration of obesity risk factors (this would increase the number of obese people by increasing population variance in weight).[82] While there is substantial evidence supporting the influence of these mechanisms on the increased prevalence of obesity, the evidence is still inconclusive, and the authors state that these are probably less influential than the ones discussed in the previous paragraph.

## Diet

*Main article: Diet and obesity*

A 2016 review supported excess food as the primary factor.[84] Dietary energy supply per capita varies markedly between different regions and countries. It has also changed significantly over time.[83] From the early 1970s to the late 1990s the average food energy available per person per day (the amount of food bought) increased in all parts of the world except Eastern Europe. The United States had the highest availability with 3,654 calories (15,290 kJ) per person in 1996.[83] This increased further in 2003 to 3,754 calories (15,710 kJ).[83] During the late 1990s Europeans had 3,394 calories (14,200 kJ) per person, in the developing areas of Asia there were 2,648 calories (11,080 kJ) per person, and in sub-Saharan Africa people had 2,176 calories (9,100 kJ) per person.[83][85] Total food energy consumption has been found to be related to obesity.[86]

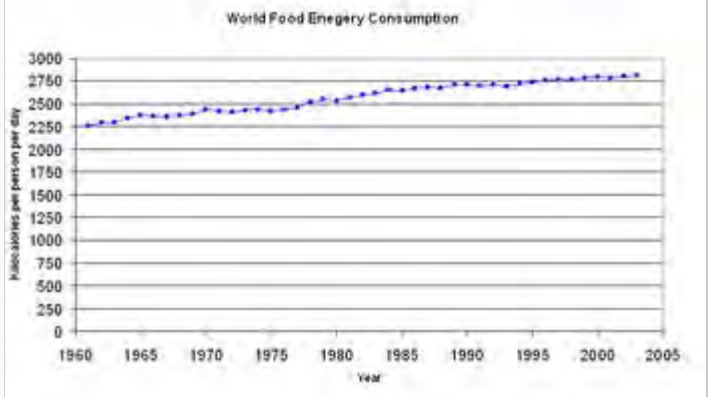
The widespread availability of nutritional guidelines[87] has done little to address the problems of overeating and poor dietary choice.[88] From 1971 to 2000, obesity rates in the United States increased from 14.5% to 30.9%.[89] During the same period, an increase occurred in the average amount of food energy consumed. For women, the average increase was 335 calories (1,400 kJ) per day (1,542 calories (6,450 kJ) in 1971 and 1,877 calories (7,850 kJ) in 2004), while for men the average increase was 168 calories (700 kJ) per day (2,450 calories (10,300 kJ) in 1971 and 2,618 calories (10,950 kJ) in 2004). Most of this extra food energy came from an increase in carbohydrate consumption rather than fat consumption.[90] The primary sources of these extra carbohydrates are sweetened beverages, which now account for almost 25 percent of daily food energy in young adults in America,[91] and potato chips.[92] Consumption of sweetened drinks such as soft drinks, fruit drinks, iced tea, and energy and vitamin water drinks is believed to be contributing to the rising rates of obesity[93][94] and to an increased risk of metabolic syndrome and type 2 diabetes.[95] Vitamin D deficiency is related to diseases associated with obesity.[96]



Average per capita energy consumption of the world from 1961 to 2002[83]

As societies become increasingly reliant on energy-dense, big-portions, and fast-food meals, the association [97]

between fast-food consumption and obesity becomes more concerning. In the United States consumption of fast-food meals tripled and food energy intake from these meals quadrupled between 1977 and 1995.[98]

Agricultural policy and techniques in the United States and Europe have led to lower food prices. In the United States, subsidization of corn, soy, wheat, and rice through the U.S. farm bill has made the main sources of processed food cheap compared to fruits and vegetables.[99] Calorie count laws and nutrition facts labels attempt to steer people toward making healthier food choices, including awareness of how much food energy is being consumed.

Obese people consistently under-report their food consumption as compared to people of normal weight.[100] This is supported both by tests of people carried out in a calorimeter room[101] and by direct observation.

## Sedentary lifestyle

*See also: Sedentary lifestyle and Exercise trends*

A sedentary lifestyle plays a significant role in obesity.[102] Worldwide there has been a large shift towards less physically demanding work,[103][104][105] and currently at least 30% of the world's population gets insufficient exercise.[104] This is primarily due to increasing use of mechanized transportation and a greater prevalence of labor-saving technology in the home.[103][104][105] In children, there appear to be declines in levels of physical activity due to less walking and physical education.[106] World trends in active leisure time physical activity are less clear. The World Health Organization indicates people worldwide are taking up less active recreational pursuits, while a study from Finland[107] found an increase and a study from the United States found leisure-time physical activity has not changed significantly.[108] A 2011 review of physical activity in children found that it may not be a significant contributor.[109]

In both children and adults, there is an association between television viewing time and the risk of obesity.[110][111][112] A review found 63 of 73 studies (86%) showed an increased rate of childhood obesity with increased media exposure, with rates increasing proportionally to time spent watching television.[113]

## Genetics

*Main article: Genetics of obesity*

Like many other medical conditions, obesity is the result of an interplay between genetic and environmental factors. Polymorphisms in various genes controlling appetite and metabolism predispose to obesity when sufficient food energy is present. As of 2006, more than 41 of these sites on the human genome have been linked to the development of obesity when a favorable environment is present.[115] People with two copies of the FTO gene (fat mass and obesity associated gene) have been found on average to weigh 3–4 kg more and have a 1.67-fold greater risk of obesity compared with those without the risk allele.[116] The differences in BMI between people that are due to genetics varies depending on the population examined from 6% to 85%.[117]

Obesity is a major feature in several syndromes, such as Prader–Willi syndrome, Bardet–Biedl syndrome, Cohen syndrome, and MOMO syndrome. (The term "non-syndromic obesity" is sometimes used to exclude these conditions.)[118] In people with early-onset severe obesity (defined by an onset before 10 years of age and body mass index over three standard deviations above normal), 7% harbor a single point

A 1680 painting by Juan Carreno de Miranda of a girl presumed to have Prader–Willi syndrome[114]

DNA mutation.[119]

Studies that have focused on inheritance patterns rather than on specific genes have found that 80% of the offspring of two obese parents were also obese, in contrast to less than 10% of the offspring of two parents who were of normal weight.[120] Different people exposed to the same environment have different risks of obesity due to their underlying genetics.[121]

The thrifty gene hypothesis postulates that, due to dietary scarcity during human evolution, people are prone to obesity. Their ability to take advantage of rare periods of abundance by storing energy as fat would be advantageous during times of varying food availability, and individuals with greater adipose reserves would be more likely to survive famine. This tendency to store fat, however, would be maladaptive in societies with stable food supplies.[122] This theory has received various criticisms, and other evolutionarily-based theories such as the drifty gene hypothesis and the thrifty phenotype hypothesis have also been proposed.[123][124]

## Other illnesses

Certain physical and mental illnesses and the pharmaceutical substances used to treat them can increase risk of obesity. Medical illnesses that increase obesity risk include several rare genetic syndromes (listed above) as well as some congenital or acquired conditions: hypothyroidism, Cushing's syndrome, growth hormone deficiency,[125] and the eating disorders: binge eating disorder and night eating syndrome.[3] However, obesity is not regarded as a psychiatric disorder, and therefore is not listed in the DSM-IVR as a psychiatric illness.[126] The risk of overweight and obesity is higher in patients with psychiatric disorders than in persons without psychiatric disorders.[127]

Certain medications may cause weight gain or changes in body composition; these include insulin, sulfonylureas, thiazolidinediones, atypical antipsychotics, antidepressants, steroids, certain anticonvulsants (phenytoin and valproate), pizotifen, and some forms of hormonal contraception.[3]

## Social determinants

*Main article: Social determinants of obesity*

While genetic influences are important to understanding

obesity, they cannot explain the current dramatic increase seen within specific countries or globally.[128] Though it is accepted that energy consumption in excess of energy expenditure leads to obesity on an individual basis, the cause of the shifts in these two factors on the societal scale is much debated. There are a number of theories as to the cause but most believe it is a combination of various factors.

The correlation between social class and BMI varies globally. A review in 1989 found that in developed countries women of a high social class were less likely to be obese. No significant differences were seen among men of different social classes. In the developing world, women, men, and children from high social classes had greater rates of obesity.[129] An update of this review carried out in 2007 found the same relationships, but they were weaker. The decrease in strength of correlation was felt to be due to the effects of globalization.[130] Among developed countries, levels of adult obesity, and percentage of teenage children who are overweight, are correlated with income inequality. A similar relationship is seen among US states: more adults, even in higher social classes, are obese in more unequal states.[131]

The disease scroll (Yamai no soshi, late 12th century) depicts a woman moneylender with obesity, considered a disease of the rich.

Many explanations have been put forth for associations between BMI and social class. It is thought that in developed countries, the wealthy are able to afford more nutritious food, they are under greater social pressure to remain slim, and have more opportunities along with greater expectations for physical fitness. In undeveloped countries the ability to afford food, high energy expenditure with physical labor, and cultural values favoring a larger body size are believed to contribute to the observed patterns.[130] Attitudes toward body weight held by people in one's life may also play a role in obesity. A correlation in BMI changes over time has been found among friends, siblings, and spouses.[132] Stress and perceived low social status appear to increase risk of obesity.[131][133][134]

Smoking has a significant effect on an individual's weight. Those who quit smoking gain an average of 4.4 kilograms (9.7 lb) for men and 5.0 kilograms (11.0 lb) for women over ten years.[135] However, changing rates of smoking have had little effect on the overall rates of obesity.[136]

In the United States the number of children a person has is related to their risk of obesity. A woman's risk increases by 7% per child, while a man's risk increases by 4% per child.[137] This could be partly explained by the fact that having dependent children decreases physical activity in Western parents.[138]

In the developing world urbanization is playing a role in increasing rate of obesity. In China overall rates of obesity are below 5%; however, in some cities rates of obesity are greater than 20%.[139]

Malnutrition in early life is believed to play a role in the rising rates of obesity in the developing world.[140] Endocrine changes that occur during periods of malnutrition may promote the storage of fat once more food energy becomes available.[140]

Consistent with cognitive epidemiological data, numerous studies confirm that obesity is associated with cognitive deficits.[141] Whether obesity causes cognitive deficits, or vice versa is unclear at present.

## Gut bacteria

*See also: Infectobesity*

The study of the effect of infectious agents on metabolism is still in its early stages. Gut flora has been shown to differ between lean and obese humans. There is an indication that gut flora in obese and lean individuals can affect the metabolic potential. This apparent alteration of the metabolic potential is believed

to confer a greater capacity to harvest energy contributing to obesity. Whether these differences are the direct cause or the result of obesity has yet to be determined unequivocally.[142]

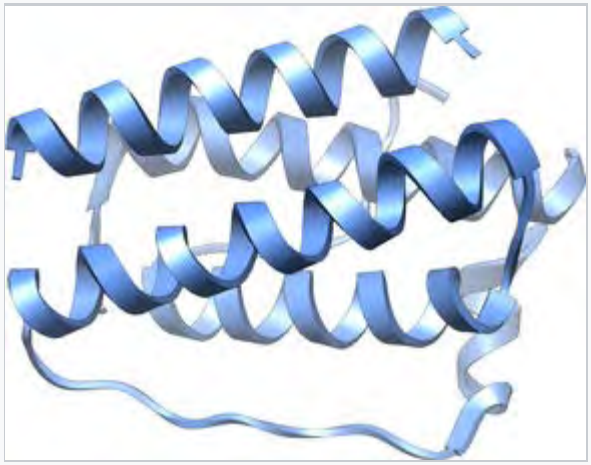
An association between viruses and obesity has been found in humans and several different animal species. The amount that these associations may have contributed to the rising rate of obesity is yet to be determined.[143]

## Pathophysiology

There are many possible pathophysiological mechanisms involved in the development and maintenance of obesity.[144] This field of research had been almost unapproached until the leptin gene was discovered in 1994 by J. M. Friedman's laboratory.[145] These investigators postulated that leptin was a satiety factor. In the ob/ob mouse, mutations in the leptin gene resulted in the obese phenotype opening the possibility of leptin therapy for human obesity. However, soon thereafter J. F. Caro's laboratory could not detect any mutations in the leptin gene in humans with obesity. On the contrary Leptin expression was increased proposing the possibility of Leptin-resistance in human obesity.[146] Since this discovery, many other hormonal mechanisms have been elucidated that participate in the regulation of appetite and food intake, storage patterns of adipose tissue, and development of insulin resistance. Since leptin's discovery, ghrelin, insulin, orexin, PYY 3-36, cholecystokinin, adiponectin, as well as many other mediators have been studied. The adipokines are mediators produced by adipose tissue; their action is thought to modify many obesity-related diseases.

A comparison of a mouse unable to produce leptin thus resulting in obesity (left) and a normal mouse (right)

Leptin and ghrelin are considered to be complementary in their influence on appetite, with ghrelin produced by the stomach modulating short-term appetitive control (i.e. to eat when the stomach is empty and to stop when the stomach is stretched). Leptin is produced by adipose tissue to signal fat storage reserves in the body, and mediates long-term appetitive controls (i.e. to eat more when fat storages are low and less when fat storages are high). Although administration of leptin may be effective in a small subset of obese individuals who are leptin-deficient, most obese individuals are thought to be leptin resistant and have been found to have high levels of leptin.[147] This resistance is thought to explain in part why administration of leptin has not been shown to be effective in suppressing appetite in most obese people.[144]



A graphic depiction of a leptin molecule

While leptin and ghrelin are produced peripherally, they control appetite through their actions on the central nervous system. In particular, they and other appetite-related hormones act on the hypothalamus, a region of the brain central to the regulation of food intake and energy expenditure. There are several circuits within the hypothalamus that contribute to its role in integrating appetite, the melanocortin pathway being the most well understood.[144] The circuit begins with an area of the hypothalamus, the arcuate nucleus, that has outputs to the lateral hypothalamus (LH) and ventromedial hypothalamus (VMH), the brain's feeding and satiety centers, respectively.[148]

The arcuate nucleus contains two distinct groups of neurons.[144] The first group coexpresses neuropeptide Y (NPY) and agouti-related peptide (AgRP) and has stimulatory inputs to the LH and inhibitory inputs to the VMH. The second

group coexpresses pro-opiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART) and has stimulatory inputs to the VMH and inhibitory inputs to the LH. Consequently, NPY/AgRP neurons stimulate feeding and inhibit satiety, while POMC/CART neurons stimulate satiety and inhibit feeding. Both groups of arcuate nucleus neurons are regulated in part by leptin. Leptin inhibits the NPY/AgRP group while stimulating the POMC/CART group. Thus a deficiency in leptin signaling, either via leptin deficiency or leptin resistance, leads to overfeeding and may account for some genetic and acquired forms of obesity.[144]

# Public health

The World Health Organization (WHO) predicts that overweight and obesity may soon replace more traditional public health concerns such as undernutrition and infectious diseases as the most significant cause of poor health.[149] Obesity is a public health and policy problem because of its prevalence, costs, and health effects.[150] The United States Preventive Services Task Force recommends screening for all adults followed by behavioral interventions in those who are obese.[151] Public health efforts seek to understand and correct the environmental factors responsible for the increasing prevalence of obesity in the population. Solutions look at changing the factors that cause excess food energy consumption and inhibit physical activity. Efforts include federally reimbursed meal programs in schools, limiting direct junk food marketing to children,[152] and decreasing access to sugar-sweetened beverages in schools.[153] The World Health Organization recommends the taxing of sugary drinks.[154] When constructing urban environments, efforts have been made to increase access to parks and to develop pedestrian routes.[155]

## Reports

Many organizations have published reports pertaining to obesity. In 1998, the first US Federal guidelines were published, titled "Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults: The Evidence Report".[156] In 2006 the Canadian Obesity Network published the "Canadian Clinical Practice Guidelines (CPG) on the Management and Prevention of Obesity in Adults and Children". This is a comprehensive evidence-based guideline to address the management and prevention of overweight and obesity in adults and children.[78]

In 2004, the United Kingdom Royal College of Physicians, the Faculty of Public Health and the Royal College of Paediatrics and Child Health released the report "Storing up Problems", which highlighted the growing problem of obesity in the UK.[157] The same year, the House of Commons Health Select Committee published its "most comprehensive inquiry [...] ever undertaken" into the impact of obesity on health and society in the UK and possible approaches to the problem.[158] In 2006, the National Institute for Health and Clinical Excellence (NICE) issued a guideline on the diagnosis and management of obesity, as well as policy implications for non-healthcare organizations such as local councils.[159] A 2007 report produced by Derek Wanless for the King's Fund warned that unless further action was taken, obesity had the capacity to cripple the National Health Service financially.[160]

Comprehensive approaches are being looked at to address the rising rates of obesity. The Obesity Policy Action (OPA) framework divides measure into 'upstream' policies, 'midstream' policies, 'downstream' policies. 'Upstream' policies look at changing society, 'midstream' policies try to alter individuals' behavior to prevent obesity, and 'downstream' policies try to treat currently afflicted people.[161]

# Management

*Main article: Management of obesity*

The main treatment for obesity consists of dieting and physical exercise.[78] Diet programs may produce weight loss over the short term,[162] but maintaining this weight loss is frequently difficult and often requires making exercise and a lower food energy diet a permanent part of a person's lifestyle.[163][164]

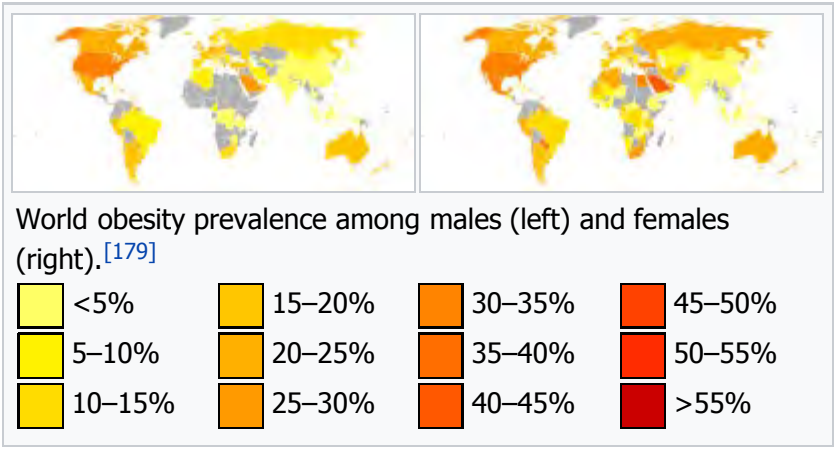
In the short-term low carbohydrate diets appear better than low fat diets for weight loss.[165] In the long term; however, all types of low-carbohydrate and low-fat diets appear equally beneficial.[165][166] A 2014 review found that the heart disease and diabetes risks associated with different diets appear to be similar.[167] Promotion of the Mediterranean diets among the obese may lower the risk of heart disease.[165] Decreased intake of sweet drinks is also related to weight-loss.[165] Success rates of long-term weight loss maintenance with lifestyle changes are low, ranging from 2–20%.[168] Dietary and lifestyle changes are effective in limiting excessive weight gain in pregnancy and improve outcomes for both the mother and the child.[169] Intensive behavioral counseling is recommended in those who are both obese and have other risk factors for heart disease.[170]

Three medications, orlistat, lorcaserin and a combination of phentermine and topiramate are currently available and have evidence for long term use.[8] Weight loss with orlistat is modest, an average of 2.9 kg (6.4 lb) at 1 to 4 years.[171] Its use is associated with high rates of gastrointestinal side effects[171] and concerns have been raised about negative effects on the kidneys.[172] The other two medications are available in the United States but not Europe.[173] Lorcaserin results in an average 3.1 kg weight loss (3% of body weight) greater than placebo over a year;[174] however, it may increase heart valve problems.[173] A combination of phentermine and topiramate is also somewhat effective;[175] however, it may be associated with heart problems.[173] There is no information on how these drugs affect longer-term complications of obesity such as cardiovascular disease or death.[8]

The most effective treatment for obesity is bariatric surgery.[9] Surgery for severe obesity is associated with long-term weight loss, improvement in obesity related conditions,[176] and decreased overall mortality. One study found a weight loss of between 14% and 25% (depending on the type of procedure performed) at 10 years, and a 29% reduction in all cause mortality when compared to standard weight loss measures.[177] Complications occur in about 17% of cases and reoperation is needed in 7% of cases.[176] Due to its cost and risks, researchers are searching for other effective yet less invasive treatments including devices that occupy space in the stomach.[178]

# Epidemiology

*Main article: Epidemiology of obesity*



World obesity prevalence among males (left) and females (right).[179]

In earlier historical periods obesity was rare, and achievable only by a small elite, although already recognised as a problem for health. But as prosperity increased in the Early Modern period, it affected increasingly larger groups of the population.[180] In 1997 the WHO formally recognized obesity as a global epidemic.[91] As of 2008 the WHO estimates that at least 500 million adults (greater than 10%) are obese, with higher rates among women than men.[181] The rate of obesity also increases with age at least up to 50 or 60 years old[182] and severe obesity in the United States, Australia, and Canada is increasing faster than the overall rate of obesity.[27][183][184]

Once considered a problem only of high-income countries, obesity rates are rising worldwide and affecting both the developed and developing world.[42] These increases have been felt most dramatically in urban settings.[181] The only remaining region of the world where obesity is not common is sub-Saharan Africa.[3]

# History

## Etymology

*Obesity* is from the Latin *obesitas*, which means "stout, fat, or plump". *Ēsus* is the past participle of *edere* (to eat), with *ob* (over) added to it.[185] *The Oxford English Dictionary* documents its first usage in 1611 by Randle Cotgrave.[186]

## Historical attitudes

Ancient Greek medicine recognizes obesity as a medical disorder, and records that the Ancient Egyptians saw it in the same way.[180] Hippocrates wrote that "Corpulence is not only a disease itself, but the harbinger of others".[3] The Indian surgeon Sushruta (6th century BCE) related obesity to diabetes and heart disorders.[188] He recommended physical work to help cure it and its side effects.[188] For most of human history mankind struggled with food scarcity.[189] Obesity has thus historically been viewed as a sign of wealth and prosperity. It was common among high officials in Europe in the Middle Ages and the Renaissance[187] as well as in Ancient East Asian civilizations.[190] In the 17th century, English medical author Tobias Venner is credited with being one of the first to refer to the term as a societal disease in a published English language book.[180][191]

During the Middle Ages and the Renaissance obesity was often seen as a sign of wealth, and was relatively common among the elite: *The Tuscan General Alessandro del Borro*, attributed to Charles Mellin, 1645[187]

With the onset of the industrial revolution it was realized that the military and economic might of nations were dependent on both the body size and strength of their soldiers and workers.[91] Increasing the average body mass index from what is now considered underweight to what is now the normal range played a significant role in the development of industrialized societies.[91] Height and weight thus both increased through the 19th century in the developed world. During the 20th century, as populations reached their genetic potential for height, weight began increasing much more than height, resulting in obesity.[91] In the 1950s increasing wealth in the developed world decreased child mortality, but as body weight increased heart and kidney disease became more common.[91][192] During this time period, insurance companies realized the connection between weight and life expectancy and increased premiums for the obese.[3]

Many cultures throughout history have viewed obesity as the result of a character flaw. The *obesus* or fat character in Greek comedy was a glutton and figure of mockery. During Christian times the food was viewed as a gateway to the sins of sloth and lust.[13] In modern Western culture, excess weight is often regarded as unattractive, and obesity is commonly associated with various negative stereotypes. People of all ages can face social stigmatization, and may be targeted by bullies or shunned by their peers.[193]

Public perceptions in Western society regarding healthy body weight differ from those regarding the weight that is considered ideal – and both have changed since the beginning of the 20th century. The weight that is viewed as an ideal has become lower since the 1920s. This is illustrated by the fact that the average height of Miss America pageant winners increased by 2% from 1922 to 1999, while their average weight decreased by 12%.[194] On the other hand, people's views concerning healthy weight have changed in the opposite direction. In Britain, the

*Venus of Willendorf* created 24,000–22,000 BC

weight at which people considered themselves to be overweight was significantly higher in 2007 than in 1999.[195] These changes are believed to be due to increasing rates of adiposity leading to increased acceptance of extra body fat as being normal.[195]

Obesity is still seen as a sign of wealth and well-being in many parts of Africa. This has become particularly common since the HIV epidemic began.[3]

### The arts

The first sculptural representations of the human body 20,000–35,000 years ago depict obese females. Some attribute the Venus figurines to the tendency to emphasize fertility while others feel they represent "fatness" in the people of the time.[13] Corpulence is, however, absent in both Greek and Roman art, probably in keeping with their ideals regarding moderation. This continued through much of Christian European history, with only those of low socioeconomic status being depicted as obese.[13]

During the Renaissance some of the upper class began flaunting their large size, as can be seen in portraits of Henry VIII of England and Alessandro del Borro.[13] Rubens (1577–1640) regularly depicted full-bodied women in his pictures, from which derives the term Rubenesque. These women, however, still maintained the "hourglass" shape with its relationship to fertility.[196] During the 19th century, views on obesity changed in the Western world. After centuries of obesity being synonymous with wealth and social status, slimness began to be seen as the desirable standard.[13]

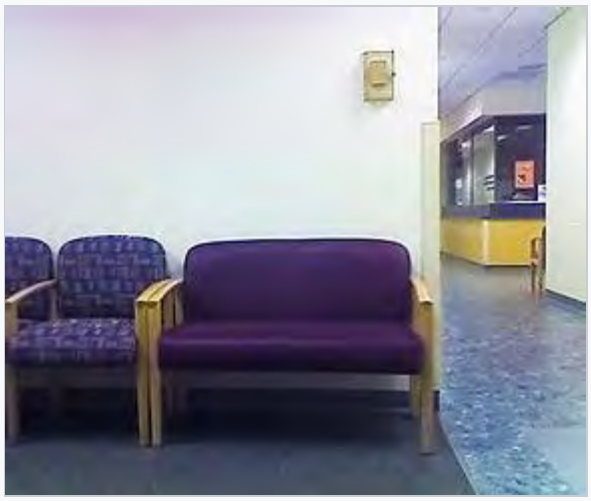
## Society and culture

### Economic impact

In addition to its health impacts, obesity leads to many problems including disadvantages in employment[197][198] and increased business costs. These effects are felt by all levels of society from individuals, to corporations, to governments.

In 2005, the medical costs attributable to obesity in the US were an estimated $190.2 billion or 20.6% of all medical expenditures,[199][200][201] while the cost of obesity in Canada was estimated at CA$2 billion in 1997 (2.4% of total health costs).[78] The total annual direct cost of overweight and obesity in Australia in 2005 was A$21 billion. Overweight and obese Australians also received A$35.6 billion in government subsidies.[202] The estimate range for annual expenditures on diet products is $40 billion to $100 billion in the US alone.[203]

Obesity prevention programs have been found to reduce the cost of treating obesity-related disease. However, the longer people live, the more medical costs they incur. Researchers, therefore, conclude that reducing obesity may improve the public's health, but it is unlikely to reduce overall health spending.[204]



Services must accommodate obese people with specialist equipment such as much wider chairs.[205]

Obesity can lead to social stigmatization and disadvantages in employment.[197] When compared to their normal weight counterparts, obese workers on average have higher rates of absenteeism from work and take more disability leave, thus increasing costs for employers and decreasing productivity.[206] A study examining Duke University employees found that people with a BMI over 40 kg/m$^2$ filed twice as many workers' compensation claims as those whose BMI was 18.5–24.9 kg/m$^2$. They also had more than 12 times as many lost work days. The most common injuries in this group were due to falls and lifting, thus affecting the lower extremities, wrists or hands, and backs.[207] The Alabama State Employees' Insurance Board approved a controversial plan to charge obese workers $25 a month for health insurance that would otherwise be free unless they take steps to lose weight and improve their health. These measures started in January 2010 and apply to those state workers whose BMI exceeds 35 kg/m$^2$ and who fail to make improvements in their health after one year.[208]

Some research shows that obese people are less likely to be hired for a job and are less likely to be promoted.[193] Obese people are also paid less than their non-obese counterparts for an equivalent job; obese women on average make 6% less and obese men make 3% less.[209]

Specific industries, such as the airline, healthcare and food industries, have special concerns. Due to rising rates of obesity, airlines face higher fuel costs and pressures to increase seating width.[210] In 2000, the extra weight of obese passengers cost airlines US$275 million.[211] The healthcare industry has had to invest in special facilities for handling severely obese patients, including special lifting equipment and bariatric ambulances.[212] Costs for restaurants are increased by litigation accusing them of causing obesity.[213] In 2005 the US Congress discussed legislation to prevent civil lawsuits against the food industry in relation to obesity; however, it did not become law.[213]

With the American Medical Association's 2013 classification of obesity as a chronic disease,[14] it is thought that health insurance companies will more likely pay for obesity treatment, counseling and surgery, and the cost of research and development of fat treatment pills or gene therapy treatments should be more affordable if insurers help to subsidize their cost.[214] The AMA classification is not legally binding, however, so health insurers still have the right to reject coverage for a treatment or procedure.[214]

In 2014, The European Court of Justice ruled that morbid obesity is a disability. The Court argued that if an employee's obesity prevents him from "full and effective participation of that person in professional life on an equal basis with other workers", then it shall be considered a disability and that firing someone on such grounds is discriminatory.[215]

## Size acceptance

*See also: Fat acceptance movement, Social stigma of obesity, and Health at Every Size*

The principal goal of the fat acceptance movement is to decrease discrimination against people who are overweight and obese.[216][217] However, some in the movement are also attempting to challenge the established relationship between [218]

obesity and negative health outcomes.

A number of organizations exist that promote the acceptance of obesity. They have increased in prominence in the latter half of the 20th century.[219] The US-based National Association to Advance Fat Acceptance (NAAFA) was formed in 1969 and describes itself as a civil rights organization dedicated to ending size discrimination.[220]

The International Size Acceptance Association (ISAA) is a non-governmental organization (NGO) which was founded in 1997. It has more of a global orientation and describes its mission as promoting size acceptance and helping to end weight-based discrimination.[221] These groups often argue for the recognition of obesity as a disability under the US Americans With Disabilities Act (ADA). The American legal system, however, has decided that the potential public health costs exceed the benefits of extending this anti-discrimination law to cover obesity.[218]

United States President William Howard Taft was often ridiculed for being overweight

### Industry influence on research

In 2015 the *New York Times* published an article on the Global Energy Balance Network, a nonprofit founded in 2014 that advocated for people to focus on increasing exercise rather than reducing calorie intake to avoid obesity and to be healthy. The organization was founded with at least $1.5M in funding from the Coca-Cola Company and the company had provided $4M in research funding to the two founding scientists Gregory A. Hand and Steven N. Blair, since 2008.[222][223]

## Childhood obesity

*Main article: Childhood obesity*

The healthy BMI range varies with the age and sex of the child. Obesity in children and adolescents is defined as a BMI greater than the 95th percentile.[21] The reference data that these percentiles are based on is from 1963 to 1994 and thus has not been affected by the recent increases in rates of obesity.[22] Childhood obesity has reached epidemic proportions in the 21st century, with rising rates in both the developed and the developing world. Rates of obesity in Canadian boys have increased from 11% in the 1980s to over 30% in the 1990s, while during this same time period rates increased from 4 to 14% in Brazilian children.[224]

As with obesity in adults, many factors contribute to the rising rates of childhood obesity. Changing diet and decreasing physical activity are believed to be the two most important causes for the recent increase in the incidence of child obesity.[225] Because childhood obesity often persists into adulthood and is associated with numerous chronic illnesses, children who are obese are often tested for hypertension, diabetes, hyperlipidemia, and fatty liver.[78] Treatments used in children are primarily lifestyle interventions and behavioral techniques, although efforts to increase activity in children have had little success.[226] In the United States, medications are not FDA approved for use in this age group.[224]

# Other animals

*Main article: Obesity in pets*

Obesity in pets is common in many countries. In the United States, 23–41% of dogs are overweight, and about 5.1% are obese.[227] The rate of obesity in cats was slightly higher at 6.4%.[227] In Australia the rate of obesity among dogs in a veterinary setting has been found to be 7.6%.[228] The risk of obesity in dogs is related to whether or not their owners are obese; however, there is no similar correlation between cats and their owners.[229]

# Primary aldosteronism

From Wikipedia, the free encyclopedia
(Redirected from Primary hyperaldosteronism)

**Primary aldosteronism**, also known as **primary hyperaldosteronism** or **Conn's syndrome**, is excess production of the hormone aldosterone by the adrenal glands resulting in low renin levels. Often it produces few symptoms.[1] Most people have high blood pressure which may cause poor vision or headaches.[1][2] Occasionally there may be muscular weakness, muscle spasms, tingling sensations, or excessive urination.[1] Complications include cardiovascular disease such as stroke, myocardial infarction, kidney failure, and abnormal heart rhythms.[3][4]

Primary hyperaldosteronism has a number of causes. About 66% of cases are due to enlargement of both adrenal glands and 33% of cases are due to an adrenal adenoma that produces aldosterone.[1] Other uncommon causes include adrenal cancer and an inherited disorder called familial hyperaldosteronism.[5] Some recommend screening people with high blood pressure who are at increased risk while others recommend screening all people with high blood pressure for the disease.[3] Screening is usually done by measuring the aldosterone-to-renin ratio in the blood with further testing used to confirm positive results. While low blood potassium is classically described this is only present in about a quarter of people. To determine the underlying cause medical imaging is carried out.[1]

Some cases may be cured by removing the adenoma by surgery.[1] A single adrenal gland may also be removed in cases where only one is enlarged.[4] In cases due to enlargement of both glands treatment is typically with medications known as aldosterone antagonists such as spironolactone or eplerenone.[1] Other medications for high blood pressure and a low salt diet may also be needed.[1][4] Some people with familial hyperaldosteronism may be treated with the steroid dexamethasone.[1]

Primary aldosteronism is present in about 10% of people with high blood pressure.[1] It occurs more often in women than men. Often it begins in those between 30 and 50 years of age.[6] Conn's syndrome is named after Jerome W. Conn (1907–1994), the American endocrinologist who first described adenomas as a cause of the condition in 1955.[7][8]

## Signs and symptoms [edit]

People often have few or no symptoms.[1] They may get occasional muscular weakness, muscle spasms, tingling sensations, or excessive urination.[1]

High blood pressure, manifestations of muscle cramps (due to hyperexcitability of neurons secondary to low blood calcium), muscle weakness (due to hypoexcitability of skeletal muscles secondary to hypokalemia), and headaches (due to low blood potassium or high blood pressure) may be seen.

Secondary hyperaldosteronism is often related to decreased cardiac output which is associated with elevated renin levels.

## Causes [edit]

The condition is due to:[9]

- Bilateral idiopathic (micronodular) adrenal hyperplasia (66%)[1]
- Adrenal adenoma (Conn's syndrome) (33%)[1]
- Primary (unilateral) adrenal hyperplasia—2% of cases
- Aldosterone-producing adrenocortical carcinoma—<1% of cases
- Familial Hyperaldosteronism (FH)
- Glucocorticoid-remediable aldosteronism (FH type I)—<1% of cases
- FH type II (APA or IHA)—<2% of cases

### Genetics [edit]

40% of people with an adrenal aldosterone producing adenoma have somatic gain-of-function mutations in a single gene (KCNJ5).[10] This gene is mutated in inherited cases albeit less frequently. These mutations tend to occur in young women with the adenoma in the cortisol secreting zona fasciculata. Adenomas without this mutation tend to occur in older men with resistant hypertension.

## Pathophysiology [edit]

Aldosterone has effects on most or all cells of the body but, clinically, the most important actions are in the kidney, on cells of the late distal convoluted tubule and medullary collecting duct. In the principal cells aldosterone increases activity of basolateral membrane sodium-potassium ATPase and apical epithelial sodium channels, ENaC, as well as potassium channels, ROMK. These actions increase sodium reabsorption and potassium secretion. Since more sodium is reabsorbed than potassium secreted, it also makes the lumen more electrically negative, causing chloride to follow sodium. Water then follows sodium and chloride by osmosis. In Conn syndrome, these actions cause increased extracellular sodium and fluid volume and reduced extracellular potassium. Aldosterone also acts on intercalated cells to stimulate an apical proton ATPase, causing proton secretion that acidifies urine and alkalizes extracellular fluid.

In summary, hyperaldosteronism causes hypernatremic, hypokalemic, metabolic alkalosis.

Finer notes on aldosterone include the fact that it stimulates sodium-potassium ATPase in muscle cells, increasing intracellular potassium and also increases sodium reabsorption all along the intestine and nephron, possibly due to widespread stimulation of sodium-potassium ATPase. Finally, epithelial cells of sweat gland ducts and distal colon surface respond exactly the same as the principal cells of the nephron. These responses are important in climate adaptation and as a cause of constipation with elevated aldosterone.

The sodium retention leads to plasma volume expansion and elevated blood pressure. The increased blood pressure will lead to increased glomerular filtration rate and cause a decrease in renin release from the granular cells of the juxtaglomerular apparatus in the kidney. If there is a primary hyperaldosteronism, the decreased renin (and subsequent decreased angiotensin II) will not lead to a decrease in aldosterone levels (a very helpful clinical tool in diagnosis of primary hyperaldosteronism).

## Diagnosis [edit]

Screening may be considered in people with high blood pressure presenting with low blood potassium, high blood pressure that is difficult to treat, other family members with the same condition, or a mass on the adrenal gland.[1]

Measuring aldosterone alone is not considered adequate to diagnose primary hyperaldosteronism. Rather, both renin and aldosterone are measured, and a resultant aldosterone-to-renin ratio is used for case detection.[11][12] A high aldosterone-to-renin ratio suggests the presence of primary hyperaldosteronism. The diagnosis is made by performing a saline suppression test, ambulatory salt loading test, or fludrocortisone suppression test.[13]

If primary hyperaldosteronism is confirmed biochemically, CT scanning or other cross-sectional imaging can confirm the presence of an adrenal abnormality, possibly an adrenal cortical adenoma (aldosteronoma), adrenal carcinoma, bilateral adrenal hyperplasia, or other less common changes. Imaging findings may ultimately lead to other necessary diagnostic studies, such as adrenal venous sampling, to clarify the etiology. It is not uncommon for adults to have bilateral sources of aldosterone hypersecretion in the presence of a nonfunctioning adrenal cortical adenoma, making adrenal venous sampling mandatory in cases where surgery is being considered.[13]

The diagnosis is best accomplished by an appropriately-trained subspecialist, though primary care providers are critical in recognizing clinical features of primary aldosteronism and obtaining the first blood tests for case detection.

### Classification [edit]

Some people only use Conn's syndrome for when it occurs due to an adrenal adenoma (a type of benign tumor).[14] In practice, however, the terms are often used interchangeably, regardless of the underlying physiology.[1]

### Differential diagnosis [edit]

Primary hyperaldosteronism can be mimicked by Liddle syndrome, and by ingestion of licorice and other foods containing glycyrrhizin. In one case report, hypertension and quadriparesis resulted from intoxication with a non-alcoholic pastis (an anise-flavored aperitif containing glycyrrhizinic acid).[15]

## Treatment [edit]

The treatment for hyperaldosteronism depends on the underlying cause. In people with a single benign tumor (adenoma), surgical removal (adrenalectomy) may be curative. This is usually performed laparoscopically, through several very small incisions. For people with hyperplasia of both glands, successful treatment is often achieved with spironolactone or eplerenone, drugs that block the effect of aldosterone. With its antiandrogen effect, spironolactone drug therapy may have a range of effects in males, including

sometimes gynecomastia. These symptoms usually do not occur with eplerenone drug therapy.[16]

In the absence of treatment, individuals with hyperaldosteronism often have poorly controlled high blood pressure, which may be associated with increased rates of stroke, heart disease, and kidney failure. With appropriate treatment, the prognosis is excellent.[17]

## Eponym [edit]

Conn's syndrome is named after Jerome W. Conn (1907–1994), the American endocrinologist who first described the condition at the University of Michigan in 1955.[7]

# Vitamin $B_{12}$ deficiency

From Wikipedia, the free encyclopedia

**Vitamin $B_{12}$ deficiency**, also known as **hypocobalaminemia**, is low blood levels of vitamin $B_{12}$.[1] A wide variety of signs and symptoms may occur including a decreased ability to think and behavioural and emotional changes such as depression, irritability, and psychosis. Abnormal sensations, changes in reflexes, and poor muscle function can also occur as may inflammation of the tongue, decreased taste, low red blood cells, reduced heart function, and decreased fertility.[2] In young children symptoms include poor growth, poor development, and difficulties with movement.[3] Without early treatment some of the changes may be permanent.[4]

Common causes include poor absorption from the stomach or intestines, decreased intake, and increased requirements. Decreased absorption may be due to pernicious anemia, surgical removal of the stomach, chronic inflammation of the pancreas, intestinal parasites, certain medications, and some genetic disorders. Decreased intake may occur in those who eat a vegan diet or are malnourished. Increased requirements occur in HIV/AIDS and in those with rapid red blood cell breakdown.[2] Diagnosis is typically based on vitamin $B_{12}$ blood levels below 120–180 picomol/L (170–250 pg/mL) in adults. Elevated methylmalonic acid levels (values >0.4 micromol/L) may also indicate a deficiency. A type of low red blood cells known as megaloblastic anemia is often but not always present.[3]

Supplementation is recommended to prevent deficiency in vegetarians who are pregnant.[3] Once identified it is easily treated with supplementation by mouth or injection.[5] There are no concerns from excess vitamin $B_{12}$ among those who are otherwise healthy.[3] Some cases may also be helped by treating the underlying cause.[6] Other cases may require ongoing supplementation as the underlying cause is not curable.[7] Vitamin $B_{12}$ deficiency is common.[2] It is estimated to occur in about 6% of those under the age of 60 and 20% of those over the age of 60. Rates may be as high as 80% in parts of Africa and Asia.[2]

## Signs and symptoms [edit]

Vitamin $B_{12}$ deficiency can lead to vitamin $B_{12}$ deficiency anemia and neurologic dysfunction.[8] A mild deficiency may not cause any discernible symptoms, but as the deficiency becomes more significant symptoms of anemia may result, such as weakness, fatigue, light-headedness, rapid heartbeat, rapid breathing and pale color to the skin. It may also cause easy bruising or bleeding, including bleeding gums. GI side effects including sore tongue, stomach upset, weight loss, and diarrhea or constipation. If the deficiency is not corrected, nerve cell damage can result. If this happens, vitamin $B_{12}$ deficiency may result in tingling or numbness to the fingers and toes, difficulty walking, mood changes, depression, memory loss, disorientation and, in severe cases, dementia.

The main syndrome of vitamin $B_{12}$ deficiency is pernicious anemia. It is characterized by a triad of symptoms:

1. Anemia with bone marrow promegaloblastosis (megaloblastic anemia). This is due to the inhibition of DNA synthesis (specifically purines and thymidine)
2. Gastrointestinal symptoms: alteration in bowel motility, such as mild diarrhea or constipation, and loss of bladder or bowel control.[9] These are thought to be due to defective DNA synthesis inhibiting replication in a site with a high turnover of cells. This may also be due to the autoimmune attack on the parietal cells of the stomach in pernicious anemia. There is an association with GAVE syndrome (commonly called watermelon stomach) and pernicious anemia.[10]
3. Neurological symptoms: Sensory or motor deficiencies (absent reflexes, diminished vibration or soft touch sensation), subacute combined degeneration of spinal cord, seizures,[11][12][13][14] or even symptoms of dementia[15] and or other psychiatric symptoms may be present. The presence of peripheral sensory-motor symptoms or subacute combined degeneration of spinal cord strongly suggests the presence of a $B_{12}$ deficiency instead of folate deficiency. Methylmalonic acid, if not properly handled by $B_{12}$, remains in the myelin sheath, causing fragility. Dementia and depression have been associated with this deficiency as well, possibly from the under-production of methionine because of the inability to convert homocysteine into this product. Methionine is a necessary cofactor in the production of several neurotransmitters.

Each of those symptoms can occur either alone or along with others. The neurological complex, defined as *myelosis funicularis*, consists of the following symptoms:

1. Impaired perception of deep touch, pressure and vibration, loss of sense of touch, very annoying and persistent paresthesias
2. Ataxia of dorsal chord type
3. Decrease or loss of deep muscle-tendon reflexes
4. Pathological reflexes — Babinski, Rossolimo and others, also severe paresis

Vitamin $B_{12}$ deficiency can cause severe and irreversible damage, especially to the brain and nervous system. These symptoms of neuronal damage may not reverse after correction of hematological abnormalities, and the chance of complete reversal decreases with the length of time the neurological

symptoms have been present.

Tinnitus may be associated with vitamin $B_{12}$ deficiency.[16]

### Psychological [edit]

Vitamin $B_{12}$ deficiency can also cause symptoms of mania and psychosis, fatigue, memory impairment, irritability, depression, ataxia, and personality changes.[17][18][19] In infants symptoms include irritability, failure to thrive, apathy, anorexia, and developmental regression.[20][21]

## Causes [edit]

- Inadequate dietary intake of vitamin $B_{12}$. Vitamin $B_{12}$ occurs in animal products (eggs, meat, milk) and recent research indicates it may also occur in some algae, such as *Chlorella*[22][23][24] and Susabi-nori (*Porphyra yezoensis*).[25][26] $B_{12}$ isolated from bacterial cultures is also added to many fortified foods, and available as a dietary supplement.[27] Vegans, and also vegetarians but to a lesser degree, may be at risk for $B_{12}$ deficiency due to inadequate dietary intake of $B_{12}$, if they do not supplement. However, $B_{12}$ deficiency can occur even in people who consume meat, poultry, and fish.[28] Children are at a higher risk for $B_{12}$ deficiency due to inadequate dietary intake, as they have fewer vitamin stores and a relatively larger vitamin need per calorie of food intake.
- Selective impaired absorption of vitamin $B_{12}$ due to intrinsic factor deficiency. This may be caused by the loss of gastric parietal cells in chronic atrophic gastritis (in which case, the resulting megaloblastic anemia takes the name of "pernicious anemia"), or may result from wide surgical resection of stomach (for any reason), or from rare hereditary causes of impaired synthesis of intrinsic factor.
- Impaired absorption of vitamin $B_{12}$ in the setting of a more generalized malabsorption or maldigestion syndrome. This includes any form of structural damage or wide surgical resection of the terminal ileum (the principal site of vitamin $B_{12}$ absorption).
- Forms of achlorhydria (including that artificially induced by drugs such as proton pump inhibitors and histamine 2 receptor antagonists) can cause $B_{12}$ malabsorption from foods, since acid is needed to split $B_{12}$ from food proteins and salivary binding proteins.[29] This process is thought to be the most common cause of low $B_{12}$ in the elderly, who often have some degree of achlorhydria without being formally low in intrinsic factor. This process does not affect absorption of small amounts of $B_{12}$ in supplements such as multivitamins, since it is not bound to proteins, as is the $B_{12}$ in foods.[30]
- Surgical removal of the small bowel (for example in Crohn's disease) such that the patient presents with short bowel syndrome and is unable to absorb vitamin $B_{12}$. This can be treated with regular injections of vitamin $B_{12}$.
- Long-term use of ranitidine hydrochloride may contribute to deficiency of vitamin $B_{12}$.[31]
- Untreated celiac disease may also cause impaired absorption of this vitamin, probably due to damage to the small bowel mucosa. In some people, vitamin B12 deficiency may persist despite treatment with a gluten-free diet and require supplementation.[32]
- Some bariatric surgical procedures, especially those that involve removal of part of the stomach, such as Roux-en-Y gastric bypass surgery. (Procedures such as the adjustable gastric band type do not appear to affect $B_{12}$ metabolism significantly).[*citation needed*]
- Bacterial overgrowth in parts of the small bowel are thought to be able to absorb $B_{12}$. An example occurs in so-called blind loop syndrome.[*citation needed*]
- The diabetes medication metformin may interfere with $B_{12}$ dietary absorption.[33]
- Hereditary causes such as severe MTHFR deficiency, homocystinuria, and transcobalamin deficiency.[*citation needed*]
- One anecdotal study has shown that giardiasis may be a cause of vitamin $B_{12}$ deficiency,[34] but larger

studies have shown no correlation.[35]
- Malnutrition of alcoholism.
- Nitrous oxide abuse.[36]

## Mechanism [edit]

The total amount of vitamin $B_{12}$ stored in the body is between two and five milligrams in adults. Approximately 50% is stored in the liver, but approximately 0.1% is lost each day, due to secretions into the gut—not all of the vitamin in the gut is reabsorbed. While bile is the main vehicle for $B_{12}$ excretion, most of the $B_{12}$ secreted in bile is recycled via enterohepatic circulation. Due to the extreme efficiency of this mechanism, the liver can store three to five years worth of vitamin $B_{12}$ under normal conditions and functioning.[37] However, the rate at which $B_{12}$ levels may change when dietary intake is low depends on the balance between several variables.[38]

### Metabolic [edit]

Vitamin $B_{12}$ deficiency causes particular changes to the metabolism of 2 clinically relevant substances in humans:

1. Homocysteine (homocysteine to methionine, catalysed by methionine synthase) leading to hyperhomocysteinemia may lead to varicose veins[*citation needed*]
2. Methylmalonic acid (methylmalonyl-CoA to succinyl-CoA, of which methylmalonyl-CoA is made from methylmalonic acid in a preceding reaction)

Methionine is activated to *S*-adenosyl methionine, which aids in purine and thymidine synthesis, myelin production, protein/neurotransmitters/fatty acid/phospholipid production and DNA methylation. 5-Methyl tetrahydrofolate provides a methyl group, which is released to the reaction with homocysteine, resulting in methionine. This reaction requires cobalamin as a cofactor. The creation of 5-methyl tetrahydrofolate is an irreversible reaction. If $B_{12}$ is absent, the forward reaction of homocysteine to methionine does not occur, and the replenishment of tetrahydrofolate stops.[39]

Because $B_{12}$ and folate are involved in the metabolism of homocysteine, hyperhomocysteinuria is a non-specific marker of deficiency. Methylmalonic acid is used as a more specific test of $B_{12}$ deficiency.

### Pathomorphology [edit]

A spongiform state of neural tissue along with edema of fibers and deficiency of tissue. The myelin decays, along with axial fiber. In later phases, fibric sclerosis of nervous tissues occurs. Those changes apply to dorsal parts of the spinal cord and to pyramidal tracts in lateral cords. The pathophysiologic state of the spinal cord is called subacute combined degeneration of spinal cord.[40]

In the brain itself, changes are less severe: They occur as small sources of nervous fibers decay and accumulation of astrocytes, usually subcortically located, and also round hemorrhages with a torus of glial cells. Pathological changes can be noticed as well in the posterior roots of the cord and, to lesser extent, in peripheral nerves. Abnormalities might be observed in MRI.[41]

## Diagnosis [edit]

Serum $B_{12}$ levels are often low in $B_{12}$ deficiency, but if other features of $B_{12}$ deficiency are present with normal $B_{12}$ then further investigation is warranted. One possible explanation for normal $B_{12}$ levels in $B_{12}$ deficiency is antibody interference in people with high titres of intrinsic factor antibody.[42] Some researchers propose that the current standard norms of vitamin B levels are too low.[43] One Japanese study states

12

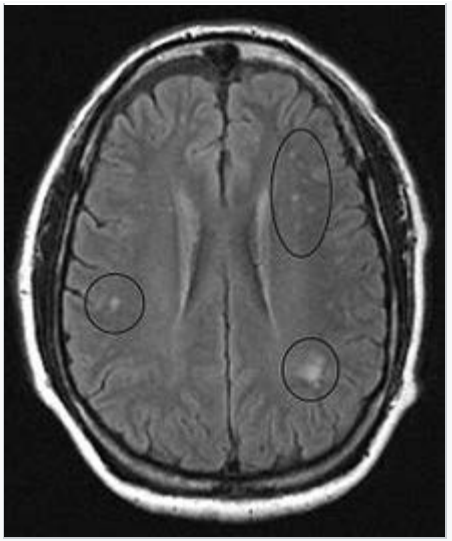
the normal limits as 500–1,300 pg/mL.[44] Range of vitamin B12 levels in humans is considered as normal: >300 pg/mL; moderate deficiency: 201–300 pg/mL; and severe deficiency: <201 pg/mL.[45]

Serum vitamin $B_{12}$ tests results are in pg/mL (picograms/milliliter) or pmol/L (picomoles/liter). The laboratory reference ranges for these units are similar, since the molecular weight of $B_{12}$ is approximately 1000, the difference between mL and L. Thus: 550 pg/mL = 400 pmol/L.

Serum homocysteine and methylmalonic acid levels are considered more reliable indicators of $B_{12}$ deficiency than the concentration of $B_{12}$ in blood.[46] The levels of these substances are high in $B_{12}$ deficiency and can be helpful if the diagnosis is unclear.

Routine monitoring of methylmalonic acid levels in urine is an option for people who may not be getting enough dietary $B_{12}$, as a rise in methylmalonic acid levels may be an early indication of deficiency.[47]

If nervous system damage is suspected, $B_{12}$ analysis in cerebrospinal fluid is possible, though such an invasive test should be considered only if blood testing is inconclusive.[48]



MRI image of the brain in an axial view showing the "precontrast FLAIR image". Note the abnormal lesions (circled) in the per ventricular area suggesting white matter pathology in someone with vitamin B12 deficiency.

The Schilling test has been largely supplanted by tests for antiparietal cell and intrinsic factor antibodies.

## Effect of folic acid [edit]

The National Institutes of Health has found that "Large amounts of folic acid can mask the damaging effects of vitamin $B_{12}$ deficiency by correcting the megaloblastic anemia caused by vitamin $B_{12}$ deficiency without correcting the neurological damage that also occurs", there are also indications that "high serum folate levels might not only mask vitamin $B_{12}$ deficiency, but could also exacerbate the anemia and worsen the cognitive symptoms associated with vitamin $B_{12}$ deficiency".[3] Due to the fact that in the United States legislation has required enriched flour to contain folic acid to reduce cases of fetal neural-tube defects, consumers may be ingesting more than they realize.[49] To counter the masking effect of $B_{12}$ deficiency the NIH recommends "folic acid intake from fortified food and supplements should not exceed 1,000 µg daily in healthy adults."[3] Most importantly, $B_{12}$ deficiency needs to be treated with $B_{12}$ repletion. Limiting folic acid will not counter the irrevocable neurological damage that is caused by untreated $B_{12}$ deficiency.[*citation needed*]

# Treatment [edit]

$B_{12}$ can be supplemented by pill or injection and appear to be equally effective in those with low levels due to absorption problems.[5]

When large doses are given by mouth its absorption does not rely on the presence of intrinsic factor or an intact ileum. Generally 1 to 2 mg daily is required as a large dose.[50] Even pernicious anemia can be treated entirely by the oral route.[51][52][53] These supplements carry such large doses of the vitamin that 1% to 5% of high oral doses of

Hydroxocobalamin injection is a clear red liquid solution of hydroxocobalamin.

free crystalline $B_{12}$ is absorbed along the entire intestine by passive diffusion.

## Epidemiology [edit]

In the developing world the deficiency is very widespread, with significant levels of deficiency in Africa, India, and South and Central America. This is theorized to be due to low intakes of animal products, particularly among the poor.[54]

$B_{12}$ deficiency is more common in the elderly.[54] This is because $B_{12}$ absorption decreases greatly in the presence of atrophic gastritis, which is common in the elderly.

The 2000 Tufts University study found no correlation between eating meat and differences in $B_{12}$ serum levels.[28]

# Appendicitis

From Wikipedia, the free encyclopedia

**Appendicitis** is inflammation of the appendix. Symptoms commonly include right lower abdominal pain, nausea, vomiting, and decreased appetite. However, approximately 40% of people do not have these typical symptoms.[2] Severe complications of a ruptured appendix include widespread, painful inflammation of the inner lining of the abdominal wall and sepsis.[3]

Appendicitis is caused by a blockage of the hollow portion of the appendix.[4] This is most commonly due to a calcified "stone" made of feces. Inflamed lymphoid tissue from a viral infection, parasites, gallstone, or tumors may also cause the blockage.[5] This blockage leads to increased pressures in the appendix, decreased blood flow to the tissues of the appendix, and bacterial growth inside the appendix causing inflammation.[5][6] The combination of inflammation, reduced blood flow to the appendix and distention of the appendix causes tissue injury and tissue death.[7] If this process is left untreated, the appendix may burst, releasing bacteria into the abdominal cavity, leading to severe abdominal pain and increased complications.[7][8]

The diagnosis of appendicitis is largely based on the person's signs and symptoms.[6] In cases where the diagnosis cannot be made based on the person's history and physical exam, close observation, radiographic imaging and laboratory tests can be helpful. The two most common imaging tests used are ultrasound and computed tomography (CT scan).[9] CT scan has been shown to be more accurate than ultrasound in detecting acute appendicitis.[10] However, ultrasound may be preferred as the first imaging test in children and pregnant women because of the risks associated with radiation exposure from CT scans.[9]

The standard treatment for acute appendicitis is surgical removal of the appendix.[5][6] This may be done by an open incision in the abdomen (laparotomy) or through a few smaller incisions with the help of cameras (laparoscopy). Surgery decreases the risk of side effects or death associated with rupture of the appendix.[3] Antibiotics may be equally effective in certain cases of non-ruptured appendicitis.[11] It is one of the most common and significant causes of severe abdominal pain that comes on quickly worldwide. In 2013 about 16 million cases of appendicitis occurred.[12] This resulted in 72,000 deaths globally.[13] In the United States, appendicitis is the most common cause of acute abdominal pain requiring surgery.[2] Each year in the United States, more than 300,000 people with appendicitis have their appendix surgically removed.[14] Reginald Fitz is credited with being the first person to describe the condition in 1886.[15]

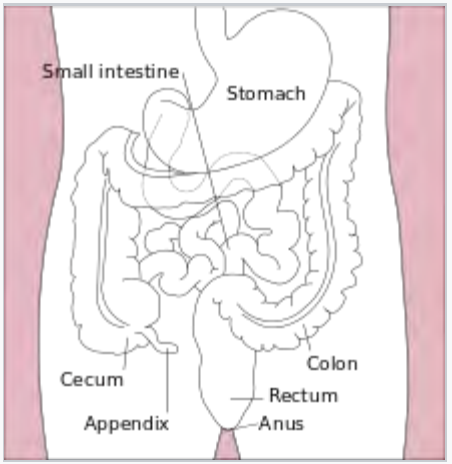
## Signs and symptoms [edit]

The presentation of acute appendicitis includes abdominal pain, nausea, vomiting, and fever. As the appendix becomes more swollen and inflamed, it begins to irritate the adjoining abdominal wall. This leads to the localization of the pain to the right lower quadrant. This classic migration of pain may not be seen in children under three years. This pain can be elicited through signs and can be severe. Signs include localized findings in the right iliac fossa. The abdominal wall becomes very sensitive to gentle pressure (palpation). There is severe pain on sudden release of deep pressure in the lower abdomen (rebound tenderness). If the appendix is retrocecal (localized behind the cecum), even deep pressure in the right lower quadrant may fail to elicit tenderness (silent appendix). This is because the cecum, distended with gas, protects the inflamed appendix from pressure. Similarly, if the appendix lies entirely within the pelvis, there is usually complete absence of abdominal rigidity. In such cases, a digital rectal examination elicits tenderness in the rectovesical pouch. Coughing causes point tenderness in this area (McBurney's point).



Location of the appendix in the digestive system

## Causes [edit]

Acute appendicitis seems to be the end result of a primary obstruction of the appendix.[16][4] Once this obstruction occurs, the appendix becomes filled with mucus and swells. This continued production of mucus leads to increased pressures within the lumen and the walls of the appendix. The increased pressure results in thrombosis and occlusion of the small vessels, and stasis of lymphatic flow. At this point spontaneous recovery rarely occurs. As the occlusion of blood vessels progresses, the appendix becomes ischemic and then necrotic. As bacteria begin to leak out through the dying walls, pus forms within and around the appendix (suppuration). The end result is appendiceal rupture (a 'burst appendix') causing peritonitis, which may lead to sepsis and eventually death. These events are responsible for the slowly evolving abdominal pain and other commonly associated symptoms.[7]

The causative agents include bezoars, foreign bodies, trauma, intestinal worms, lymphadenitis and, most commonly, calcified fecal deposits that are known as appendicoliths or fecaliths.[17][18] The occurrence of obstructing fecaliths has attracted attention since their presence in people with appendicitis is higher in developed than in developing countries.[19] In addition an appendiceal fecalith is commonly associated with complicated appendicitis.[20] Fecal stasis and arrest may play a role, as demonstrated by people with acute

appendicitis having fewer bowel movements per week compared with healthy controls.[18][21]

The occurrence of a fecalith in the appendix was thought to be attributed to a right-sided fecal retention reservoir in the colon and a prolonged transit time. However, a prolonged transit time was not observed in subsequent studies.[22] From epidemiological data, it has been stated that diverticular disease and adenomatous polyps were unknown and colon cancer exceedingly rare in communities exempt from appendicitis.[23][24] And acute appendicitis has been shown to occur antecedent to cancer in the colon and rectum.[25] Several studies offer evidence that a low fiber intake is involved in the pathogenesis of appendicitis.[26][27][28] This low intake of dietary fiber is in accordance with the occurrence of a right-sided fecal reservoir and the fact that dietary fiber reduces transit time.[29]

# Diagnosis [edit]

Diagnosis is based on a medical history (symptoms) and physical examination which can be supported by an elevation of neutrophilic white blood cells and imaging studies if needed. (Neutrophils are the primary white blood cells that respond to a bacterial infection.) Histories fall into two categories, typical and atypical.

Appendicitis as seen on CT imaging

Typical appendicitis includes several hours of generalized abdominal pain that begins in the region of the umbilicus with associated anorexia, nausea, or vomiting. The pain then "localizes" into the right lower quadrant where the tenderness increases in intensity. It is possible the pain could localize to the left lower quadrant in people with situs inversus totalis. The combination of pain, anorexia, leukocytosis, and fever is classic.

Atypical histories lack this typical progression and may include pain in the right lower quadrant as an initial symptom. Irritation of the peritoneum (inside lining of the abdominal wall) can lead to increased pain on movement, or jolting, for example going over speedbumps.[30] Atypical histories often require imaging with ultrasound and/or CT scanning.[31]

## Clinical [edit]

- Aure-Rozanova's sign: Increased pain on palpation with finger in right Petit triangle (can be a positive Shchetkin-Bloomberg's).[32]
- Bartomier-Michelson's sign: Increased pain on palpation at the right iliac region as the person being examined lies on his or her left side compared to when he/she lies on the back.[32]
- Dunphy's sign: Increased pain in the right lower quadrant with coughing.[33]
- Hamburger sign: The patient refuses to eat (anorexia is 80% specific for appendicitis)[34]
- Kocher's (Kosher's) sign: From the person's medical history, the start of pain in the umbilical region with a subsequent shift to the right iliac region.[32]
- Massouh sign: Developed in and popular in southwest England, the examiner performs a firm swish with his or her index and middle finger across the abdomen from the xiphoid process to the left and the right iliac fossa. A positive Massouh sign is a grimace of the person being examined upon a right sided (and not left) sweep.[35]
- Obturator sign: The person being evaluated lies on her or his back with the hip and knee both flexed at ninety degrees. The examiner holds the person's ankle with one hand and knee with the other hand. The examiner rotates the hip by moving the person's ankle away from his or her body while allowing the knee to move only inward. A positive test is pain with internal rotation of the hip.[36]
- Psoas sign, also known as "Obraztsova's sign", is right lower-quadrant pain that is produced with either the passive extension of the right hip or by the active flexion of the person's right hip while supine. The pain that is elicited is due to inflammation of the peritoneum overlying the iliopsoas muscles and

inflammation of the psoas muscles themselves. Straightening out the leg causes pain because it stretches these muscles, while flexing the hip activates the iliopsoas and causes pain.[36]

- Rovsing's sign: Pain in the lower right abdominal quadrant with continuous deep palpation starting from the left iliac fossa upwards (counterclockwise along the colon). The thought is there will be increased pressure around the appendix by pushing bowel contents and air toward the ileocaecal valve provoking right-sided abdominal pain.[37]
- Sitkovskiy (Rosenstein)'s sign: Increased pain in the right iliac region as the person is being examined lies on his/her left side.[38]

## Blood and urine test [edit]

While there is no laboratory test specific for appendicitis, a complete blood count (CBC) is done to check for signs of infection. Although 70-90 percent of people with appendicitis may have an elevated white blood cell (WBC) count, there are many other abdominal and pelvic conditions that can cause the WBC count to be elevated.[39]

A urinalysis generally does not show infection, but it is important for determining pregnancy status, especially the possibility of an ectopic pregnancy in woman of childbearing age. The urinalysis is also important for ruling out a urinary tract infection as the cause of abdominal pain. The presence of more than 20 WBC per high-power field in the urine is more suggestive of a urinary tract disorder.[39]

## Imaging [edit]

In children the clinical examination is important to determine which children with abdominal pain should receive immediate surgical consultation and which should receive diagnostic imaging.[40] Because of the health risks of exposing children to radiation, ultrasound is the preferred first choice with CT scan being a legitimate follow-up if the ultrasound is inconclusive.[41][42][43] CT scan is more accurate than ultrasound for the diagnosis of appendicitis in adults and adolescents. CT scan has a sensitivity of 94%, specificity of 95%. Ultrasonography had an overall sensitivity of 86%, a specificity of 81%.[44]

## Ultrasound [edit]

Ultrasonography and Doppler sonography are useful to detect appendicitis, especially in children. Ultrasound can show free fluid collection in the right iliac fossa, along with a visible appendix with increased blood flow when using color Doppler, and noncompressibility of the appendix, as it is essentially a walled off abscess. Other secondary sonographic signs of acute appendicitis include the presence of echogenic mesenteric fat surrounding the appendix and the acoustic shadowing of an appendicolith.[45] In some cases (approximately 5%),[46] ultrasonography of the iliac fossa does not reveal any abnormalities despite the presence of appendicitis. This false negative finding is especially true of early appendicitis before the appendix has become significantly distended. In addition, false negative findings are more common in adults where larger amounts of fat and bowel gas make visualizing the appendix technically difficult. Despite these limitations, sonographic imaging in experienced hands can often distinguish between appendicitis and other diseases with similar symptoms. Some of these conditions include inflammation of lymph nodes near the appendix or pain originating from other pelvic organs such as the ovaries or Fallopian tubes.

## Computed tomography [edit]

Where it is readily available, computed tomography (CT) has become frequently used, especially in people whose diagnosis is not obvious on history and physical examination. Concerns about radiation tend to limit

use of CT in pregnant women and children, especially with the increasingly widespread usage of MRI.[47][48]

The accurate diagnosis of appendicitis is multi-tiered, with the size of the appendix having the strongest positive predictive value, while indirect features can either increase or decrease sensitivity and specificity. A size of over 6 mm is both 95% sensitive and specific for appendicitis.[49]

However, because the appendix can be filled with fecal material, causing intraluminal distention, this criterion has shown limited utility in more recent meta analyses.[50] This is as opposed to ultrasound, in which the wall of the appendix can be more easily distinguished from intraluminal feces. In such scenarios, ancillary features such as increased wall enhancement as compared to adjacent bowel and inflammation of the surrounding fat, or fat stranding, can be supportive of the diagnosis, although their absence does not preclude it. In severe cases with perforation, an adjacent phlegmon or abscess can be seen. Dense fluid layering in the pelvis can also result, related to either pus or enteric spillage. When patients are thin or younger, the relative absence of fat can make the appendix and surrounding fat stranding difficult to see.[50]

## Magnetic resonance imaging [edit]

MRI use has become increasingly common for diagnosis of appendicitis in children and pregnant patients due to the radiation dosage that, while of nearly negligible risk in healthy adults, can be harmful to children or the developing fetus. In pregnancy, it has been found to be more useful during the second and third trimester, particularly as the enlargening uterus displaces the appendix, making it difficult to find by ultrasound. The periappendiceal stranding that is reflected on CT by fat stranding on MRI appears as increased fluid signal on T2 weighted sequences. First trimester pregnancies are usually not candidates for MRI, as the fetus is still undergoing organogenesis, and there are no long-term studies to date regarding its potential risks or side effects.[51]

## X-ray [edit]

In general, plain abdominal radiography (PAR) is not useful in making the diagnosis of appendicitis and should not be routinely obtained from a person being evaluated for appendicitis.[52][53] Plain abdominal films may be useful for the detection of ureteral calculi, small bowel obstruction, or perforated ulcer, but these conditions are rarely confused with appendicitis.[54] An opaque fecalith can be identified in the right lower quadrant in fewer than 5% of people being evaluated for appendicitis.[39] A barium enema has proven to be a poor diagnostic tool for appendicitis. While failure of the appendix to fill during a barium enema has been associated with appendicitis, up to 20% of normal appendices do not fill.[54]

appendicitis.[55] The Alvarado score and pediatric appendicitis score are useful but not definitive.[55]

The Alvarado score is the most widely used scoring system. A score below 5 suggests against a diagnosis of appendicitis, whereas a score of 7 or more is predictive of acute appendicitis. In a person with an equivocal score of 5 or 6, a CT scan or ultrasound exam may be used to reduce the rate of negative appendectomy.

## Pathology [edit]

The definitive diagnosis is based on pathology. The histologic finding of appendicitis is neutrophilic infiltrate of the muscularis propria.

Periappendicits, inflammation of tissues around the appendix, is often found in conjunction with other abdominal pathology.[56]

## Differential diagnosis [edit]

Children: Gastroenteritis, mesenteric adenitis, Meckel's diverticulitis, intussusception, Henoch–Schönlein purpura, lobar pneumonia, urinary tract infection (abdominal pain in the absence of other symptoms can occur in children with UTI), new-onset Crohn's disease or ulcerative colitis, pancreatitis, and abdominal trauma from child abuse; distal intestinal obstruction syndrome in children with cystic fibrosis; typhlitis in children with leukemia.

Women: A pregnancy test is important for all women of childbearing age since an ectopic pregnancy can have signs and symptoms similar to those of appendicitis. Other obstetrical/gynecological causes of similar abdominal pain in women include pelvic inflammatory disease, ovarian torsion, menarche, dysmenorrhea, endometriosis, and Mittelschmerz (the passing of an egg in the ovaries approximately two weeks before menstruation).[57]

Men: testicular torsion

Adults: new-onset Crohn's disease, ulcerative colitis, regional enteritis, renal colic, perforated peptic ulcer, pancreatitis, rectus sheath hematoma and epiploic appendagitis.

Elderly: diverticulitis, intestinal obstruction, colonic carcinoma, mesenteric ischemia, leaking aortic aneurysm.

The term "pseudoappendicitis" is used to describe a condition mimicking appendicitis.[58] It can be associated with *Yersinia enterocolitica*.[59]

# Management [edit]

Acute appendicitis is typically managed by surgery. However, in uncomplicated cases antibiotics are

effective and safe.[11][60] While antibiotics are effective for treating uncomplicated appendicitis, 26% of people had a recurrence within a year and required eventual appendectomy.[61]

In people with inflammatory bowel disease such as Crohn's disease or ulcerative colitis who present with appendicitis, surgical intervention is contraindicated, as the normal healing response following surgery is impaired by the underlying disease process, and the patients form non healing fistulas, sinus tracts and enteric leakage. In such scenarios, the underlying disease process must be treated medically with DMARDs, as opposed to surgically.[62]

## Pain [edit]

Pain medications (such as morphine) do not appear to affect the accuracy of the clinical diagnosis of appendicitis and therefore should be given early in the patient's care.[63] Historically there were concerns among some general surgeons that analgesics would affect the clinical exam in children, and some recommended that they not be given until the surgeon was able to examine the person.[63]

## Surgery [edit]

*See also: Appendectomy*

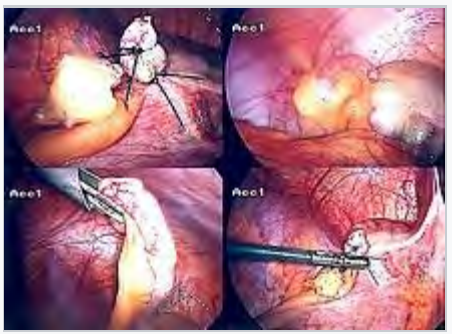
The surgical procedure for the removal of the appendix is called an appendectomy. Appendectomy can be performed through open or laparoscopic surgery. Laparoscopic appendectomy has several advantages over open appendectomy as an intervention for acute appendicitis.[64]

Inflamed appendix removal by open surgery

## Open appendectomy [edit]

For over a century, laparotomy (open appendectomy) was the standard treatment for acute appendicitis.[65] This procedure consists of the removal of the infected appendix through a single large incision in the lower right area of the abdomen.[66] The incision in a laparotomy is usually 2 to 3 inches (51 to 76 mm) long.

During an open appendectomy, the person with suspected appendicitis is placed under general anesthesia to keep the muscles completely relaxed and to keep the person unconscious. The incision is two to three inches (76 mm) long and it is made in the right lower abdomen, several inches above the hip bone. Once the incision opens the abdomen cavity and the appendix is identified, the surgeon removes the infected tissue and cuts the appendix from the surrounding tissue. After careful and close inspection of the infected area, and ensuring there are no signs that surrounding tissues are damaged or infected, the surgeon will start closing the incision. This means sewing the muscles and using surgical staples or stitches to close the skin up. To prevent infections, the incision is covered with a sterile bandage.



Laparoscopic appendectomy.

## Laparoscopic appendectomy [edit]

Laparoscopic appendectomy has become an increasingly prevalent intervention for acute appendicitis since its introduction in 1983.[67] This surgical procedure consists of making three to four incisions in the abdomen, each 0.25 to 0.5 inches (6.4 to 12.7 mm) long. This type of appendectomy is made by inserting a special surgical tool called laparoscope into one of the incisions. The laparoscope is connected to a monitor outside the person's body and it is designed to help the surgeon to inspect the infected area in the abdomen. The other two incisions are made for the specific removal of the appendix by using surgical instruments. Laparoscopic surgery requires general anesthesia, and it can last up to two hours. Laparoscopic appendectomy has several advantages over open appendectomy, including a shorter post-

operative recovery, less post-operative pain, and lower superficial surgical site infection rate. However, the occurrence of intra-abdominal abscess is almost three times more prevalent in laparoscopic appendectomy than open appendectomy.[68]

### Pre-surgery [edit]

The treatment begins by keeping the person who will be having surgery from eating or drinking for a given period, usually overnight. An intravenous drip is used to hydrate the person who will be having surgery. Antibiotics given intravenously such as cefuroxime and metronidazole may be administered early to help kill bacteria and thus reduce the spread of infection in the abdomen and postoperative complications in the abdomen or wound. Equivocal cases may become more difficult to assess with antibiotic treatment and benefit from serial examinations. If the stomach is empty (no food in the past six hours) general anaesthesia is usually used. Otherwise, spinal anaesthesia may be used.

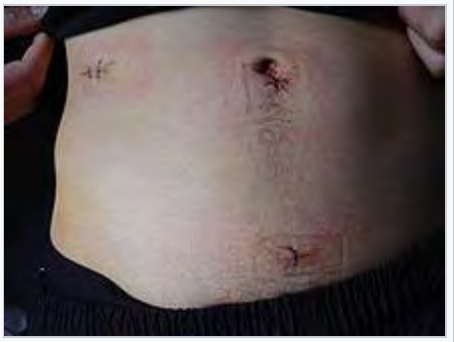
Once the decision to perform an appendectomy has been made, the preparation procedure takes approximately one to two hours. Meanwhile, the surgeon will explain the surgery procedure and will present the risks that must be considered when performing an appendectomy. (With all surgeries there are risks that must be evaluated before performing the procedures.) The risks are different depending on the state of the appendix. If the appendix has not ruptured, the complication rate is only about 3% but if the appendix has ruptured, the complication rate rises to almost 59%.[69] The most usual complications that can occur are pneumonia, hernia of the incision, thrombophlebitis, bleeding or adhesions. Recent evidence indicates that a delay in obtaining surgery after admission results in no measurable difference in outcomes to the person with appendicitis.[70][71]

The surgeon will explain how long the recovery process should take. Abdomen hair is usually removed to avoid complications that may appear regarding the incision.

In most cases, patients going in for surgery experience nausea or vomiting that requires medication before surgery. Antibiotics along with pain medication may be administrated before appendectomies.

### After surgery [edit]

Hospital lengths of stay typically range from a few hours to a few days but can be a few weeks if complications occur. The recovery process may vary depending on the severity of the condition: if the appendix had ruptured or not before surgery. Appendix surgery recovery is generally a lot faster if the appendix did not rupture.[72] It is important that people undergoing surgery respect their doctor's advice and limit their physical activity so the tissues can heal faster. Recovery after an appendectomy may not require diet changes or a lifestyle change.



The stitches the day after having the appendix removed by laparoscopic surgery

Length of hospital stays for appendicitis varies on the severity of the condition. A study from the United States found that in 2010, the average appendicitis hospital stay was 1.8 days. For stays where the person's appendix had ruptured, the average length of stay was 5.2 days.[8]

After surgery, the patient will be transferred to a postanesthesia care unit so his or her vital signs can be closely monitored to detect anesthesia- and/or surgery-related complications. Pain medication may be administered if necessary. After patients are completely awake, they are moved to a hospital room to recover. Most individuals will be offered clear liquids the day after the surgery, then progress to a regular diet when the intestines start to function properly. Patients are recommended to sit up on the edge of the bed and walk short distances several times a day. Moving is mandatory and pain medication may be given if necessary. Full recovery from appendectomies takes about four to six weeks but can be prolonged to up to eight weeks if the appendix had ruptured.

## Prognosis [edit]

Most people with appendicitis recover easily after surgical treatment, but complications can occur if treatment is delayed or if peritonitis occurs. Recovery time depends on age, condition, complications, and other circumstances, including the amount of alcohol consumption, but usually is between 10 and 28 days. For young children (around 10 years old), the recovery takes three weeks.

The possibility of peritonitis is the reason why acute appendicitis warrants speedy evaluation and treatment. People with suspected appendicitis may have to undergo a medical evacuation. Appendectomies have occasionally been performed in emergency conditions (i.e., not in a proper hospital), when a timely medical evacuation was impossible.

Typical acute appendicitis responds quickly to appendectomy and occasionally will resolve spontaneously. If appendicitis resolves spontaneously, it remains controversial whether an elective interval appendectomy should be performed to prevent a recurrent episode of appendicitis. Atypical appendicitis (associated with suppurative appendicitis) is more difficult to diagnose and is more apt to be complicated even when operated early. In either condition, prompt diagnosis and appendectomy yield the best results with full recovery in two to four weeks usually. Mortality and severe complications are unusual but do occur, especially if peritonitis persists and is untreated.

Another entity known as appendicular lump is talked about. It happens when the appendix is not removed early during infection and omentum and intestine adhere to it, forming a palpable lump. During this period, surgery is risky unless there is pus formation evident by fever and toxicity or by USG. Medical management treats the condition.

An unusual complication of an appendectomy is "stump appendicitis": inflammation occurs in the remnant appendiceal stump left after a prior incomplete appendectomy.[73] Stump appendicitis can occur months to years after initial appendectomy and can be identified with imaging modalities like ultrasound.[74]

## Epidemiology [edit]

Appendicitis is most common between the ages of 5 and 40;[76] the median age is 28. It tends to affect males, those in lower income groups and, for unknown reasons, people living in rural areas.[77] In 2013 it resulted in 72,000 deaths globally down from 88,000 in 1990.[13]

In the United States, there were nearly 293,000 hospitalizations involving appendicitis in 2010.[8] Appendicitis is one of the most frequent diagnoses for emergency department visits resulting in hospitalization among children ages 5–17 years in the United States.[78]

# Bowel obstruction

From Wikipedia, the free encyclopedia

**Bowel obstruction**, also known as **intestinal obstruction**, is a mechanical or functional obstruction of the intestines which prevents the normal movement of the products of digestion.[1][2] Either the small bowel or large bowel may be affected.[3] Symptoms include abdominal pain, vomiting, bloating, and not passing gas.[3] Mechanical obstruction is the cause of about 5 to 15% of cases of severe abdominal pain of sudden onset requiring admission to hospital.[3][1]

Causes of bowel obstruction include adhesions, hernias, volvulus, endometriosis, inflammatory bowel disease, appendicitis, tumors, diverticulitis, ischemic bowel, tuberculosis, and intussusception.[3][1] Small bowel obstructions are most often due to adhesions and hernias while large bowel obstructions are most often due to tumors and volvulus.[3][1] The diagnosis may be made on plain X-rays, however, CT scan is more accurate.[3] Ultrasound or MRI may help in the diagnosis of children or pregnant women.[3]

The condition may be treated conservatively or with surgery.[1] Typically intravenous fluids are given, a tube is placed through the nose into the stomach to decompress the intestines, and pain medications are given.[1] Antibiotics are often given.[1] In small bowel obstruction about 25% require surgery.[4] Complications may include sepsis, bowel ischemia, and bowel perforation.[3]

About 2.5 million cases of or bowel obstruction occurred in 2013 which resulted in 236,000 deaths.[5][6] Both sexes are equally affected and the condition can occur at any age.[4] Bowel obstruction has been documented throughout history with cases detailed in the Ebers Papyrus of 1550 BC and by Hippocrates.[7]

## Signs and symptoms [edit]

Depending on the level of obstruction, bowel obstruction can present with abdominal pain, swollen abdomen, abdominal distension, vomiting, fecal vomiting, and constipation.[8]

Bowel obstruction may be complicated by dehydration and electrolyte abnormalities due to vomiting; respiratory compromise from pressure on the diaphragm by a distended abdomen, or aspiration of vomitus; bowel ischaemia or perforation from prolonged distension or pressure from a foreign body.

*Problems playing this file? See media help.*

In small bowel obstruction the pain tends to be colicky (cramping and intermittent) in nature, with spasms lasting a few minutes. The pain tends to be central and mid-abdominal. Vomiting may occur before constipation[*citation needed*].

In large bowel obstruction, the pain is felt lower in the abdomen and the spasms last longer. Constipation occurs earlier and vomiting may be less prominent. Proximal obstruction of the large bowel may present as small bowel obstruction.[*citation needed*]

## Causes [edit]

### Small bowel obstruction [edit]

Causes of small bowel obstruction include:[1]

- Adhesions from previous abdominal surgery (most common cause)
- Barbed sutures.[9]
- Pseudoobstruction
- Hernias containing bowel
- Crohn's disease causing adhesions or inflammatory strictures
- Neoplasms, benign or malignant
- Intussusception in children
- Volvulus
- Superior mesenteric artery syndrome, a compression of the duodenum by the superior mesenteric artery and the abdominal aorta
- Ischemic strictures
- Foreign bodies (e.g. gallstones in gallstone ileus, swallowed objects)
- Intestinal atresia

Upright abdominal X-ray demonstrating a small bowel obstruction. Note multiple air fluid levels.

### Large bowel obstruction [edit]

Causes of large bowel obstruction include:

- Neoplasms
- Diverticulitis / Diverticulosis
- Hernias
- Inflammatory bowel disease
- Colonic volvulus (sigmoid, caecal, transverse colon)

- Adhesions
- Constipation
- Fecal impaction
- Fecaloma
- Colon atresia
- Intestinal pseudoobstruction
- Endometriosis
- Narcotic induced (especially with the large doses given to cancer or palliative care patients)

### Outlet obstruction [edit]

Outlet obstruction is a sub-type of large bowel obstruction and refers to conditions affecting the anorectal region that obstruct defecation, specifically conditions of the pelvic floor and anal sphincters. Outlet obstruction can be classified into 4 groups.[10]

- Functional outlet obstruction
  - Inefficient inhibition of the internal anal sphincter
    - Short-segment Hirschsprung's disease
    - Chagas disease
    - Hereditary internal sphincter myopathy
  - Inefficient relaxation of the striated pelvic floor muscles
    - Anismus (pelvic floor dyssynergia)
    - Multiple sclerosis
    - Spinal cord lesions
- Mechanical outlet obstruction
  - Internal intussusception
  - Enterocele
- Dissipation of force vector
  - rectocele
  - Descending perineum
  - Rectal prolapse
- Impaired rectal sensitivity
  - Megarectum
  - Rectal hyposensitivity

### Differential diagnosis [edit]

Differential diagnoses of bowel obstruction include:

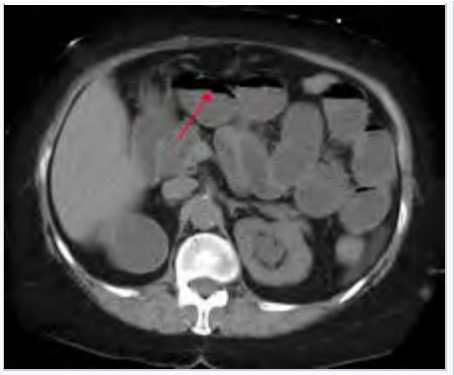
- Ileus
- Pseudo-obstruction or Ogilvie's syndrome
- Intra-abdominal sepsis
- Pneumonia or other systemic illness[*citation needed*].

## Diagnosis [edit]

Upright abdominal X-ray of a patient with a large bowel obstruction showing multiple air fluid levels and dilated loops of bowel.

The main diagnostic tools are blood tests, X-rays of the abdomen, CT scanning, and/or ultrasound. If a mass is identified, biopsy may determine the nature of the mass.

Radiological signs of bowel obstruction include bowel distension and the presence of multiple (more than six) gas-fluid levels on supine and erect



A small bowel obstruction as seen on CT

abdominal radiographs.[*medical citation needed*]

Contrast enema or small bowel series or CT scan can be used to define the level of obstruction, whether the obstruction is partial or complete, and to help define the cause of the obstruction.

According to a meta-analysis of prospective studies by the Cochrane Collaboration, the appearance of water-soluble contrast in the cecum on an abdominal radiograph within 24 hours of oral administration predicts resolution of an adhesive small bowel obstruction with a pooled sensitivity of 96% and specificity of 96%.[11][*needs update*]Colonoscopy, small bowel investigation with ingested camera or push endoscopy, and laparoscopy are other diagnostic options.

# Treatment [edit]

Some causes of bowel obstruction may resolve spontaneously;[12] many require operative treatment.[13] In adults, frequently the surgical intervention and the treatment of the causative lesion are required. In malignant large bowel obstruction, endoscopically placed self-expanding metal stents may be used to temporarily relieve the obstruction as a bridge to surgery,[14] or as palliation.[15] Diagnosis of the type of bowel obstruction is normally conducted through initial plain radiograph of the abdomen, luminal contrast studies, computed tomography scan, or ultrasonography prior to determining the best type of treatment.[16]

## Small bowel obstruction [edit]

In the management of small bowel obstructions, a commonly quoted surgical aphorism is: "never let the sun rise or set on small-bowel obstruction"[17] because about 5.5%[17] of small bowel obstructions are ultimately fatal if treatment is delayed. However improvements in radiological imaging of small bowel obstructions allow for confident distinction between simple obstructions, that can be treated conservatively, and obstructions that are surgical emergencies (volvulus, closed-loop obstructions, ischemic bowel, incarcerated hernias, etc.).[1]

A small flexible tube (nasogastric tube) may be inserted from the nose into the stomach to help decompress the dilated bowel. This tube is uncomfortable but does relieve the abdominal cramps, distension and vomiting. Intravenous therapy is utilized and the urine output is monitored with a catheter in the bladder.[18]

Most people with SBO are initially managed conservatively because in many cases, the bowel will open up. Some adhesions loosen up and the obstruction resolves. However, when conservative management is undertaken, the patient is examined several times a day, and X-ray images are obtained to ensure that the individual is not getting clinically worse.[19]

Conservative treatment involves insertion of a nasogastric tube, correction of dehydration and electrolyte abnormalities. Opioid pain relievers may be used for patients with severe pain. Antiemetics may be administered if the patient is vomiting. Adhesive obstructions often settle without surgery. If obstruction is complete a surgery is usually required.

Most patients do improve with conservative care in 2–5 days. However, in some occasions, the cause of obstruction may be a cancer and in such cases, surgery is the only treatment. These individuals undergo surgery where the cause of SBO is removed. Individuals who have bowel resection or lysis of adhesions usually stay in the hospital a few more days until they are able to eat and walk.[20]

Small bowel obstruction caused by Crohn's disease, peritoneal carcinomatosis, sclerosing peritonitis,

radiation enteritis, and postpartum bowel obstruction are typically treated conservatively, i.e. without surgery.

### Children [edit]

*Main article: Neonatal bowel obstruction*

Fetal and neonatal bowel obstructions are often caused by an intestinal atresia, where there is a narrowing or absence of a part of the intestine. These atresias are often discovered before birth via a sonogram, and treated with using laparotomy after birth. If the area affected is small, then the surgeon may be able to remove the damaged portion and join the intestine back together. In instances where the narrowing is longer, or the area is damaged and cannot be used for a period of time, a temporary stoma may be placed.

## Prognosis [edit]

The prognosis for non-ischemic cases of SBO is good with mortality rates of 3-5%, while prognosis for SBO with ischemia is fair with mortality rates as high as 30%.[21]

Cases of SBO related to cancer are more complicated and require additional intervention to address the malignancy, recurrence, and metastasis, and thus are associated with poorer prognosis.[*citation needed*]

All cases of abdominal surgical intervention are associated with increased risk of future small-bowel obstructions. Statistics from U.S. healthcare report 18.1% re-admittance rate within 30 days for patients who undergo SBO surgery.[22] More than 90% of patients also form adhesions after major abdominal surgery.[23] Common consequences of these adhesions include small-bowel obstruction, chronic abdominal pain, pelvic pain, and infertility.[23]

# Coeliac disease

From Wikipedia, the free encyclopedia
(Redirected from Celiac disease)

## Variants

**Coeliac disease**, also spelled **celiac disease**, is an autoimmune disorder affecting primarily the small intestine that occurs in people who are genetically predisposed.[1] Classic symptoms include gastrointestinal problems such as chronic diarrhoea, abdominal distention, malabsorption, loss of appetite, and among children failure to grow normally. This often begins between six months and two years of age.[2] Non-classic symptoms are the most common, especially in people older than two years.[3][4][5] There may be mild or absent gastrointestinal symptoms, a wide number of symptoms involving any part of the body, or no obvious symptoms.[2] Coeliac disease was first described in childhood;[3][6] however, it may develop at any age.[2][3] It is associated with other autoimmune diseases, such as diabetes mellitus type 1 and thyroiditis, among others.[6]

Coeliac disease is caused by a reaction to gluten, which are various proteins found in wheat and in other grains such as barley, and rye.[7][8][9] Moderate quantities of oats, free of contamination with other gluten-containing grains, are usually tolerated[8] but problems may depend on the type consumed.[8][10] Upon exposure to gluten, an abnormal immune response may lead to the production of several different autoantibodies that can affect a number of different organs.[11][12] In the small-bowel this causes an inflammatory reaction and may produce shortening of the villi lining the small intestine (villous atrophy).[1][13] This affects the absorption of nutrients, frequently leading to anaemia.[1][9]

Diagnosis is typically made by a combination of blood antibody tests and intestinal biopsies, helped by specific genetic testing.[1] Making the diagnosis is not always straightforward.[14] Frequently, the autoantibodies in the blood are negative[15][16] and many people have only minor intestinal changes with normal villi.[4][17] People may have severe symptoms and be investigated for years before a diagnosis is achieved.[18] Increasingly, the diagnosis is being made in people without symptoms as a result of screening.[19] While the disease is caused by a permanent intolerance to wheat proteins, it not a form of wheat allergy.[1]

The only known effective treatment is a strict lifelong gluten-free diet, which leads to recovery of the intestinal mucosa, improves symptoms, and reduces risk of developing complications in most people.[20] If untreated it may result in cancers such as intestinal lymphoma and a slight increased risk of early death.[21] Rates vary between different regions of the world, from as few as 1 in 300 to as many as 1 in 40, with an average of between 1 in 100 and 1 in 170 people.[22] In developed countries, it is estimated that five out of six cases (83%) remain undiagnosed, usually because of non-classic,

minimal, or absent complaints. Coeliac disease is slightly more common in women than in men. The term "coeliac" is from the Greek κοιλιακός (*koiliakós*, "abdominal") and was introduced in the 19th century in a translation of what is generally regarded as an ancient Greek description of the disease by Aretaeus of Cappadocia.[25][26]

## Signs and symptoms [edit]

The classic symptoms of coeliac disease include pale, loose, and greasy stool (steatorrhoea) and weight loss or failure to gain weight. More commonly symptoms are subtle or primarily occur in organs other than the bowel itself.[27] It is also possible to have coeliac disease without any symptoms whatsoever.[9] This represents at least in 43% of the cases in children.[28] Many adults with subtle disease only have fatigue or anaemia.[19]

### Gastrointestinal [edit]

The diarrhoea that is characteristic of coeliac disease is (chronic) pale, of large volume, and abnormally bad smelling. Abdominal pain and cramping, bloatedness with abdominal distension (thought to be due to fermentative production of bowel gas), and mouth ulcers[29] may be present. As the bowel becomes more damaged, a degree of lactose intolerance may develop.[9] Frequently, the symptoms are ascribed to irritable bowel syndrome (IBS), only later to be recognised as coeliac disease; a small proportion of people with symptoms of IBS have underlying coeliac disease, and screening for coeliac disease is recommended for those with IBS symptoms.[30]

Coeliac disease leads to an increased risk of both adenocarcinoma and lymphoma of the small bowel (enteropathy-associated T-cell lymphoma (EATL) or other non-Hodgkin's lymphomas).[31] This risk is also higher in first-degree relatives such as siblings, parents, and children. Whether or not a gluten-free diet brings this risk back to baseline is not clear.[32] Long-standing and untreated disease may lead to other complications, such as ulcerative jejunitis (ulcer formation of the small bowel) and stricturing (narrowing as a result of scarring with obstruction of the bowel).[33]

### Malabsorption-related [edit]

The changes in the bowel make it less able to absorb nutrients, minerals, and the fat-soluble vitamins A, D, E, and K.[9][34]

- The inability to absorb carbohydrates and fats may cause weight loss (or failure to thrive/stunted growth in children) and fatigue or lack of energy.
- Anaemia may develop in several ways: iron malabsorption may cause iron deficiency anaemia, and folic acid and vitamin $B_{12}$ malabsorption may give rise to megaloblastic anaemia.
- Calcium and vitamin D malabsorption (and compensatory secondary hyperparathyroidism) may cause osteopenia (decreased mineral content of the bone) or osteoporosis (bone weakening and risk of fragility fractures).
- Selenium malabsorption in coeliac disease, combined with low selenium content in many gluten-free foods, confers a risk of selenium deficiency,[35]
- Copper and zinc deficiencies have also been associated with coeliac disease.[35]
- A small proportion have abnormal coagulation due to vitamin K deficiency and are slightly at risk for abnormal bleeding.

### Miscellaneous [edit]

Coeliac disease has been linked with a number of conditions. In many cases, it is unclear whether the gluten-induced bowel disease is a causative factor or whether these conditions share a common predisposition.

- IgA deficiency is present in 2.3% of people with coeliac disease, and in turn this condition features a tenfold increased risk of coeliac disease. Other features of this condition are an increased risk of infections and autoimmune disease.[36]
- Dermatitis herpetiformis, an itchy cutaneous condition, has been linked to a transglutaminase enzyme in the skin, features small-bowel changes identical to those in coeliac disease, and may respond to gluten withdrawal even if no gastrointestinal symptoms are present.[37][38]
- Growth failure and/or pubertal delay in later childhood can occur even without obvious bowel symptoms or severe malnutrition. Evaluation of growth failure often includes coeliac screening.[9]
- Pregnancy complications can occur in case of coeliac disease as an intercurrent disease in pregnancy, with significant complications including miscarriage, intrauterine growth restriction, low birthweight and preterm birth.[39]
- Hyposplenism (a small and underactive spleen)[40] occurs in about a third of cases and may predispose to infection given the role of the spleen in protecting against bacteria.[9]
- Abnormal liver function tests (randomly detected on blood tests) may be seen.[9]

Coeliac disease is associated with a number of other medical conditions, many of which are autoimmune disorders: diabetes mellitus type 1, hypothyroidism, primary biliary cirrhosis, microscopic colitis, gluten ataxia, psoriasis, vitiligo, autoimmune hepatitis, dermatitis herpetiformis, primary sclerosing cholangitis, and more.[11]

A more controversial area is a group of diseases in which antigliadin antibodies (an older and nonspecific test for coeliac disease) are sometimes detected but no small bowel disease can be demonstrated. Sometimes these conditions improve by removing gluten from the diet. This includes cerebellar ataxia, peripheral neuropathy, schizophrenia, and autism.[41]

## Cause [edit]

Coeliac disease is caused by a reaction to gliadin, a prolamin (gluten protein) found in wheat, and similar proteins found in the crops of the tribe Triticeae (which includes other common grains such as barley and rye).[9]

### Other grains [edit]

Wheat subspecies (such as spelt, durum and Kamut) and related species (such as barley, rye and triticale) also induce symptoms of coeliac disease.[42]

A small number of people with coeliac also react to oats.[9] Oats toxicity in coeliac people depends on the oat cultivar consumed because of prolamin genes, protein amino acid sequences, and the immunoreactivities of toxic prolamins which are different among oat varieties.[10][43] Also, oat products are frequently cross-contaminated with gluten-containing cereals.[10][43][44] Pure oat refers to oats uncontaminated with gluten.[10] The long-term effects of pure oats consumption are still unclear[45] and further studies identifying the cultivars used are needed before making final recommendations on their inclusion in the gluten-free diet.[44] Celiac people who choose to consume oats need a more rigorous lifelong follow-up, possibly including periodic performance of intestinal

biopsies.[45]

Other cereals such as corn, millet, sorghum, teff, rice, and wild rice are safe for people with coeliac to consume, as well as noncereals such as amaranth, quinoa, and buckwheat.[42][46] Noncereal carbohydrate-rich foods such as potatoes and bananas do not contain gluten and do not trigger symptoms.[42]

### Risk modifiers [edit]

There are various theories as to what determines whether a genetically susceptible individual will go on to develop coeliac disease. Major theories include infection by rotavirus[47] or human intestinal adenovirus.[48] Some research has suggested that smoking is protective against adult-onset coeliac disease.[49]

The eating of gluten early in a baby's life does not appear to increase the risk of CD but later introduction after 6 months may increase it.[50][51] There is uncertainty whether breastfeeding reduces risk. Prolonging breastfeeding until the introduction of gluten-containing grains into the diet appears to be associated with a 50% reduced risk of developing coeliac disease in infancy; whether this persists into adulthood is not clear.[52] These factors may just influence the timing of onset.[53] Factors that can trigger symptoms include: surgery, pregnancy, infection and emotional stress.[54]

## Pathophysiology [edit]

Coeliac disease appears to be multifactorial, both in that more than one genetic factor can cause the disease and in that more than one factor is necessary for the disease to manifest in a person.

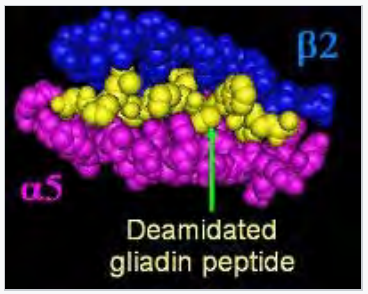
Video explaining celiac disease

Almost all people (95%) with coeliac disease have either the variant HLA-DQ2 allele or (less commonly) the HLA-DQ8 allele.[19][55] However, about 20–30% of people without coeliac disease have also inherited either of these alleles.[56] This suggests additional factors are needed for coeliac disease to develop; that is, the predisposing HLA risk allele is necessary but not sufficient to develop coeliac disease. Furthermore, around 5% of those people who do develop coeliac disease do not have typical HLA-DQ2 or HLA-DQ8 alleles (see below).[19]

### Genetics [edit]



DQ $\alpha^5$-$\beta^2$ -binding cleft with a deamidated gliadin peptide (yellow), modified from PDB: 1S9V [57]

The vast majority of people with coeliac have one of two types of the HLA-DQ protein.[56] HLA-DQ is part of the MHC class II antigen-presenting receptor (also called the human leukocyte antigen) system and distinguishes cells between self and non-self for the purposes of the immune system. The two subunits of the HLA-DQ protein are encoded by the HLA-DQA1 and HLA-DQB1 genes, located on the short arm of the sixth chromosome.

There are seven HLA-DQ variants (DQ2 and DQ4–DQ9). Over 95% of people with coeliac have the isoform of DQ2 or DQ8, which is inherited in families. The reason these genes produce an increase in risk of coeliac disease is that the receptors formed by these genes bind to gliadin peptides more tightly than other forms of the antigen-presenting receptor. Therefore, these forms of the receptor are more likely to activate T lymphocytes and initiate the autoimmune process.[19]

Most people with coeliac bear a two-gene HLA-DQ2 haplotype referred to as DQ2.5 haplotype. This haplotype is composed of two adjacent gene alleles, DQA1*0501 and DQB1*0201, which encode the two subunits, DQ $\alpha^5$ and DQ $\beta^2$. In most individuals, this DQ2.5 isoform is encoded by one of two chromosomes 6 inherited from parents (DQ2.5cis). Most coeliacs inherit only one copy of this DQ2.5 haplotype, while some inherit it from *both* parents; the latter are especially at risk for coeliac disease as well as being more susceptible to severe complications.[58]

Some individuals inherit DQ2.5 from one parent and an additional portion of the haplotype (either DQB1*02 or DQA1*05) from the other parent, increasing risk. Less commonly, some individuals inherit the DQA1*05 allele from one parent and the DQB1*02 from the other parent (DQ2.5trans) (called a trans-haplotype association), and these individuals are at similar risk for coeliac disease as those with a single DQ2.5-bearing chromosome 6, but in this instance disease tends not to be familial. Among the 6% of European coeliacs that do not have DQ2.5 (cis or

trans) or DQ8 (encoded by the haplotype DQA1*03:DQB1*0302), 4% have the DQ2.2 isoform, and the remaining 2% lack DQ2 or DQ8.[59]

The frequency of these genes varies geographically. DQ2.5 has high frequency in peoples of North and Western Europe (Basque Country and Ireland[60] with highest frequencies) and portions of Africa and is associated with disease in India,[61] but it is not found along portions of the West Pacific rim. DQ8 has a wider global distribution than DQ2.5 and is particularly common in South and Central America; up to 90% of individuals in certain Amerindian populations carry DQ8 and thus may display the coeliac phenotype.[62]

Other genetic factors have been repeatedly reported in coeliac disease; however, involvement in disease has variable geographic recognition. Only the HLA-DQ loci show a consistent involvement over the global population.[63] Many of the loci detected have been found in association with other autoimmune diseases. One locus, the LPP or lipoma-preferred partner gene, is involved in the adhesion of extracellular matrix to the cell surface, and a minor variant (SNP = rs1464510) increases the risk of disease by approximately 30%. This gene strongly associates with coeliac disease ($p < 10^{-39}$) in samples taken from a broad area of Europe and the US.[63]

The prevalence of coeliac disease genotypes in the modern population is not completely understood. Given the characteristics of the disease and its apparent strong heritability, it would normally be expected that the genotypes would undergo negative selection and to be absent in societies where agriculture has been practised the longest (compare with a similar condition, Lactose intolerance, which has been negatively selected so strongly that its prevalence went from ~100% in ancestral populations to less than 5% in some European countries). This expectation was first proposed by Simoons (1981).[64] By now, however, it is apparent that this is not the case; on the contrary, there is evidence of *positive* selection in coeliac disease genotypes. It is suspected that some of them may have been beneficial by providing protection against bacterial infections.[65][66]

## Prolamins [edit]

The majority of the proteins in food responsible for the immune reaction in coeliac disease are the prolamins. These are storage proteins rich in proline (*prol-*) and glutamine (*-amin*) that dissolve in alcohols and are resistant to proteases and peptidases of the gut.[19][67] Prolamins are found in cereal grains with different grains having different but related prolamins: wheat (gliadin), barley (hordein), rye (secalin), corn (zein) and as a minor protein, avenin in oats. One region of α-gliadin stimulates membrane cells, enterocytes, of the intestine to allow larger molecules around the sealant between cells. Disruption of tight junctions allow peptides larger than three amino acids to enter the intestinal lining[68]

Membrane leaking permits peptides of gliadin that stimulate two levels of immune response, the innate response and the adaptive (T-helper cell mediated) response. One protease-resistant peptide from α-gliadin contains a region that stimulates lymphocytes and results in the release of interleukin-15. This innate response to gliadin results in immune-system signalling that attracts inflammatory cells and increases the release of inflammatory chemicals.[19] The strongest and most common adaptive response to gliadin is directed toward an α2-gliadin fragment of 33 amino acids in length.[19]

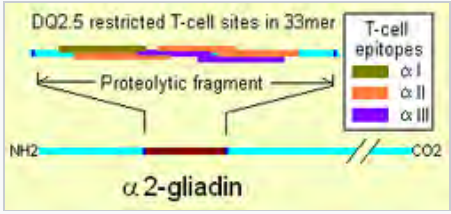


Illustration of deamidated α-2 gliadin's 33mer, amino acids 56–88, showing the overlapping of three varieties of T-cell epitope[69]

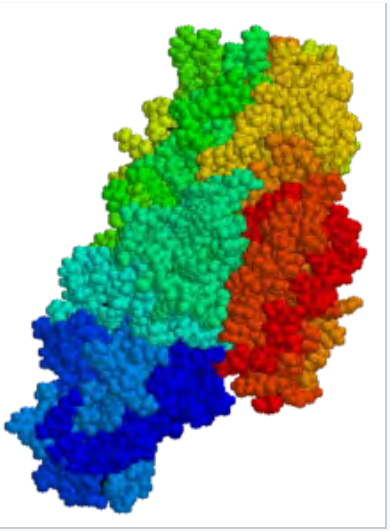
The response to the 33mer occurs in most coeliacs who have a DQ2 isoform. This peptide, when altered by intestinal transglutaminase, has a high density of overlapping T-cell epitopes. This increases the likelihood that the DQ2 isoform will bind and stay bound to peptide when recognised by T-cells.[69] Gliadin in wheat is the best-understood member of this family, but other prolamins exist, and hordein (from barley) and secalin (from rye) may contribute to coeliac disease.[19][70] However, not all prolamins will cause this immune reaction, and there is ongoing controversy on the ability of avenin (the prolamin found in oats) to induce this response in coeliac disease.

## Tissue transglutaminase [edit]

Anti-transglutaminase antibodies to the enzyme tissue transglutaminase (tTG) are found in the blood of the majority of people with classic symptoms and complete villous atrophy, but only in 70% of the cases with partial villous atrophy and 30% of the cases with minor mucosal lesions.[15] Tissue transglutaminase modifies gluten peptides into a form that may stimulate the immune system more effectively.[19] These peptides are modified by tTG in two ways, deamidation or transamidation.[71]



Tissue transglutaminase, drawn from PDB: 1FAU

Deamidation is the reaction by which a glutamate residue is formed by cleavage of the epsilon-amino group of a glutamine side chain. Transamidation, which occurs three times more often than deamidation, is the cross-linking of a glutamine residue from the gliadin peptide to a lysine residue of tTg in a reaction which is catalysed by the transglutaminase. Crosslinking may occur either within or outside the active site of the enzyme. The latter case yields a permanently covalently linked complex between the gliadin and the tTg.[72] This results in the formation of new epitopes which are believed to trigger the primary immune response by which the autoantibodies against tTg develop.[73][74][75]

Stored biopsies from people with suspected coeliac disease have revealed that autoantibody deposits in the subclinical coeliacs are detected prior to clinical disease. These deposits are also found in people who present with other autoimmune diseases, anaemia, or malabsorption phenomena at a much increased rate over the normal population.[76] Endomysial components of antibodies (EMA) to tTG are believed to be directed toward cell-surface transglutaminase, and these antibodies are still used in confirming a coeliac disease diagnosis. However, a 2006 study showed that EMA-negative people with coeliac tend to be older males with more severe abdominal symptoms and a lower frequency of "atypical" symptoms, including autoimmune disease.[77] In this study, the anti-tTG antibody deposits did not correlate with the severity of villous destruction. These findings, coupled with recent work showing that gliadin has an innate response component,[78] suggest that gliadin may be more responsible for the primary manifestations of coeliac disease, whereas tTG is a bigger factor in secondary effects such as allergic responses and secondary autoimmune diseases. In a large percentage of people with coeliac, the anti-tTG antibodies also recognise a rotavirus protein called VP7. These antibodies stimulate monocyte proliferation, and rotavirus infection might explain some early steps in the cascade of immune cell proliferation.[79]

Indeed, earlier studies of rotavirus damage in the gut showed this causes a villous atrophy.[80] This suggests that viral proteins may take part in the initial flattening and stimulate self-crossreactive anti-VP7 production. Antibodies to VP7 may also slow healing until the gliadin-mediated tTG presentation provides a second source of crossreactive antibodies.

Other intestinal disorders may have biopsy that look like coeliac disease including lesions caused by Candida.[81]

### Villous atrophy and malabsorption [edit]

The inflammatory process, mediated by T cells, leads to disruption of the structure and function of the small bowel's mucosal lining and causes malabsorption as it impairs the body's ability to absorb nutrients, minerals, and fat-soluble vitamins A, D, E, and K from food. Lactose intolerance may be present due to the decreased bowel surface and reduced production of lactase but typically resolves once the condition is treated.

Alternative causes of this tissue damage have been proposed and involve release of interleukin 15 and activation of the innate immune system by a shorter gluten peptide (p31–43/49). This would trigger killing of enterocytes by lymphocytes in the epithelium.[19] The villous atrophy seen on biopsy may also be due to unrelated causes, such as tropical sprue, giardiasis and radiation enteritis. While positive serology and typical biopsy are highly suggestive of coeliac disease, lack of response to diet may require these alternative diagnoses to be considered.[33]

## Diagnosis [edit]

Diagnosis is often very difficult so that most cases are diagnosed with great delay.[14] There are several tests that can be used. The level of symptoms may determine the order of the tests, but *all* tests lose their usefulness if the person is already eating a gluten-free diet. Intestinal damage begins to heal within weeks of gluten being removed from the diet, and antibody levels decline over months. For those who have already started on a gluten-free diet, it may be necessary to perform a rechallenge with some gluten-containing food in one meal a day over 6 weeks before repeating the investigations.[12]

## Blood tests [edit]

Serological blood tests are the first-line investigation required to make a diagnosis of coeliac disease. Its sensitivity correlates with the degree of histological lesions. People who present minor damage of the small intestine may have seronegative findings so many patients with coeliac disease often are missed. In patients with villous atrophy, anti-endomysial (EMA) antibodies of the immunoglobulin A (IgA) type can detect coeliac disease with a sensitivity and specificity of 90% and 99%, respectively.[82] Serology for anti-transglutaminase antibodies (anti-tTG) was initially reported to have a higher sensitivity (99%) and specificity (>90%). However, it is now thought to have similar characteristics to anti-endomysial antibody.[82] Both anti-transglutaminase and anti-endomysial antibodies have high sensitivity to diagnose people with classic symptoms and complete villous atrophy, but they are only found in 30-89% of the cases with partial villous atrophy and in less than 50% of the people who have minor mucosal lesions (duodenal lymphocytosis) with normal villi.[15][16]

Tissue transglutaminase modifies gluten peptides into a form that may stimulate the immune system more effectively.[19] These peptides are modified by tTG in two ways, deamidation or transamidation.[71] Modern anti-tTG assays rely on a human recombinant protein as an antigen.[83] tTG testing should be done first as it is an easier test to perform. An equivocal result on tTG testing should be followed by anti-endomysial antibodies.[12]

Guidelines recommend that a total serum IgA level is checked in parallel, as people with coeliac with IgA deficiency may be unable to produce the antibodies on which these tests depend ("false negative"). In those people, IgG antibodies against transglutaminase (IgG-tTG) may be diagnostic.[12][84]

If all these antibodies are negative, then it should be determined anti-DGP antibodies (antibodies against deamidated gliadin peptides). IgG class anti-DGP antibodies may be useful in people with IgA deficiency. In children younger than two years, anti-DGP antibodies perform better than anti-endomysial and anti-transglutaminase antibodies tests.[3]

Because of the major implications of a diagnosis of coeliac disease, professional guidelines recommend that a positive blood test is still followed by an endoscopy/gastroscopy and biopsy. A negative serology test may still be followed by a recommendation for endoscopy and duodenal biopsy if clinical suspicion remains high.[12][33][85]

Historically three other antibodies were measured: anti-reticulin (ARA), anti-gliadin (AGA) and anti-endomysial (EMA) antibodies.[86] ARA testing, however, is not accurate enough for routine diagnostic use.[87] Serology may be unreliable in young children, with anti-gliadin performing somewhat better than other tests in children under five.[86] Serology tests are based on indirect immunofluorescence (reticulin, gliadin and endomysium) or ELISA (gliadin or tissue transglutaminase, tTG).[88]

Antibody testing may be combined with HLA testing if the diagnosis is unclear. TGA and EMA testing are the most sensitive serum antibody tests, but as a negative HLA-DQ type excludes the diagnosis of coeliac disease, testing also for HLA-DQ2 or DQ8 maximises sensitivity and negative predictive values.[56] However, widespread use of HLA typing to rule out coeliac disease is not currently recommended.[12]

## Endoscopy [edit]

An upper endoscopy with biopsy of the duodenum (beyond the duodenal bulb) or jejunum is performed to obtain multiple samples (four to eight) from the duodenum. Not all areas may be equally affected; if biopsies are taken from healthy bowel tissue, the result would be a false negative.[33] Even in the same bioptic fragment, different degrees of damage may be present.[5]

Most people with coeliac disease have a small intestine that appears to be normal on endoscopy before the biopsies are examined. However, five findings have been associated with a high specificity for coeliac disease: scalloping of the small bowel folds (*pictured*), paucity in the folds, a mosaic pattern to the mucosa (described as a "cracked-mud" appearance), prominence of the submucosa blood vessels, and a nodular pattern to the mucosa.[89]

Endoscopic still of duodenum of person with coeliac disease showing scalloping of folds and

European guidelines suggest that in children and adolescents with symptoms which are compatible with coeliac disease, the diagnosis can be made without

the need for intestinal biopsy if anti-tTG antibodies titres are very high (10 times the upper limit of normal).[3]

Until the 1970s, biopsies were obtained using metal capsules attached to a suction device. The capsule was swallowed and allowed to pass into the small intestine. After x-ray verification of its position, suction was applied to collect part of the intestinal wall inside the capsule. Often-utilised capsule systems were the Watson capsule and the Crosby–Kugler capsule. This method has now been largely replaced by fibre-optic endoscopy, which carries a higher sensitivity and a lower frequency of errors.[90]

Capsule endoscopy (CE) allows identification of typical mucosal changes observed in coeliac disease but has a lower sensitivity compared to regular endoscopy and histology. CE is therefore not the primary diagnostic tool for coeliac disease. However, CE can be used for diagnosing T-cell lymphoma, ulcerative jejunoileitis and adenocarcinoma in refractory or complicated coeliac disease.[91]

## Pathology [edit]

The classic pathology changes of coeliac disease in the small bowel are categorised by the "Marsh classification":[92]

- Marsh stage 0: normal mucosa
- Marsh stage 1: increased number of intra-epithelial lymphocytes (IELs), usually exceeding 20 per 100 enterocytes
- Marsh stage 2: proliferation of the crypts of Lieberkühn
- Marsh stage 3: partial or complete villous atrophy and crypt hypertrophy[93]
- Marsh stage 4: hypoplasia of the small intestine architecture

Marsh's classification, introduced in 1992, was subsequently modified in 1999 to six stages, where the previous stage 3 was split in three substages.[94] Further studies demonstrated that this system was not always reliable and that the changes observed in coeliac disease could be described in one of three stages:[9][95]

- A representing lymphocytic infiltration with normal villous appearance;
- B1 describing partial villous atrophy; and
- B2 describing complete villous atrophy.

The changes classically improve or reverse after gluten is removed from the diet. However, most guidelines do not recommend a repeat biopsy unless there is no improvement in the symptoms on diet.[33][85] In some cases, a deliberate gluten challenge, followed by biopsy, may be conducted to confirm or refute the diagnosis. A normal biopsy and normal serology after challenge indicates the diagnosis may have been incorrect.[33]

In untreated coeliac disease, villous atrophy is more common in children younger than three years, but in older children and adults, it is common to find minor intestinal lesions (duodenal lymphocytosis) with normal intestinal villi.[4][13][17]

## Other diagnostic tests [edit]

At the time of diagnosis, further investigations may be performed to identify complications, such as iron deficiency (by full blood count and iron studies), folic acid and vitamin $B_{12}$ deficiency and hypocalcaemia (low calcium levels, often due to decreased vitamin D levels). Thyroid function tests may be requested during blood tests to identify hypothyroidism, which is more common in people with coeliac disease.[34]

Osteopenia and osteoporosis, mildly and severely reduced bone mineral density, are often present in people with coeliac disease, and investigations to measure bone density may be performed at diagnosis, such as dual-energy X-ray absorptiometry (DXA) scanning, to identify risk of fracture and need for bone protection medication.[33][34]

## Gluten withdrawal [edit]

Although blood antibody tests, biopsies, and genetic tests usually provide a clear diagnosis,[16][82] occasionally the response to gluten withdrawal on a gluten-free diet is needed to support the diagnosis. Currently, gluten challenge is no longer required to confirm the diagnosis in patients with intestinal lesions compatible with coeliac disease and a positive response to a gluten-free diet.[16] Nevertheless, in some cases, a gluten challenge with a subsequent biopsy may be useful to support the diagnosis, for example in people with a high suspicion for coeliac disease, [16]

without a biopsy confirmation, who have negative blood antibodies and are already on a gluten-free diet. Gluten challenge is discouraged before the age of 5 years and during pubertal growth.[96] The alternative diagnosis of non-coeliac gluten sensitivity may be made where there is only symptomatic evidence of gluten sensitivity.[97] Gastrointestinal and extraintestinal symptoms of people with non-coeliac gluten sensitivity can be similar to those of coeliac disease,[5] and improve when gluten is removed from the diet,[98][99] after coeliac disease and wheat allergy are reasonably excluded.[100]

Up to 30% of people often continue having or redeveloping symptoms after starting a gluten-free diet.[20] A careful interpretation of the symptomatic response is needed, as a lack of response in a person with coeliac disease may be due to continued ingestion of small amounts of gluten, either voluntary or inadvertent,[13] or be due to other commonly associated conditions such as small intestinal bacterial overgrowth (SIBO), lactose intolerance, fructose,[101] sucrose,[102] and sorbitol[103] malabsorption, exocrine pancreatic insufficiency,[104][105] and microscopic colitis,[105] among others. In untreated coeliac disease, these are often transient conditions derived from the intestinal damage.[102][103][106][107][108] They normally revert or improve several months after starting a gluten-free diet, but may need temporary interventions such as supplementation with pancreatic enzymes,[107][108] dietary restrictions of lactose, fructose, sucrose or sorbitol containing foods,[102][106] or treatment with oral antibiotics in the case of associated bacterial overgrowth.[108] In addition to gluten withdrawal, some people need to follow a low-FODMAPs diet or avoid consumption of commercial gluten-free products, which are usually rich in preservatives and additives (such as sulfites, glutamates, nitrates and benzoates) and which might have a role in triggering functional gastrointestinal symptoms.[109]

## Screening [edit]

There is significant debate as to the benefits of screening. Some studies suggest that early detection would decrease the risk of osteoporosis and anaemia. In contrast, a cohort study suggested that people with undetected coeliac disease had a beneficial risk profile for cardiovascular disease (less overweight, lower cholesterol levels).[19] There is limited evidence that screen-detected cases benefit from a diagnosis in terms of morbidity and mortality; hence, population-level screening is not presently thought to be beneficial.[9]

In the United Kingdom, the National Institute for Health and Clinical Excellence (NICE) recommends screening for coeliac disease in people with newly diagnosed chronic fatigue syndrome[110] and irritable bowel syndrome,[30] as well as in type 1 diabetics, especially those with insufficient weight gain or unexplained weight loss.[12][111] It is also recommended in autoimmune thyroid disease, dermatitis herpetiformis, and in the first-degree relatives of those with confirmed coeliac disease.[12]

In 2016 the United States Preventive Services Task Force found inadequate evidence for benefits or harms from screening people at any age who do not have symptoms.[112]

Serology has been proposed as a screening measure, because the presence of antibodies would detect some previously undiagnosed cases of coeliac disease and prevent its complications in those people. However, serologic tests have high sensitivity only in people with total villous atrophy and have very low ability to detect cases with partial villous atrophy or minor intestinal lesions.[16] Testing for coeliac disease may be offered to those with commonly associated conditions.[9][12]

## Treatment [edit]

### Diet [edit]

*Main article: Gluten-free diet*

At present, the only effective treatment is a lifelong gluten-free diet.[42] No medication exists that will prevent damage or prevent the body from attacking the gut when gluten is present. Strict adherence to the diet allows the intestines to heal, leading to resolution of all symptoms in most cases and, depending on how soon the diet is begun, can also eliminate the heightened risk of osteoporosis and intestinal cancer and in some cases sterility.[113] The diet can be cumbersome; failure to comply with the diet may cause relapse.

Dietitian input is generally requested to ensure the person is aware which foods contain gluten, which foods are safe, and how to have a balanced diet despite the limitations. In many countries, gluten-free products are available on prescription and may be reimbursed by health insurance plans. Gluten-free products are usually more expensive and harder to find than common gluten-containing foods.[114] Since ready-made products often contain traces of gluten, some coeliacs may find it necessary to cook from scratch.[115]

The term *gluten-free* is generally used to indicate a supposed harmless level of gluten rather than a complete absence.[116] The exact level at which gluten is harmless is uncertain and controversial. A recent systematic review tentatively concluded that consumption of less than 10 mg of gluten per day is unlikely to cause histological abnormalities, although it noted that few reliable studies had been done.[116] Regulation of the label *gluten-free* varies. In the European Union, the European Commission issued regulations in 2009 limiting the use of "gluten-free" labels for food products to those with less than 20 mg/kg of gluten, and "very low gluten" labels for those with less than 100 mg/kg.[117] In the United States, the FDA issued regulations in 2013 limiting the use of "gluten-free" labels for food products to those with less than 20 ppm of gluten.[118][119][120] The current international Codex Alimentarius standard allows for 20 ppm of gluten in so-called "gluten-free" foods.[121] Several organisations, such as the Gluten-Free Certification Organization (GFCO), the Celiac Sprue Association (CSA), and the National Foundation for Celiac Awareness (NFCA), also certify products and companies as gluten-free.[122]

Gluten-free diet improves healthcare-related quality of life, and strict adherence to the diet gives more benefit than incomplete adherence. Nevertheless, gluten-free diet doesn't completely normalise the quality of life.[123]

### Refractory disease [edit]

Between 0.3% and 10% of people have refractory disease, which means that they have persistent villous atrophy on a gluten-free diet despite the lack of gluten exposure for more than 12 months.[105] Nevertheless, inadvertent exposure to gluten is the main cause of persistent villous atrophy, and must be ruled out before a diagnosis of refractory disease is made.[105] People with poor basic education and understanding of gluten-free diet often believe that they are strictly following the diet, but are making regular errors.[20][105][124] Also, a lack of symptoms is not a reliable indicator of intestinal recuperation.[105]

If alternative causes of villous atrophy have been eliminated, steroids or immunosuppressants (such as azathioprine) may be considered in this scenario.[33]

Refractory coeliac disease should not be confused with the persistence of symptoms despite gluten withdrawal[105] caused by transient conditions derived from the intestinal damage,[102][103][106] which generally revert or improve several months after starting a gluten-free diet,[107][108] such as small intestinal bacterial overgrowth, lactose intolerance, fructose,[101] sucrose,[102] and sorbitol[103] malabsorption, exocrine pancreatic insufficiency,[104][105] and microscopic colitis,[105] among others.

## Epidemiology [edit]

Globally coeliac diseases affects between 1 in 100 and 1 in 170 people.[22][125] Rates, however, vary between different regions of the world from as few as 1 in 300 to as many as 1 in 40.[22] In the United States it is thought to affect between 1 in 1750 (defined as clinical disease including dermatitis herpetiformis with limited digestive tract symptoms) to 1 in 105 (defined by presence of IgA TG in blood donors).[126] Due to variable signs and symptoms it is believed that about 85% of people affected are undiagnosed.[127] The percentage of people with clinically diagnosed disease (symptoms prompting diagnostic testing) is 0.05–0.27% in various studies. However, population studies from parts of Europe, India, South America, Australasia and the USA (using serology and biopsy) indicate that the percentage of people with the disease may be between 0.33 and 1.06% in children (but 5.66% in one study of children of the predisposed Sahrawi people[128]) and 0.18–1.2% in adults.[19] Among those in primary care populations who report gastrointestinal symptoms, the rate of coeliac disease is about 3%.[82] The rate amongst adult blood donors in Iran, Israel, Syria and Turkey is 0.60%, 0.64%, 1.61% and 1.15%, respectively.[32]

People of African, Japanese and Chinese descent are rarely diagnosed;[129] this reflects a much lower prevalence of the genetic risk factors, such as HLA-B8.[130] People of Indian ancestry seem to have a similar risk to those of Western Caucasian ancestry.[32] Population studies also indicate that a large proportion of coeliacs remain undiagnosed; this is due, in part, to many clinicians being unfamiliar with the condition and also due to the fact it can be asymptomatic.[131] Coeliac disease is slightly more common in women than in men.[24] A large multicentre study in the U.S. found a prevalence of 0.75% in not-at-risk groups, rising to 1.8% in symptomatic people, 2.6% in second-degree relatives (like grandparents, aunt or uncle, grandchildren, etc.) of a person with coeliac disease and 4.5% in first-degree relatives (siblings, parents or children).[32] This profile is similar to the prevalence in Europe.[32] Other populations at increased risk for coeliac disease, with prevalence rates ranging from 5% to 10%, include individuals with Down and Turner syndromes, type 1 diabetes, and autoimmune thyroid disease, including both hyperthyroidism (overactive thyroid) and hypothyroidism (underactive thyroid).[132]

Historically, coeliac disease was thought to be rare, with a prevalence of about 0.02%.[132] The reason for the recent increases in the number of reported cases is unclear.[125] It may be at least in part due to changes in diagnostic practice.[133] There also appears to be an approximately 4.5 fold true increase that may be due to less exposure to bacteria and other pathogens in Western environments.[125]

## History [edit]

Humans first started to cultivate grains in the Neolithic period (beginning about 9500 BCE) in the Fertile Crescent in Western Asia, and it is likely that coeliac disease did not occur before this time. Aretaeus of Cappadocia, living in the second century in the same area, recorded a malabsorptive syndrome with chronic diarrhoea, causing a debilitation of the whole body.[25] His "Cœliac Affection" (*coeliac* from Greek κοιλιακός *koiliakos*, "abdominal") gained the attention of Western medicine when Francis Adams presented a translation of Aretaeus's work at the Sydenham Society in 1856. The patient described in Aretaeus' work had stomach pain and was atrophied, pale, feeble and incapable of work. The diarrhoea manifested as loose stools that were white, malodorous and flatulent, and the disease was intractable and liable to periodic return. The problem, Aretaeus believed, was a lack of heat in the stomach necessary to digest the food and a reduced ability to distribute the digestive products throughout the body, this incomplete digestion resulting in the diarrhoea. He regarded this as an affliction of the old and more commonly affecting women, explicitly excluding children. The cause, according to Aretaeus, was sometimes either another chronic disease or even consuming "a copious draught of cold water."[25][26]

The paediatrician Samuel Gee gave the first modern-day description of the condition in children in a lecture at Hospital for Sick Children, Great Ormond Street, London, in 1887. Gee acknowledged earlier descriptions and terms for the disease and adopted the same term as Aretaeus (coeliac disease). He perceptively stated: "If the patient can be cured at all, it must be by means of diet." Gee recognised that milk intolerance is a problem with coeliac children and that highly starched foods should be avoided. However, he forbade rice, sago, fruit and vegetables, which all would have been safe to eat, and he recommended raw meat as well as thin slices of toasted bread. Gee highlighted particular success with a child "who was fed upon a quart of the best Dutch mussels daily." However, the child could not bear this diet for more than one season.[26][134]

Christian Archibald Herter, an American physician, wrote a book in 1908 on children with coeliac disease, which he called "intestinal infantilism." He noted their growth was retarded and that fat was better tolerated than carbohydrate. The eponym *Gee-Herter disease* was sometimes used to acknowledge both contributions.[135][136] Sidney V. Haas, an American paediatrician, reported positive effects of a diet of bananas in 1924.[137] This diet remained in vogue until the actual cause of coeliac disease was determined.[26]

While a role for carbohydrates had been suspected, the link with wheat was not made until the 1940s by the Dutch paediatrician Dr. Willem Karel Dicke.[138] It is likely that clinical improvement of his patients during the Dutch famine of 1944 (during which flour was scarce) may have contributed to his discovery.[139] Dicke noticed that the shortage of bread led to a significant drop in the death rate among children affected by coeliac disease from greater than 35% to essentially zero. He also reported that once wheat was again available after the conflict, the mortality rate soared to previous levels.[140] The link with the gluten component of wheat was made in 1952 by a team from Birmingham, England.[141] Villous atrophy was described by British physician John W. Paulley in 1954 on samples taken at surgery.[142] This paved the way for biopsy samples taken by endoscopy.[26]

Throughout the 1960s, other features of coeliac disease were elucidated. Its hereditary character was recognised in 1965.[143] In 1966, dermatitis herpetiformis was linked to gluten sensitivity.[26][37]

May has been designated as "Coeliac Awareness Month" by several coeliac organisations.[144][145]

### Christian churches and the Eucharist [edit]

Speaking generally, the various denominations of Christians celebrate a Eucharist in which a wafer or small piece of sacramental bread from wheat bread is blessed and then eaten. A typical wafer weighs about half a gram.[146] Wheat flour contains around 10 to 13% gluten, so a single communion wafer may have more than 50 mg of gluten, an amount which will harm the health of many people with coeliac especially if consumed every day (see Diet above).

Many Christian churches offer their communicants gluten-free alternatives, usually in the form of a rice-based

cracker or gluten-free bread. These include the United Methodist, Christian Reformed, Episcopal, the Anglican Church (Church of England, UK) and Lutheran. Catholics may receive from the Chalice alone, or ask for gluten-reduced hosts; gluten-free ones however are not considered to still be wheat bread, and hence invalid matter.[147]

### Roman Catholic position [edit]

Roman Catholic doctrine states that for a valid Eucharist, the bread to be used at Mass must be made from wheat. In 2002, the Congregation for the Doctrine of the Faith approved German-made low-gluten hosts, which meet all of the Catholic Church's requirements, for use in Italy; although not entirely gluten-free, they were also approved by the Italian Coeliac Association.[148] Some Catholics with coeliac have requested permission to use rice wafers; such petitions have always been denied.[149] As Catholic doctrine affirms that Christ is wholly and equally present under both species, it is possible to receive under the species of wine alone.

The issue is more complex for priests. As a celebrant, a priest is, for the fullness of the sacrifice of the Mass, absolutely required to receive under both species. On 24 July 2003, the Congregation for the Doctrine of the Faith stated, "Given the centrality of the celebration of the Eucharist in the life of a priest, one must proceed with great caution before admitting to Holy Orders those candidates unable to ingest gluten or alcohol without serious harm."[150]

By January 2004, extremely low-gluten Church-approved hosts had become available in the United States, Italy and Australia.[151]

### Passover [edit]

The Jewish festival of Pesach (Passover) may present problems with its obligation to eat matzo, which is unleavened bread made in a strictly controlled manner from wheat, barley, spelt, oats, or rye. This rules out many other grains that are normally used as substitutes for people with gluten sensitivity, especially for Ashkenazi Jews, who also avoid rice. Many kosher-for-Passover products avoid grains altogether and are therefore gluten-free. Potato starch is the primary starch used to replace the grains. Consuming matzo is mandatory on the first night of Pesach only. Jewish law holds that one should not seriously endanger one's health in order to fulfill a commandment. Thus, a person with coeliac disease is not allowed, let alone required, to eat any matzo other than gluten-free matzo.[152]

## Research directions [edit]

Various other approaches are being studied that would reduce the need of dieting. All are still under development, and are not expected to be available to the general public for a while.[19][153][154]

Three main approaches have been proposed as new therapeutic modalities for coeliac disease: gluten detoxification, modulation of the intestinal permeability, and modulation of the immune response.[155]

Using genetically engineered wheat species, or wheat species that have been selectively bred to be minimally immunogenic, may allow the consumption of wheat. This, however, could interfere with the effects that gliadin has on the quality of dough. Alternatively, gluten exposure can be minimised by the ingestion of a combination of enzymes (prolyl endopeptidase and a barley glutamine-specific cysteine endopeptidase (EP-B2)) that degrade the putative 33-mer peptide in the duodenum.[19]

Alternative treatments under investigation include the inhibition of zonulin, an endogenous signalling protein linked to increased permeability of the bowel wall and hence increased presentation of gliadin to the immune system. One inhibitor of this pathway is larazotide acetate, which is currently scheduled for phase 3 clinical trials.[156] Other modifiers of other well-understood steps in the pathogenesis of coeliac disease, such as the action of HLA-DQ2 or tissue transglutaminase and the MICA/NKG2D interaction that may be involved in the killing of enterocytes.[19]

Attempts to modulate the immune response with regard to coeliac disease are mostly still in phase I of clinical testing; one agent (CCX282-B) has been evaluated in a phase II clinical trial on the basis of small-intestinal biopsies taken from people with coeliac disease before and after gluten exposure.[155]

"In addition, the presence of intraepithelial lymphocytosis and/or villous atrophy and crypt hyperplasia of small-bowel mucosa, and clinical remission after withdrawal of gluten from the diet, are also used for diagnosis antitransglutaminase antibody (tTGA) titers and the degree of histological lesions inversely correlate with age. Thus, as the age of diagnosis increases antibody titers decrease and histological damage is less marked. It is common to find adults without villous atrophy showing only an inflammatory pattern in duodenal mucosa biopsies: Lymphocytic enteritis (Marsh I) or added crypt hyperplasia (Marsh II)"

"Celiac disease occurs in about 1% of the population worldwide, although most people with the condition are undiagnosed. It can cause a wide variety of symptoms, both intestinal and extra-intestinal because it is a systemic autoimmune disease that is triggered by dietary gluten. Patients with celiac disease are at increased risk of cancer, including a twofold to fourfold increased risk of non-Hodgkin's lymphoma and a more than 30-fold increased risk of small intestinal adenocarcinoma, and they have a 1.4-fold increased risk of death."

"Most studies used similar histological criteria for diagnosing celiac disease (Marsh grade ≥III), but the level of damage may vary across populations. Only 4 studies presented the proportion of patients in whom only partial villous atrophy was found (Marsh grade of IIIA), which ranged from 4% to 100%. The presence of positive serum antibodies has been shown to correlate with the degree of villous atrophy, and patients with celiac disease who have less severe histological damage may have seronegative findings. This could be important, especially in primary care, in which levels of mucosal damage may be lower, and consequently, more patients with celiac disease may be missed."

This is the lowest level that can be consistently detected in foods using valid scientific analytical tools. Also, most people with celiac disease can tolerate foods with very small amounts of gluten. This level is consistent with those set by other countries and international bodies that set food safety standards."

# Crohn's disease

From Wikipedia, the free encyclopedia

*"Crohn" redirects here. It is not to be confused with Croan, Krone, or Crone.*

**Crohn's disease** is a type of inflammatory bowel disease (IBD) that may affect any part of the gastrointestinal tract from mouth to anus.[2] Signs and symptoms often include abdominal pain, diarrhea (which may be bloody if inflammation is severe), fever, and weight loss.[1][2] Other complications may occur outside the gastrointestinal tract and include anemia, skin rashes, arthritis, inflammation of the eye, and feeling tired. The skin rashes may be due to infections as well as pyoderma gangrenosum or erythema nodosum. Bowel obstruction also commonly occurs and those with the disease are at greater risk of bowel cancer.[1]

Crohn's disease is caused by a combination of environmental, immune and bacterial factors in genetically susceptible individuals.[3][4][5] It results in a chronic inflammatory disorder, in which the body's immune system attacks the gastrointestinal tract possibly directed at microbial antigens.[4][6] While Crohn's is an immune related disease, it does not appear to be an autoimmune disease (in that the immune system is not being triggered by the body itself).[7] The exact underlying immune problem is not clear; however, it may be an immunodeficiency state.[6][8][9] About half of the overall risk is related to genetics with more than 70 genes found to be involved.[1][10] Tobacco smokers are two times more likely to develop Crohn's disease than nonsmokers.[11] It also often begins after gastroenteritis. Diagnosis is based on a number of findings including biopsy and appearance of the bowel wall, medical imaging and description of the disease. Other conditions that can present similarly include irritable bowel syndrome and Behçet's disease.[1]

There are no medications or surgical procedures that can cure Crohn's disease. Treatment options help with symptoms, maintain remission, and prevent relapse. In those newly diagnosed, a corticosteroid may be used for a brief period of time to quickly improve the disease with another medication such as either methotrexate or a thiopurine used to prevent recurrence. An important part of treatment is the stopping of smoking among those who do. One in five people with the disease are admitted to hospital each year, and half of those with the disease will require surgery for the disease at some point over a ten-year period. While surgery should be used as

little as possible, it is necessary to address some abscesses, certain bowel obstructions, and cancers. Checking for bowel cancer via colonoscopy is recommended every few years, starting eight years after the disease has begun.[1]

Crohn's disease affects about 3.2 per 1,000 people in Europe and North America.[12] It is less common in Asia and Africa.[13][14] It has historically been more common in the developed world.[15] Rates have, however, been increasing, particularly in the developing world, since the 1970s.[14][15] Inflammatory bowel disease resulted in 35,000 deaths in 2010[16] and those with Crohn's disease have a slightly reduced life expectancy.[1] It tends to start in the teens and twenties, although it can occur at any age.[1][2] Males and females are equally affected.[2] The disease was named after gastroenterologist Burrill Bernard Crohn, who, in 1932, together with two other colleagues at Mount Sinai Hospital in New York, described a series of patients with inflammation of

the terminal ileum of the small intestine, the area most commonly affected by the illness.[17]

A video explanation of Crohn disease.

Many people with Crohn's disease have symptoms for years prior to the diagnosis.[20] The usual onset is between 15 and 30 years of age, but can occur at any age.[21] Because of the 'patchy' nature of the gastrointestinal disease and the depth of tissue involvement, initial symptoms can be more subtle than those of ulcerative colitis. People with Crohn's

disease experience chronic recurring periods of flare-ups and remission.[22]

Abdominal pain may be the initial symptom of Crohn's disease usually in the lower right area.[23] It is often accompanied by diarrhea, especially in those who have had surgery. The diarrhea may or may not be bloody. The nature of the diarrhea in Crohn's disease depends on the part of the small intestine or colon involved. Ileitis typically results in large-volume, watery feces. Colitis may result in a smaller volume of feces of higher frequency. Fecal consistency may range from solid to watery. In severe cases, an individual may have more than 20 bowel movements per day and may need to awaken at night to defecate.[1][24][25][26] Visible bleeding in the feces is less common in Crohn's disease than in ulcerative colitis, but may be seen in the setting of Crohn's colitis.[1] Bloody bowel movements typically come and go, and may be bright or dark red in color. In the setting of severe Crohn's colitis, bleeding may be copious.[24] Flatulence and bloating may also add to the intestinal discomfort.[24]

Symptoms caused by intestinal stenosis are also common in Crohn's disease. Abdominal pain is often most severe in areas of the bowel with stenoses. Persistent vomiting and nausea may indicate stenosis from small bowel obstruction or disease involving the stomach, pylorus, or duodenum.[24] Although the association is greater in the context of ulcerative colitis, Crohn's disease may also be associated with primary sclerosing cholangitis, a type of inflammation of the bile ducts.[27]

Perianal discomfort may also be prominent in Crohn's disease. Itchiness or pain around the anus may be suggestive of inflammation, fistulization or abscess around the anal area[1] or anal fissure. Perianal skin tags are also common in Crohn's disease.[28] Fecal incontinence may accompany perianal Crohn's disease. At the opposite end of the gastrointestinal tract, the mouth may be affected by non-healing sores (aphthous ulcers). Rarely, the esophagus, and stomach may be involved in Crohn's disease. These can cause symptoms including difficulty swallowing (dysphagia), upper abdominal pain, and vomiting.[29]

## Systemic [edit]

Crohn's disease, like many other chronic, inflammatory diseases, can cause a variety of systemic symptoms.[1] Among children, growth failure is common. Many children are first diagnosed with Crohn's disease based on inability to maintain growth.[30] As it may manifest at the time of the growth spurt in puberty, up to 30% of children with Crohn's disease may have retardation of growth.[31] Fever may also be present, though fevers greater than 38.5 °C (101.3 °F) are uncommon unless there is a complication such as an abscess.[1] Among older individuals, Crohn's disease may manifest as weight loss, usually related to decreased food intake, since individuals with intestinal symptoms from Crohn's disease often feel better when they do not eat and might lose their appetite.[30] People with extensive small intestine disease may also have malabsorption of carbohydrates or lipids, which can further exacerbate weight loss.[32]

## Extraintestinal [edit]

In addition to systemic and gastrointestinal involvement, Crohn's disease can affect many other organ systems.[33]

Inflammation of the interior portion of the eye, known as uveitis, can cause blurred vision and eye pain, especially when exposed to light (photophobia).[34] Inflammation may also involve the white part of the eye (sclera), a condition called episcleritis.[34] Both episcleritis and uveitis can lead to loss of vision if untreated.

Crohn's disease that affects the ileum may result in an increased risk for gallstones. This is due to a decrease in bile acid resorption in the ileum and the bile gets excreted in the stool. As a result, the cholesterol/bile ratio increases in the gallbladder, resulting in an increased risk for gallstones.[34]

Crohn's disease is associated with a type of rheumatologic disease known as seronegative spondyloarthropathy.[34] This group of diseases is characterized by inflammation of one or more joints (arthritis) or muscle insertions (enthesitis).[34] The arthritis in Crohn's disease can be divided into two types. The first type affects larger weight-bearing joints such as the knee (most common), hips, shoulders, wrists, or elbows.[34] The second type symmetrically involves five or more of the small joints of the hands and feet.[34] The arthritis may also involve the spine, leading to ankylosing spondylitis if the entire spine is involved or simply sacroiliitis if only the sacroiliac joint is involved.[34] The symptoms of arthritis include painful, warm, swollen, stiff joints, and loss of joint mobility or function.[35]

Erythema nodosum on the back of a person with Crohn's disease

Pyoderma gangrenosum on the leg of a person with Crohn's disease

Crohn's disease may also involve the skin, blood, and endocrine system. The most common type of skin manifestation, erythema nodosum, presents as raised, tender red nodules usually appearing on the shins.[34][36] Erythema nodosum is due to inflammation of the underlying subcutaneous tissue, and is characterized by septal panniculitis.[36] Another skin lesion, pyoderma gangrenosum, is typically a painful ulcerating nodule. Crohn's disease also increases the risk of blood clots;[34] painful swelling of the lower legs can be a sign of deep venous thrombosis, while difficulty breathing may be a result of pulmonary embolism. Autoimmune hemolytic anemia, a condition in which the immune system attacks the red blood cells, is also more common in Crohn's disease and may cause fatigue, a pale appearance, and other symptoms common in anemia. Clubbing, a deformity of the ends of the fingers, may also be a result of Crohn's disease. Finally, Crohn's disease increases the risk of osteoporosis, or thinning of the bones.[34] Individuals with osteoporosis are at increased risk of bone fractures.[37]

People with Crohn's disease often have anemia due to vitamin $B_{12}$, folate, iron deficiency, or due to anemia of chronic disease.[38][39] The most common is iron deficiency anemia[38] from chronic blood loss, reduced dietary intake, and persistent inflammation leading to increased hepcidin levels, restricting iron absorption in the duodenum.[39] As Crohn's disease most commonly affects the terminal ileum where the vitamin B12/intrinsic factor complex is absorbed, B12 deficiency may be seen.[39] This is particularly common after [38]

surgery to remove the ileum. Involvement of the duodenum and jejunum can impair the absorption of many other nutrients including folate. If Crohn's disease affects the stomach, production of intrinsic factor can be reduced.

Crohn's disease can also cause neurological complications (reportedly in up to 15%).[40] The most common of these are seizures, stroke, myopathy, peripheral neuropathy, headache and depression.[40]

People with Crohn's often also have issues with small bowel bacterial overgrowth syndrome, which has similar symptoms.[41]

In the oral cavity people with Crohn's may develop cheilitis granulomatosa and other forms of orofacial granulomatosis, pyostomatitis vegetans, recurrent aphthous stomatitis, geographic tongue, and migratory stomatitis in higher prevalence than the general population.[42]

## Cause [edit]

While the exact cause is unknown,[45] Crohn's disease seems to be due to a combination of environmental factors and genetic predisposition.[46] Crohn's is the first genetically complex disease in which the relationship between genetic risk factors and the immune system is understood in considerable detail.[47] Each individual risk mutation makes a small contribution to the overall risk of Crohn's (approximately 1:200). The genetic data, and direct assessment of immunity, indicates a malfunction in the innate immune system.[48] In this view, the chronic inflammation of Crohn's is caused when the adaptive immune system tries to compensate for a deficient innate immune system.[49]

### Genetics [edit]

Crohn's has a genetic component.[51] Because of this, siblings of known people with Crohn's are 30 times more likely to develop Crohn's than the general population.

The first mutation found to be associated with Crohn's was a frameshift in the NOD2 gene (also known as the CARD15 gene),[52] followed by the discovery of point mutations.[53] Over thirty genes have been associated with Crohn's; a biological function is known for most of them. For example, one association is with mutations in the XBP1 gene, which is involved in the unfolded protein response pathway of the endoplasmatic reticulum.[54][55] The gene variants of NOD2/CARD15 seem to be related with small-bowel involvement.[56] Other well documented genes which increase the risk of developing Crohn disease are ATG16L1,[57] IL23R,[58] IRGM,[59] and SLC11A1.[60] There is considerable overlap between susceptibility loci for IBD and mycobacterial infections.[61] Recent genome-wide association studies have shown that Crohn's disease is genetically linked to coeliac disease.[62]

primary T cell autoimmune disorder, however, a newer theory hypothesizes that Crohn's results from an impaired innate immunity.[63] The later hypothesis describes impaired cytokine secretion by macrophages, which contributes to impaired innate immunity and leads to a sustained microbial-induced inflammatory response in the colon, where the bacterial load is high.[4][48] Another theory is that the inflammation of Crohn's was caused by an overactive $T_h1$ and $T_h17$ cytokine response.[64][65]

In 2007, the ATG16L1 gene has been implicated in Crohn's disease, which may induce autophagy and hinder the body's ability to attack invasive bacteria.[57] Another study has theorized that the human immune system traditionally evolved with the presence of parasites inside the body, and that the lack thereof due to modern hygiene standards has weakened the immune system. Test subjects were reintroduced to harmless parasites, with positive response.[66]

## Microbes [edit]

Current thinking is that microorganisms are taking advantage of their host's weakened mucosal layer and inability to clear bacteria from the intestinal walls, which are both symptoms of Crohn's.[67] Different strains found in tissue and different outcomes to antibiotics therapy and resistance suggest Crohn's Disease is not one disease, but an umbrella of diseases related to different pathogens.[68]

A number of studies have suggested a causal role for *Mycobacterium avium* subspecies *paratuberculosis* (MAP), which causes a similar disease, Johne's disease, in cattle.[69][70]

NOD2 is a gene involved in Crohn's genetic susceptibility. It is associated with macrophages' diminished ability to phagocytize MAP. This same gene may reduce innate and adaptive immunity in gastrointestinal tissue and impair the ability to resist infection by the MAP bacterium.[71] Macrophages that ingest the MAP bacterium are associated with high production of TNF-α.[72][73]

Other studies have linked specific strains of enteroadherent *E. coli* to the disease.[74] Adherent-invasive Escherichia coli (AIEC), are more common in people with CD,[75][76][77] have the ability to make strong biofilms compared to non-AIEC strains correlating with high adhesion and invasion indices[78][79] of neutrophils and the ability to block autophagy at the autolysosomal step, which allows for intracellular survival of the bacteria and induction of inflammation.[80] Inflammation drives the proliferation of AIEC and dysbiosis in the ileum, irrespective of genotype.[81] AIEC strains replicate extensively into macrophages inducing the secretion of very large amounts of TNF-α.[82]

Mouse studies have suggested some symptoms of Crohn's disease, ulcerative colitis, and irritable bowel syndrome have the same underlying cause. Biopsy samples taken from the colons of all three patient groups were found to produce elevated levels of a serine protease.[83] Experimental introduction of the serine protease into mice has been found to produce widespread pain associated with irritable bowel syndrome, as well as colitis, which is associated with all three diseases.[84] Regional and temporal variations in those illnesses follow those associated with infection with the protozoan Blastocystis.[85]

The "cold-chain" hypothesis is that psychrotrophic bacteria such as *Yersinia* and *Listeria* species contribute to the disease. A statistical correlation was found between the advent of the use of refrigeration in the United States and various parts of Europe and the rise of the disease.[86][87][88]

There is an apparent connection between Crohn's disease, *Mycobacterium*, other pathogenic bacteria, and genetic markers.[89][90] In many individuals, genetic factors predispose individuals to *Mycobacterium avium* subsp. *paratuberculosis* infection. This bacterium then produces mannins, which protect both itself and various bacteria from phagocytosis, which causes a variety of secondary infections.[91]

Still, this relationship between specific types of bacteria and Crohn's disease remains unclear.[92][93]

There is a tentative association between *Candida* colonization and Crohn's disease.[94]

## Environmental factors [edit]

The increased incidence of Crohn's in the industrialized world indicates an environmental component. Crohn's is associated with an increased intake of animal protein, milk protein and an increased ratio of omega-6 to omega-3 polyunsaturated fatty acids.[95] Those who consume vegetable proteins appear to have a lower incidence of Crohn's disease. Consumption of fish protein has no association.[95] Smoking increases the risk of the return of active disease (flares).[11] The introduction of hormonal contraception in the United States in the 1960s is associated with a dramatic increase in incidence, and one hypothesis is that these drugs work on the digestive system in ways similar to smoking.[96] Isotretinoin is associated with Crohn's.[97][98][99] Although stress is sometimes claimed to exacerbate Crohn's disease, there is no concrete evidence to support such claim.[100] Dietary microparticles, such as those found in toothpaste, have been studied as they produce effects on immunity, but they were not consumed in greater amounts in patients with Crohn's.[101][102]

# Pathophysiology [edit]

During a colonoscopy, biopsies of the colon are often taken to confirm the diagnosis. Certain characteristic features of the pathology seen point toward Crohn's disease; it shows a transmural pattern of inflammation, meaning the inflammation may span the entire depth of the intestinal wall.[1] Ulceration is an outcome seen in highly active disease. There is usually an abrupt transition between unaffected tissue and the ulcer—a characteristic sign known as skip lesions. Under a microscope, biopsies of the affected colon may show mucosal inflammation, characterized by focal infiltration of neutrophils, a type of inflammatory cell, into the epithelium. This typically occurs in the area overlying lymphoid aggregates. These neutrophils, along with mononuclear cells, may infiltrate the crypts, leading to inflammation (crypititis) or abscess (crypt abscess). Granulomas, aggregates of macrophage derivatives known as giant cells, are found in 50% of cases and are most specific for Crohn's disease. The granulomas of Crohn's disease do not show "caseation", a cheese-like appearance on microscopic examination characteristic of granulomas associated with infections, such as tuberculosis. Biopsies may also show chronic mucosal damage, as evidenced by blunting of the intestinal villi, atypical branching of the crypts, and a change in the tissue type (metaplasia). One example of such metaplasia, *Paneth cell metaplasia*, involves development of Paneth cells (typically found in the small intestine and a key regulator of intestinal microbiota) in other parts of the gastrointestinal system.[104][105]

# Diagnosis [edit]

The diagnosis of Crohn's disease can sometimes be challenging,[20] and a number of tests are often required to assist the physician in making the diagnosis.[24] Even with a full battery of tests, it may not be possible to diagnose Crohn's with complete certainty; a colonoscopy is approximately 70% effective in diagnosing the disease, with further tests being less effective. Disease in the small bowel is particularly difficult to diagnose, as a traditional colonoscopy allows access to only the colon and lower portions of the small intestines; introduction of the capsule endoscopy[106] aids in endoscopic diagnosis. Multinucleated giant cells, a common finding in the lesions of Crohn's disease, are less common in the lesions of lichen nitidus.[107]

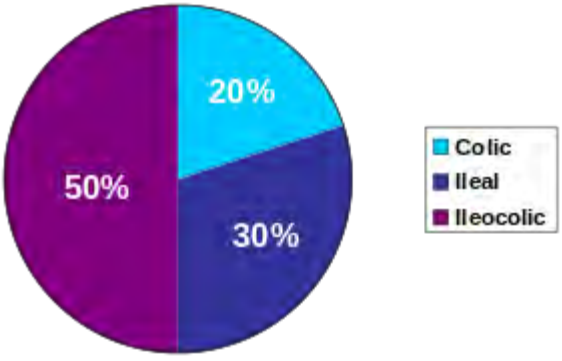
## Classification [edit]

Crohn's disease is one type of inflammatory bowel disease (IBD). It typically manifests in the gastrointestinal tract and can be categorized by the specific tract region affected. A disease of both the ileum (the last part of the small intestine that connects to the large intestine), and the large intestine, Ileocolic Crohn's accounts for fifty percent of cases. Crohn's ileitis, manifest in the ileum only, accounts for thirty percent of cases, while Crohn's colitis, of the large intestine, accounts for the remaining twenty percent of cases and may be particularly difficult to distinguish from ulcerative colitis. Gastroduodenal Crohn's disease causes inflammation in the stomach and first part of the small intestine, called the duodenum. Jejunoileitis causes spotty patches of inflammation in the top half of the small intestine, called the jejunum.[108] The disease can attack any part of the digestive tract, from mouth to anus. However, individuals affected by the disease rarely fall outside these three classifications, with presentations in other areas.[1]



Distribution of gastrointestinal Crohn's disease.

Crohn's disease may also be categorized by the behavior of disease as it progresses. These categorizations formalized in the Vienna classification of the disease.[109] There are three categories of disease presentation in Crohn's disease: stricturing, penetrating, and inflammatory. Stricturing disease causes narrowing of the bowel that may lead to bowel obstruction or changes in the caliber of the feces. Penetrating disease creates abnormal passageways (fistulae) between the bowel and other structures, such as the skin. Inflammatory disease (or nonstricturing, nonpenetrating disease) causes inflammation without causing strictures or fistulae.[109][110]

## Endoscopy [edit]

A colonoscopy is the best test for making the diagnosis of Crohn's disease, as it allows direct visualization of the colon and the terminal ileum, identifying the pattern of disease involvement. On occasion, the colonoscope can travel past the terminal ileum, but it varies from person to person. During the procedure, the gastroenterologist can also perform a biopsy, taking small samples of tissue for laboratory analysis, which may help confirm a diagnosis. As 30% of Crohn's disease involves only the ileum,[1] cannulation of the terminal ileum is required in making the diagnosis. Finding a patchy distribution of disease, with involvement of the colon or ileum, but not the rectum, is suggestive of Crohn's disease, as are other endoscopic stigmata.[111] The utility of capsule endoscopy for this, however, is still uncertain.[112] A "cobblestone"-like appearance is seen in approximately 40% of cases of Crohn's disease upon colonoscopy, representing areas of ulceration separated by narrow areas of healthy tissue.

## Radiologic tests [edit]

A small bowel follow-through may suggest the diagnosis of Crohn's disease and is useful when the disease involves only the small intestine. Because colonoscopy and gastroscopy allow direct visualization of only the terminal ileum and beginning of the duodenum, they cannot be used to evaluate the remainder of the small intestine. As a result, a barium follow-through X-ray, wherein barium sulfate suspension is ingested and fluoroscopic images of the bowel are taken over time, is useful for looking for inflammation and narrowing of the small bowel.[111][113] Barium enemas, in which barium is inserted into the rectum and fluoroscopy is used to image the bowel, are rarely used in the work-up of Crohn's disease due to the advent of colonoscopy. They remain useful for identifying anatomical abnormalities when strictures of the colon are too small for a colonoscope to pass through, or in the detection of colonic fistulae (in this case contrast should be performed with iodate substances).[114]

CT and MRI scans are useful for evaluating the small bowel with enteroclysis protocols.[115] They are also useful for looking for intra-abdominal complications of Crohn's disease, such as abscesses, small bowel obstructions, or fistulae.[116] Magnetic resonance imaging (MRI) is another option for imaging the small bowel as well as looking for complications, though it is more expensive and less readily available.[117]

## Blood tests [edit]

A complete blood count may reveal anemia, which commonly is caused by blood loss leading to iron deficiency (a microcytic anemia) or by vitamin $B_{12}$ deficiency (a macrocytic anemia), usually caused by ileal disease impairing vitamin $B_{12}$ absorption. Rarely autoimmune hemolysis may occur.[118] Ferritin levels help assess if iron deficiency is contributing to the anemia. Erythrocyte sedimentation rate (ESR) and C-reactive protein help assess the degree of inflammation, which is important as ferritin can also be raised in inflammation.[119] Serum iron, total iron binding capacity and transferrin saturation may be more easily interpreted in inflammation. Anemia of chronic disease results in a normocytic anemia. Other causes of anemia include medication used in treatment of inflammatory bowel disease, like azathioprine, which can lead to cytopenia, and sulfasalazine, which can also result in folate deficiency. Testing for *Saccharomyces cerevisiae* antibodies (ASCA) and antineutrophil cytoplasmic antibodies (ANCA) has been evaluated to identify inflammatory diseases of the intestine[120] and to differentiate Crohn's disease from ulcerative colitis.[121] Furthermore, increasing amounts and levels of serological antibodies such as ASCA, antilaminaribioside [Glc(β1,3)Glb(β); ALCA], antichitobioside [GlcNAc(β1,4)GlcNAc(β); ACCA], antimannobioside [Man(α1,3)Man(α)AMCA], antiLaminarin [(Glc(β1,3))3n(Glc(β1,6))n; anti-L] and antichitin [GlcNAc(β1,4)n; anti-C] associate with disease behavior and surgery, and may aid in the prognosis of Crohn's disease.[122][123][124][125]

Low serum levels of vitamin D are associated with Crohn's disease.[126] Further studies are required to determine the significance of this association.[126]

## Comparison with ulcerative colitis [edit]

The most common disease that mimics the symptoms of Crohn's disease is ulcerative colitis, as both are inflammatory bowel diseases that can affect the colon with similar symptoms. It is important to differentiate these diseases, since the course of the diseases and treatments may be different. In some cases, however, it may not be possible to tell the difference, in which case the disease is classified as indeterminate colitis.[1][24][25]

**Diagnostic findings**

| | Crohn's disease | Ulcerative colitis |
|---|---|---|
| Terminal ileum involvement | Commonly | Seldom |
| Colon involvement | Usually | Always |
| Rectum involvement | Seldom | Usually[43] |
| Involvement around the anus | Common[19] | Seldom |
| Bile duct involvement | No increase in rate of primary sclerosing cholangitis | Higher rate[127] |
| Distribution of disease | Patchy areas of inflammation (skip lesions) | Continuous area of inflammation[43] |
| Endoscopy | Deep geographic and serpiginous (snake-like) ulcers | Continuous ulcer |
| Depth of inflammation | May be transmural, deep into tissues[19][128] | Shallow, mucosal |
| Stenosis | Common | Seldom |
| Granulomas on biopsy | May have non-necrotizing non-peri-intestinal crypt granulomas[19][129][130] | Non-peri-intestinal crypt granulomas not seen[43] |

## Differential diagnosis [edit]

Other conditions with similar symptoms as Crohn's disease includes intestinal tuberculosis, Behçet's disease, ulcerative colitis, nonsteroidal anti-inflammatory drug enteropathy, irritable bowel syndrome and celiac disease.[131] Irritable bowel syndrome is excluded when there are inflammatory changes.[131] Celiac disease can't be excluded if specific antibodies (anti-transglutaminase antibodies) are negative,[132][133] nor in absence of intestinal villi atrophy.[134][135]

# Management [edit]

*Main article: Management of Crohn's disease*

There is no cure for Crohn's disease and remission may not be possible or prolonged if achieved. In cases where remission is possible, relapse can be prevented and symptoms controlled with medication, lifestyle and dietary changes, changes to eating habits (eating smaller amounts more often), reduction of stress, moderate activity

**Management**

| | Crohn's disease | Ulcerative colitis |
|---|---|---|
| Mesalazine | Less useful[136] | More useful[136] |
| Antibiotics | Effective in long-term[137] | Generally not useful[138] |
| Surgery | Often returns following removal of affected part | Usually cured by removal of colon |

and exercise. Surgery is generally contraindicated and has not been shown to prevent remission. Adequately controlled, Crohn's disease may not significantly restrict daily living.[139] Treatment for Crohn's disease is only when symptoms are active and involve first treating the acute problem, then maintaining remission.

## Lifestyle changes [edit]

Certain lifestyle changes can reduce symptoms, including dietary adjustments, elemental diet, proper hydration, and smoking cessation. Diets that include higher levels of fiber and fruit are associated with reduced risk, while diets rich in total fats, polyunsaturated fatty acids, meat, and omega-6 fatty acids may increase the risk of Crohn's.[140] Smoking may increase Crohn's disease; stopping is recommended. Eating small meals frequently instead of big meals may also help with a low appetite. To manage symptoms have a balanced diet with proper portion control. Fatigue can be helped with regular exercise, a healthy diet, and enough sleep. A food diary may help with identifying foods that trigger symptoms. Some people should follow a low dietary fiber diet to control symptoms especially if fibrous foods cause symptoms.[139] Some find relief in eliminating casein (protein found in cow's milk) and gluten (protein found in wheat, rye and barley) from their diets. They may have specific dietary intolerances (not allergies).[141]

## Medication [edit]

Acute treatment uses medications to treat any infection (normally antibiotics) and to reduce inflammation (normally aminosalicylate anti-inflammatory drugs and corticosteroids). When symptoms are in remission, treatment enters maintenance, with a goal of avoiding the recurrence of symptoms. Prolonged use of corticosteroids has significant side-effects; as a result, they are, in general, not used for long-term treatment. Alternatives include aminosalicylates alone, though only a minority are able to maintain the treatment, and many require immunosuppressive drugs.[19] It has been also suggested that antibiotics change the enteric flora, and their continuous use may pose the risk of overgrowth with pathogens such as *Clostridium difficile*.[142]

Medications used to treat the symptoms of Crohn's disease include 5-aminosalicylic acid (5-ASA) formulations, prednisone, immunomodulators such as azathioprine (given as the prodrug for 6-mercaptopurine), methotrexate, infliximab, adalimumab,[25] certolizumab[143] and natalizumab.[144][145] Hydrocortisone should be used in severe attacks of Crohn's disease.[146] Biological therapies (biopharmaceuticals) are medications used to avoid long-term steroid use, decrease inflammation, and treat people who have fistulas with abscesses.[23] The monoclonal antibody ustekinumab appears to be a safe treatment option, and may help people with moderate to severe active crohn's disease.[147] The long term safety and effectiveness of monoclonal antibody treatment is not known. The monoclonal antibody briakinumab is not effective for people with active crohn's disease.[147]

The gradual loss of blood from the gastrointestinal tract, as well as chronic inflammation, often leads to anemia, and professional guidelines suggest routinely monitoring for this.[148][149][150] Adequate disease control usually improves anemia of chronic disease, but iron deficiency may require treatment with iron supplements. Guidelines vary as to how iron should be administered. Besides other, problems include a limitation in possible daily resorption and an increased growth of intestinal bacteria. Some[150] advise parenteral iron as first line as it works faster, has fewer gastrointestinal side effects, and is unaffected by inflammation reducing enteral absorption.

Other guidelines[149] advise oral iron as first line with parenteral iron reserved for those that fail to adequately respond as oral iron is considerably cheaper. All agree that severe anemia (hemoglobin under 10g/dL) should be treated with parenteral iron. Blood transfusion should be reserved for those who are cardiovascularly unstable, due to its relatively poor safety profile, lack of long term efficacy, and cost.[149]

## Surgery [edit]

Crohn's cannot be cured by surgery, as the disease eventually recurs, though it is used in the case of partial or full blockage of the intestine.[151] Surgery may also be required for complications such as

obstructions, fistulas, or abscesses, or if the disease does not respond to drugs. After the first surgery, Crohn's usually comes back at the site where the diseased intestine was removed and the healthy ends were rejoined, however it can come back in other locations. After a resection, scar tissue builds up, which can cause strictures, which form when the intestines become too small to allow excrement to pass through easily, which can lead to a blockage. After the first resection, another resection may be necessary within five years.[152] For patients with an obstruction due to a stricture, two options for treatment are strictureplasty and resection of that portion of bowel. There is no statistical significance between strictureplasty alone versus strictureplasty and resection in cases of duodenal involvement. In these cases, re-operation rates were 31% and 27%, respectively, indicating that strictureplasty is a safe and effective treatment for selected people with duodenal involvement.[153]

Postsurgical recurrence of Crohn's disease is relatively common. Crohn's lesions are nearly always found at the site of the resected bowel. The join (or anastomosis) after surgery may be inspected, usually during a colonoscopy, and disease activity graded. The "Rutgeert's score" is an endoscopic scoring system for post-operative disease recurrence in Crohn's disease. Mild postsurgical recurrences of Crohn's disease are graded i1 and i2, moderate to severe recurrences are graded i3 and i4.[154] Fewer lesions result in a lower grade. Based on the score, treatment plans can be designed to give the patient the best chance of managing recurrence of the disease.[155]

Short bowel syndrome (SBS, also short gut syndrome or simply short gut) is caused by the surgical removal of part of the small intestine. It usually develops in those patients who have had half or more of their small intestines removed.[156] Diarrhea is the main symptom, but others may include weight loss, cramping, bloating, and heartburn. Short bowel syndrome is treated with changes in diet, intravenous feeding, vitamin and mineral supplements, and treatment with medications. In some cases of SBS, intestinal transplant surgery may be considered; though the number of transplant centres offering this procedure is quite small and it comes with a high risk due to the chance of infection and rejection of the transplanted intestine.[157]

Bile acid diarrhea is another complication following surgery for Crohn's disease in which the terminal ileum has been removed. This leads to the development of excessive watery diarrhea. It is usually thought to be due to an inability of the ileum to reabsorb bile acids after resection of the terminal ileum and was the first type of bile acid malabsorption recognized.[158]

### Alternative medicine [edit]

More than half of people with Crohn's disease have tried complementary or alternative therapy.[159] These include diets, probiotics, fish oil and other herbal and nutritional supplements. Some scientists have suggested more research into these is needed to discriminate between effective therapies and those that have not been found to be effective.[160]

- Acupuncture is used to treat inflammatory bowel disease in China, and is being used more frequently in Western society.[161] At this time, evidence is insufficient to recommend the use of acupuncture.[162]
- Homeopathy is frequently used in Germany as a treatment for Crohn's disease, though no clinical trials exist that demonstrate homeopathy is effective.[163]
- There are contradicting studies regarding the effect of medical cannabis on inflammatory bowel disease.[164]

## Prognosis [edit]

Crohn's disease is a chronic condition for which there is no cure. It is characterised by periods of improvement followed by episodes when symptoms flare up. With treatment, most people achieve a healthy weight, and the mortality rate for the disease is relatively low. It can vary from being benign to very severe and people with CD could experience just one episode or have continuous symptoms. It usually reoccurs, although some people can remain disease free for years or decades. Most people with Crohn's live a normal lifespan.[165] However, Crohn's disease is associated with a small increase in risk of small bowel and colorectal carcinoma (bowel cancer).[166]

## Complications [edit]

Crohn's disease can lead to several mechanical complications within the intestines, including obstruction,[168] fistulae,[169] and abscesses.[170] Obstruction typically occurs from strictures or adhesions that narrow the lumen, blocking the passage of the intestinal contents. A fistula can develop between two loops of bowel, between the bowel and bladder, between the bowel and vagina, and between the bowel and skin. Abscesses are walled off concentrations of infection, which can occur in the abdomen or in the perianal area. Crohn's is responsible for 10% of vesicoenteric fistulae, and is the most common cause of ileovesical fistulae.[171]

**Complications**

| | | Crohn's disease | Ulcerative colitis |
|---|---|---|---|
| Nutrient deficiency | | Higher risk | |
| Colon cancer risk | | Slight | Considerable |
| Prevalence of **extraintestinal complications**[167] | | | |
| Iritis/uveitis | Females | 2.2% | 3.2% |
| | Males | 1.3% | 0.9% |
| Primary sclerosing cholangitis | Females | 0.3% | 1% |
| | Males | 0.4% | 3% |
| Ankylosing spondylitis | Females | 0.7% | 0.8% |
| | Males | 2.7% | 1.5% |
| Pyoderma gangrenosum | Females | 1.2% | 0.8% |
| | Males | 1.3% | 0.7% |
| Erythema nodosum | Females | 1.9% | 2% |
| | Males | 0.6% | 0.7% |

Crohn's disease also increases the risk of cancer in the area of inflammation. For example, individuals with Crohn's disease involving the small bowel are at higher risk for small intestinal cancer. Similarly, people with Crohn's colitis have a relative risk of 5.6 for developing colon cancer.[172] Screening for colon cancer with colonoscopy is recommended for anyone who has had Crohn's colitis for at least eight years.[173] Some studies suggest there is a role for chemoprotection in the prevention of colorectal cancer in Crohn's involving the colon; two agents have been suggested, folate and mesalamine preparations.[174] Also, immunomodulators and biologic agents used to treat this disease may promote developing extra-intestinal cancers.[175]

Individuals with Crohn's disease are at risk of malnutrition for many reasons, including decreased food intake and malabsorption. The risk increases following resection of the small bowel. Such individuals may require oral supplements to increase their caloric intake, or in severe cases, total parenteral nutrition (TPN). Most people with moderate or severe Crohn's disease are referred to a dietitian for assistance in nutrition.[176]

The major significant complications of Crohn's disease include bowel obstruction, abscesses, free perforation and hemorrhage, which in rare cases may be fatal.[177][178]

Crohn's disease can be problematic during pregnancy, and some medications can cause adverse outcomes for the fetus or mother. Consultation with an obstetrician and gastroenterologist about Crohn's disease and all medications facilitates preventative measures. In some cases, remission occurs during pregnancy. Certain medications can also lower sperm count or otherwise adversely affect a man's fertility.[179]

# Epidemiology [edit]

The percentage of people with Crohn's disease has been determined in Norway and the United States and is similar at 6 to 7.1:100,000. The Crohn's and Colitis Foundation of America cites this number as approx 149:100,000; NIH cites 28 to 199 per 100,000.[180][181] Crohn's disease is more common in northern countries, and with higher rates still in the northern areas of these countries.[182] The incidence of Crohn's disease is thought to be similar in Europe but lower in Asia and Africa.[180] It also has a higher incidence in Ashkenazi Jews[1][183] and smokers.[184]

Crohn's disease begins most commonly in people in their teens and 20s, and people in their 50s through to their 70s.[1][24] It is rarely diagnosed in early childhood. It usually affects female children more severely than males.[185] However, only slightly more women than men have Crohn's disease.[186] Parents, siblings or children of people with Crohn's disease are 3 to 20 times more likely to develop the disease.[187] Twin studies find that if one has the disease there is a 55% chance the other will too.[188]

The incidence of Crohn's disease is increasing in Europe.[189]

## History [edit]

*Main article: List of people diagnosed with Crohn's disease*

Inflammatory bowel diseases were described by Giovanni Battista Morgagni (1682–1771) and by Scottish physician T. Kennedy Dalziel in 1913.[190]

*Ileitis terminalis* was first described by Polish surgeon Antoni Leśniowski in 1904, although it was not conclusively distinguished from intestinal tuberculosis.[191] In Poland, it is still called Leśniowski-Crohn's disease (Polish: *choroba Leśniowskiego-Crohna*). Burrill Bernard Crohn, an American gastroenterologist at New York City's Mount Sinai Hospital, described fourteen cases in 1932, and submitted them to the American Medical Association under the rubric of "Terminal ileitis: A new clinical entity". Later that year, he, along with colleagues Leon Ginzburg and Gordon Oppenheimer, published the case series as "Regional ileitis: a pathologic and clinical entity". However, due to the precedence of Crohn's name in the alphabet, it later became known in the worldwide literature as Crohn's disease.[17]

## Research [edit]

Some evidence supports the hypothesis that the bacterium *Mycobacterium avium* subspecies *paratuberculosis* (MAP) is a cause of Crohn's disease (see also Johne's disease). As a result, researchers are looking at the eradication of MAP as a therapeutic option.[192] Treating MAP using antibiotics has been examined and the results are unclear but tentatively beneficial.[193][194] Vaccination against MAP is also being studied. An anti-MAP vaccine appears effective in mice and cattle with MAP with no apparent side effects.[192][195] Trials in human are pending.[196]

Crohn's is common in parts of the world where helminthic colonisation is rare and uncommon in those areas where most people carry worms. Infections with helminths may alter the autoimmune response that causes the disease. Trials of extracts from the worm *Trichuris suis* showed promising results when used in people with IBD.[197][198][199] However these trials (TRUST -I & TRUST -II) failed in Phase 2 clinical trials and were then discontinued after consistent failure in both North America and Europe.[200][201]

Numerous preclinical studies demonstrate that activation of the CB1 and CB2 cannabinoid receptors exert biological functions on the gastrointestinal tract.[202] Activation of CB1 and CB2 receptors in animals has shown a strong anti-inflammatory effect.[203] Cannabinoids and/or modulation of the endocannabinoid system is a novel therapeutic means for the treatment of numerous GI disorders, including inflammatory bowel diseases like Crohn's disease.[204] A few small trials have looked at medical cannabis but further evidence is required to determine its usefulness.[164]

There is no good evidence that thalidomide or lenalidomide is useful to bring about or maintain remission.[205][206]

"Both the endomysial antibody and tissue transglutaminase antibody have very high sensitivities (93% for both) and specificities (>99% and >98% respectively) for the diagnosis of typical coeliac disease with villous atrophy. (...) As the detection of at least partial villous atrophy was used to make a diagnosis of coeliac disease in the vast majority of studies, we can't assume that the same LRs apply to coeliac patients with lesser abnormality such as an increase in intraepithelial lymphocytes or electron-microscopic changes only. In fact, if such lesser abnormalities were used as criteria for diagnosing (and excluding) coeliac disease, the sensitivity of the tests could be lower (i.e. more false negatives), especially since a number of studies suggest that the EMA and tTG antibody tests are less sensitive with lesser degrees of mucosal abnormality"

# Diarrhea

From Wikipedia, the free encyclopedia

*For other uses, see Diarrhea (disambiguation).*

**Diarrhea**, also spelled **diarrhoea**, is the condition of having at least three loose or liquid bowel movements each day. It often lasts for a few days and can result in dehydration due to fluid loss. Signs of dehydration often begin with loss of the normal stretchiness of the skin and irritable behaviour. This can progress to decreased urination, loss of skin color, a fast heart rate, and a decrease in responsiveness as it becomes more severe. Loose but non-watery stools in babies who are breastfed, however, may be normal.[2]

The most common cause is an infection of the intestines due to either a virus, bacteria, or parasite; a condition known as gastroenteritis. These infections are often acquired from food or water that has been contaminated by stool, or directly from another person who is infected. It may be divided into three types: short duration watery diarrhea, short duration bloody diarrhea, and if it lasts for more than two weeks, persistent diarrhea. The short duration watery diarrhea may be due to an infection by cholera, although this is rare in the developed world. If blood is present it is also known as dysentery.[2] A number of non-infectious causes may also result in diarrhea, including hyperthyroidism, lactose intolerance, inflammatory bowel disease, a number of medications, and irritable bowel syndrome.[3] In most cases, stool cultures are not required to confirm the exact cause.[4]

Prevention of infectious diarrhea is by improved sanitation, clean drinking water, and hand washing with soap. Breastfeeding for at least six months is also recommended as is vaccination against rotavirus. Oral rehydration solution (ORS), which is clean water with modest amounts of salts and sugar, is the treatment of choice. Zinc tablets are also recommended.[2] These treatments have been estimated to have saved 50 million children in the past 25 years.[1] When people have diarrhea it is recommended that they continue to eat healthy food and babies continue to be breastfed.[2] If commercial ORS are not available, homemade solutions may be used.[5] In those with severe dehydration, intravenous fluids may be required.[2] Most cases; however, can be managed well with fluids by mouth.[6] Antibiotics, while rarely used, may be recommended in a few cases such as those who have bloody diarrhea and a high fever, those with severe diarrhea following travelling, and those who grow specific bacteria or parasites in their stool.[4] Loperamide may help decrease the number of bowel movements but is not [4]

recommended in those with severe disease.

About 1.7 to 5 billion cases of diarrhea occur per year.[2][3][7] It is most common in developing countries, where young children get diarrhea on average three times a year.[2] Total deaths from diarrhea are estimated at 1.26 million in 2013 – down from 2.58 million in 1990.[8] In 2012, it was the second most common cause of deaths in children younger than five (0.76 million or 11%).[2][9] Frequent episodes of diarrhea are also a common cause of malnutrition and the most common cause in those younger than five years of age.[2] Other long term problems that can result include stunted growth and poor intellectual development.[9]

# Definition

Diarrhea is defined by the World Health Organization as having three or more loose or liquid stools per day, or as having more stools than is normal for that person.[2]

Acute diarrhea is defined as an abnormally frequent discharge of semisolid or fluid fecal matter from the bowel, lasting less than 14 days, by World

## Secretory

Secretory diarrhea means that there is an increase in the active secretion, or there is an inhibition of absorption. There is little to no structural damage. The most common cause of this type of diarrhea is a cholera toxin that stimulates the secretion of anions, especially chloride ions. Therefore, to maintain a charge balance in the gastrointestinal tract, sodium is carried with it, along with water. In this type of diarrhea intestinal fluid secretion is isotonic with plasma even during fasting.[11] It continues even when there is no oral food intake.

## Osmotic

Osmotic diarrhea occurs when too much water is drawn into the bowels. If a person drinks solutions with excessive sugar or excessive salt, these can draw water from the body into the bowel and cause osmotic diarrhea.[12] Osmotic diarrhea can also be the result of maldigestion (e.g., pancreatic disease or Coeliac disease), in which the nutrients are left in the lumen to pull in water. Or it can be caused by osmotic laxatives (which work to alleviate constipation by drawing water into the bowels). In healthy individuals, too much magnesium or vitamin C or undigested lactose can produce osmotic diarrhea and distention of the bowel. A person who has lactose intolerance can have difficulty absorbing lactose after an extraordinarily high intake of dairy products. In persons who have fructose malabsorption, excess fructose intake can also cause diarrhea. High-fructose foods that also have a high glucose content are more absorbable and less likely to cause diarrhea. Sugar alcohols such as sorbitol (often found in sugar-free foods) are difficult for the body to absorb and, in large amounts, may lead to osmotic diarrhea.[11] In most of these cases, osmotic diarrhea stops when the offending agent (e.g. milk, sorbitol) is stopped.

## Exudative

Exudative diarrhea occurs with the presence of blood and pus in the stool. This occurs with inflammatory bowel diseases, such as Crohn's disease or ulcerative colitis, and other severe infections such as *E. coli* or other forms of food poisoning.[11]

## Inflammatory

Inflammatory diarrhea occurs when there is damage to the mucosal lining or brush border, which leads to a passive loss of protein-rich fluids and a decreased ability to absorb these lost fluids. Features of all three of the other types of diarrhea [*clarification needed*] can be found in this type of diarrhea. It can be caused by bacterial infections, viral infections, parasitic infections, or autoimmune problems such as inflammatory bowel diseases. It can also be caused by tuberculosis, colon cancer, and enteritis.[*citation needed*]

## Dysentery

If there is blood visible in the stools, it is also known as dysentery. The blood is a trace of an invasion of bowel tissue. Dysentery is a symptom of, among others, *Shigella*, *Entamoeba histolytica*, and *Salmonella*.

# Health effects

Diarrheal disease may have a negative impact on both physical fitness and mental development. "Early childhood malnutrition resulting from any cause reduces physical fitness and work productivity in adults,"[13] and diarrhea is a primary cause of childhood malnutrition.[14] Further, evidence suggests that diarrheal disease has significant impacts on mental development and health; it has been shown that, even when controlling for helminth infection and early breastfeeding, children who had experienced severe diarrhea had significantly lower scores on a series of tests of intelligence.[13][15]

# Differential diagnosis

Acute diarrhea is most commonly due to viral gastroenteritis with rotavirus, which accounts for 40% of cases in children under five.[1] (p. 17) In travelers however bacterial infections predominate.[16] Various toxins such as mushroom poisoning and drugs can also cause acute diarrhea.

Chronic diarrhea can be the part of the presentations of a number of chronic medical conditions affecting the intestine. Common causes include ulcerative colitis, Crohn's disease, microscopic colitis, celiac disease, irritable bowel syndrome and bile acid malabsorption.

## Infections

*Main article: Infectious diarrhea*

There are many causes of infectious diarrhea, which include viruses, bacteria and parasites.[17] Infectious diarrhea is frequently referred to as gastroenteritis.[18] Norovirus is the most common cause of viral diarrhea in adults,[19] but rotavirus is the most common cause in children under five years old.[20] Adenovirus types 40 and 41,[21] and astroviruses cause a significant number of infections.[22]

*Campylobacter* spp. are a common cause of bacterial diarrhea, but infections by *Salmonella* spp., *Shigella* spp. and some strains of *Escherichia coli* are also a frequent cause.[23]

In the elderly, particularly those who have been treated with antibiotics for unrelated infections, a toxin produced by *Clostridium difficile* often causes severe diarrhea.[24]

Parasites, particularly protozoa (e.g., *Cryptosporidium* spp., *Giardia* spp., *Entamoeba histolytica*, *Blastocystis* spp., *Cyclospora cayetanensis*), are frequently the cause of diarrhea that involves chronic infection. The broad-spectrum antiparasitic agent nitazoxanide has shown efficacy against many diarrhea-causing parasites.[25]

Other infectious agents, such as parasites or bacterial toxins, may exacerbate symptoms.[16] In sanitary living conditions where there is ample food and a supply of clean water, an otherwise healthy person usually recovers from viral infections in a few days. However, for ill or malnourished individuals, diarrhea can lead to severe dehydration and can become life-threatening.[26]

## Malabsorption

*Main article: Malabsorption*

Malabsorption is the inability to absorb food fully, mostly from disorders in the small bowel, but also due to maldigestion from diseases of the pancreas.

Causes include:

- *enzyme deficiencies or mucosal abnormality*, as in food allergy and food intolerance, e.g. celiac disease (gluten intolerance), lactose intolerance (intolerance to milk sugar, common in non-Europeans), and fructose malabsorption.
- *pernicious anemia*, or impaired bowel function due to the inability to absorb vitamin $B_{12}$,
- *loss of pancreatic secretions*, which may be due to cystic fibrosis or pancreatitis,
- *structural defects*, like short bowel syndrome (surgically removed bowel) and radiation fibrosis, such as usually follows cancer treatment and other drugs, including agents used in chemotherapy; and
- *certain drugs*, like orlistat, which inhibits the absorption of fat.

### Inflammatory bowel disease

*Main article: Inflammatory bowel disease*

The two overlapping types here are of unknown origin:

- Ulcerative colitis is marked by chronic bloody diarrhea and inflammation mostly affects the distal colon near the rectum.
- Crohn's disease typically affects fairly well demarcated segments of bowel in the colon and often affects the end of the small bowel.

### Irritable bowel syndrome

*Main article: Irritable bowel syndrome*

Another possible cause of diarrhea is irritable bowel syndrome (IBS), which usually presents with abdominal discomfort relieved by defecation and unusual stool (diarrhea or constipation) for at least 3 days a week over the previous 3 months.[27] Symptoms of diarrhea-predominant IBS can be managed through a combination of dietary changes, soluble fiber supplements, and/or medications such as loperamide or codeine. About 30% of patients with diarrhea-predominant IBS have bile acid malabsorption diagnosed with an abnormal SeHCAT test.[28]

### Other diseases

Diarrhea can be caused by other diseases and conditions, namely:

- Chronic ethanol ingestion[29]
- Ischemic bowel disease: This usually affects older people and can be due to blocked arteries.
- Microscopic colitis, a type of inflammatory bowel disease where changes are only seen on histological examination of colonic biopsies.
- Bile salt malabsorption (primary bile acid diarrhea) where excessive bile acids in the colon produce a secretory diarrhea.
- Hormone-secreting tumors: some hormones (e.g., serotonin) can cause diarrhea if excreted in excess (usually from a tumor).
- Chronic mild diarrhea in infants and toddlers may occur with no obvious cause and with no other ill effects; this condition is called toddler's diarrhea.
- Environmental enteropathy
- Radiation enteropathy following treatment for pelvic and abdominal cancers.

## Causes

### Sanitation

Open defecation is a leading cause of infectious diarrhea leading to death.[30]

Poverty is a good indicator of the rate of infectious diarrhea in a population. This association does not stem from poverty itself, but rather from the conditions under which impoverished people live. The

Poverty often leads to unhygienic living conditions, as in this community in the Indian Himalayas. Such conditions promote contraction of diarrheal diseases, as a result of poor sanitation and hygiene.
