absence of certain resources compromises the ability of the poor to defend themselves against infectious diarrhea. "Poverty is associated with poor housing, crowding, dirt floors, lack of access to clean water or to sanitary disposal of fecal waste (sanitation), cohabitation with domestic animals that may carry human pathogens, and a lack of refrigerated storage for food, all of which increase the frequency of diarrhea... Poverty also restricts the ability to provide age-appropriate, nutritionally balanced diets or to modify diets when diarrhea develops so as to mitigate and repair nutrient losses. The impact is exacerbated by the lack of adequate, available, and affordable medical care."[31]

### Water

One of the most common causes of infectious diarrhea, is a lack of clean water. Often, improper fecal disposal leads to contamination of groundwater. This can lead to widespread infection among a population, especially in the absence of water filtration or purification. Human feces contains a variety of potentially harmful human pathogens.[32]

### Nutrition

Proper nutrition is important for health and functioning, including the prevention of infectious diarrhea. It is especially important to young children who do not have a fully developed immune system. Zinc deficiency, a condition often found in children in developing countries can, even in mild cases, have a significant impact on the development and proper functioning of the human immune system.[33][34] Indeed, this relationship between zinc deficiency and reduced immune functioning corresponds with an increased severity of infectious diarrhea. Children who have lowered levels of zinc have a greater number of instances of diarrhea, severe diarrhea, and diarrhea associated with fever.[35] Similarly, vitamin A deficiency can cause an increase in the severity of diarrheal episodes. However, there is some discrepancy when it comes to the impact of vitamin A deficiency on the rate of disease. While some argue that a relationship does not exist between the rate of disease and vitamin A status,[36] others suggest an increase in the rate associated with deficiency.[37] Given that estimates suggest 127 million preschool children worldwide are vitamin A deficient, this population has the potential for increased risk of disease contraction.[38]

## Pathophysiology

### Evolution

According to two researchers, Nesse and Williams, diarrhea may function as an evolved expulsion defense mechanism. As a result, if it is stopped, there might be a delay in recovery.[39] They cite in support of this argument research published in 1973 that found that treating *Shigella* with the anti-diarrhea drug (Co-phenotrope, Lomotil) caused people to stay feverish twice as long as those not so treated. The researchers indeed themselves observed that: "Lomotil may be contraindicated in shigellosis. Diarrhea may represent a defense mechanism".[40]

## Diagnostic approach

The following types of diarrhea may indicate further investigation is needed:

- In infants

- Moderate or severe diarrhea in young children
- Associated with blood
- Continues for more than two days
- Associated non-cramping abdominal pain, fever, weight loss, etc.
- In travelers
- In food handlers, because of the potential to infect others;
- In institutions such as hospitals, child care centers, or geriatric and convalescent homes.

A severity score is used to aid diagnosis in children.[41]

# Prevention

## Sanitation

Numerous studies have shown that improvements in drinking water and sanitation (WASH) lead to decreased risks of diarrhoea.[42] Such improvements might include for example use of water filters, provision of high-quality piped water and sewer connections.[42]

In institutions, communities, and households, interventions that promote hand washing with soap lead to significant reductions in the incidence of diarrhea.[43] The same applies to preventing open defecation at a community-wide level and providing access to improved sanitation.[44][45] This includes use of toilets and implementation of the entire sanitation chain connected to the toilets (collection, transport, disposal or reuse of human excreta).

## Hand washing

Basic sanitation techniques can have a profound effect on the transmission of diarrheal disease. The implementation of hand washing using soap and water, for example, has been experimentally shown to reduce the incidence of disease by approximately 42–48%.[46][47] Hand washing in developing countries, however, is compromised by poverty as acknowledged by the CDC: "Handwashing is integral to disease prevention in all parts of the world; however, access to soap and water is limited in a number of less developed countries. This lack of access is one of many challenges to proper hygiene in less developed countries." Solutions to this barrier require the implementation of educational programs that encourage sanitary behaviours.[48]

## Water

Given that water contamination is a major means of transmitting diarrheal disease, efforts to provide clean water supply and improved sanitation have the potential to dramatically cut the rate of disease incidence. In fact, it has been proposed that we might expect an 88% reduction in child mortality resulting from diarrheal disease as a result of improved water sanitation and hygiene.[32][49] Similarly, a meta-analysis of numerous studies on improving water supply and sanitation shows a 22–27% reduction in disease incidence, and a 21–30% reduction in mortality rate associated with diarrheal disease.[50]

Chlorine treatment of water, for example, has been shown to reduce both the risk of diarrheal disease, and of contamination of stored water with diarrheal pathogens.[51]

## Vaccination

Immunization against the pathogens that cause diarrheal disease is a viable prevention strategy, however it does require targeting certain pathogens for vaccination. In the case of Rotavirus, which was responsible for around 6% of diarrheal episodes and 20% of diarrheal disease deaths in the children of developing countries, use of a Rotavirus vaccine in trials in 1985 yielded a slight (2-3%) decrease in total diarrheal disease incidence, while reducing overall mortality by 6-10%. Similarly, a Cholera vaccine showed a strong reduction in morbidity and mortality, though the overall impact of vaccination was minimal as Cholera is not

one of the major causative pathogens of diarrheal disease.[52] Since this time, more effective vaccines have been developed that have the potential to save many thousands of lives in developing nations, while reducing the overall cost of treatment, and the costs to society.[53][54]

A rotavirus vaccine decrease the rates of diarrhea in a population.[1] New vaccines against rotavirus, *Shigella*, Enterotoxigenic Escherichia coli (ETEC), and cholera are under development, as well as other causes of infectious diarrhea.[*medical citation needed*]

### Nutrition

Dietary deficiencies in developing countries can be combated by promoting better eating practices. Supplementation with vitamin A and/or zinc. Zinc supplementation proved successful showing a significant decrease in the incidence of diarrheal disease compared to a control group.[55][56] The majority of the literature suggests that vitamin A supplementation is advantageous in reducing disease incidence.[57] Development of a supplementation strategy should take into consideration the fact that vitamin A supplementation was less effective in reducing diarrhea incidence when compared to vitamin A and zinc supplementation, and that the latter strategy was estimated to be significantly more cost effective.[58]

### Breastfeeding

Breastfeeding practices have been shown to have a dramatic effect on the incidence of diarrheal disease in poor populations. Studies across a number of developing nations have shown that those who receive exclusive breastfeeding during their first 6 months of life are better protected against infection with diarrheal diseases.[59] Exclusive breastfeeding is currently recommended during, at least, the first six months of an infant's life by the WHO.[60]

### Others

Probiotics decrease the risk of diarrhea in those taking antibiotics.[61]

## Management

In many cases of diarrhea, replacing lost fluid and salts is the only treatment needed. This is usually by mouth – oral rehydration therapy – or, in severe cases, intravenously.[1] Diet restrictions such as the BRAT diet are no longer recommended.[62] Research does not support the limiting of milk to children as doing so has no effect on duration of diarrhea.[63] To the contrary, WHO recommends that children with diarrhea continue to eat as sufficient nutrients are usually still absorbed to support continued growth and weight gain, and that continuing to eat also speeds up recovery of normal intestinal functioning.[12] CDC recommends that children and adults with cholera also continue to eat.[64]

Medications such as loperamide (Imodium) and bismuth subsalicylate may be beneficial; however they may be contraindicated in certain situations.[65]

### Fluids

*See also: Management of dehydration*

Oral rehydration solution (ORS) (a slightly sweetened and salty water) can be used to prevent dehydration. Standard home solutions such as salted rice water, salted yogurt drinks, vegetable and chicken soups with salt can be given. Home solutions such as water in which cereal has been cooked, unsalted soup, green coconut water, weak tea (unsweetened), and unsweetened fresh fruit juices can have from half a teaspoon to full teaspoon of salt (from one-and-a-half to three grams) added per liter. Clean plain water can also be one of several fluids

A person consuming oral rehydration solution.

given.[12] There are commercial solutions such as Pedialyte, and relief agencies such as UNICEF widely distribute packets of salts and sugar. A WHO publication for physicians recommends a homemade ORS consisting of one liter water with one teaspoon salt (3 grams) and two tablespoons sugar (18 grams) added[12] (approximately the "taste of tears"[66]). Rehydration Project recommends adding the same amount of sugar but only one-half a teaspoon of salt, stating that this more dilute approach is less risky with very little loss of effectiveness.[67] Both agree that drinks with too much sugar or salt can make dehydration worse.[12][67]

Appropriate amounts of supplemental zinc and potassium should be added if available. But the availability of these should not delay rehydration. As WHO points out, the most important thing is to begin preventing dehydration as early as possible.[12] In another example of prompt ORS hopefully preventing dehydration, CDC recommends for the treatment of cholera continuing to give Oral Rehydration Solution during travel to medical treatment.[64]

Vomiting often occurs during the first hour or two of treatment with ORS, especially if a child drinks the solution too quickly, but this seldom prevents successful rehydration since most of the fluid is still absorbed. WHO recommends that if a child vomits, to wait five or ten minutes and then start to give the solution again more slowly.[12]

Drinks especially high in simple sugars, such as soft drinks and fruit juices, are not recommended in children under 5 years of age as they may *increase* dehydration. A too rich solution in the gut draws water from the rest of the body, just as if the person were to drink sea water.[12][68] Plain water may be used if more specific and effective ORT preparations are unavailable or are not palatable.[68] Additionally, a mix of both plain water and drinks perhaps too rich in sugar and salt can alternatively be given to the same person, with the goal of providing a medium amount of sodium overall.[12] A nasogastric tube can be used in young children to administer fluids if warranted.[69]

## Eating

WHO recommends a child with diarrhea continue to be fed. Continued feeding speeds the recovery of normal intestinal function. In contrast, children whose food is restricted have diarrhea of longer duration and recover intestinal function more slowly. A child should also continue to be breastfed. The WHO states "Food should *never* be withheld and the child's usual foods should *not* be diluted. Breastfeeding should *always* be continued."[12] And in the specific example of cholera, CDC also makes the same recommendation.[64] In young children who are not breast-fed and live in the developed world, a lactose-free diet may be useful to speed recovery.[70]

## Medications

While antibiotics are beneficial in certain types of acute diarrhea, they are usually not used except in specific situations.[71][72] There are concerns that antibiotics may increase the risk of hemolytic uremic syndrome in people infected with Escherichia coli O157:H7.[73] In resource-poor countries, treatment with antibiotics may be beneficial.[72] However, some bacteria are developing antibiotic resistance, particularly *Shigella*.[74] Antibiotics can also cause diarrhea, and antibiotic-associated diarrhea is the most common adverse effect of treatment with general antibiotics.

While bismuth compounds (Pepto-Bismol) decreased the number of bowel movements in those with travelers' diarrhea, they do not decrease the length of illness.[75] Anti-motility agents like loperamide are also effective at reducing the number of stools but not the duration of disease.[4] These agents should only be used if bloody diarrhea is not present.[76]

Bile acid sequestrants such as cholestyramine can be effective in chronic diarrhea due to bile acid malabsorption. Therapeutic trials of these drugs are indicated in chronic diarrhea if bile acid malabsorption cannot be diagnosed with a specific test, such as SeHCAT retention.

### Alternative therapies

Zinc supplementation benefits children with diarrhea in developing countries, but only in infants over six months old. This supports the World Health Organization guidelines for zinc, but not in the very young.[77]

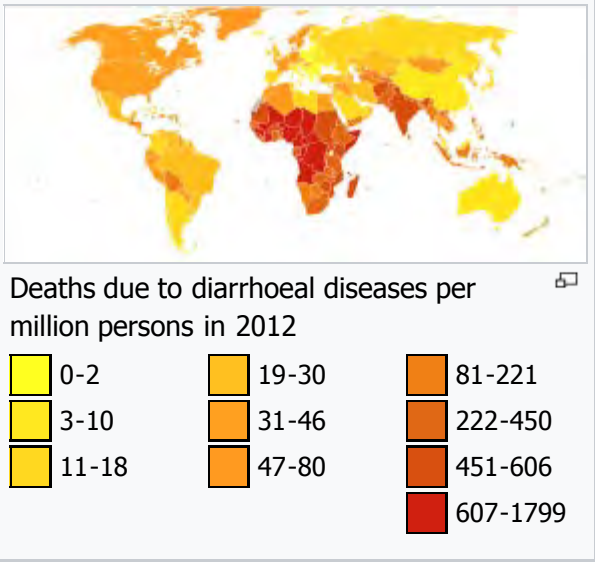
Probiotics reduce the duration of symptoms by one day and reduced the chances of symptoms lasting longer than four days by 60%.[78] The probiotic lactobacillus can help prevent antibiotic-associated diarrhea in adults but possibly not children.[79] For those with lactose intolerance, taking digestive enzymes containing lactase when consuming dairy products often improves symptoms.

## Epidemiology

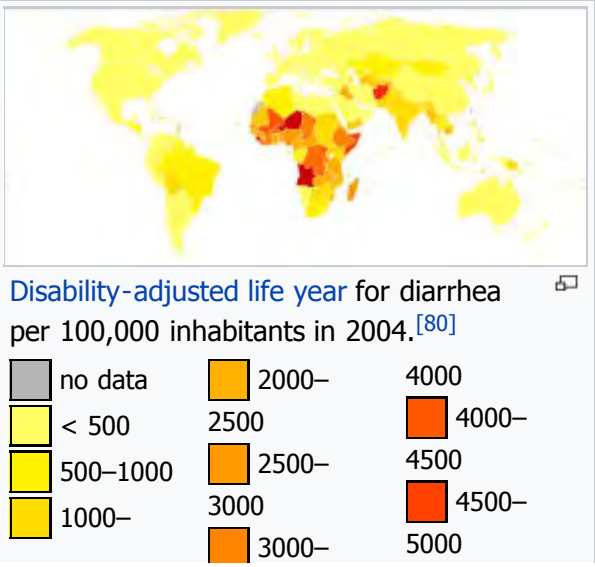
Worldwide in 2004, approximately 2.5 billion cases of diarrhea occurred, which resulted in 1.5 million deaths among children under the age of five.[1] Greater than half of these were in Africa and South Asia.[1] This is down from a death rate of 4.5 million in 1980 for gastroenteritis.[81] Diarrhea remains the second leading cause of infant mortality (16%) after pneumonia (17%) in this age group.[1]

The majority of such cases occur in the developing world, with over half of the recorded cases of childhood diarrhea occurring in Africa and Asia, with 696 million and 1.2 billion cases, respectively, compared to only 480 million in the rest of the world.[82]

Infectious diarrhea resulted in about 0.7 million deaths in children under five years old in 2011 and 250 million lost school days.[44][83] In the Americas, diarrheal disease accounts for a total of 10% of deaths among children aged 1–59 months while in South East Asia, it accounts for 31.3% of deaths.[84] It is estimated that around 21% of child mortalities in developing countries are due to diarrheal disease.[85]



Deaths due to diarrhoeal diseases per million persons in 2012



Disability-adjusted life year for diarrhea per 100,000 inhabitants in 2004.[80]

## Etymology

The word diarrhea is from the Ancient Greek διάρροια from διά *dia* "through" and ῥέω *rheo* "flow".

Diarrhea is the spelling in American English while diarrhoea is the spelling in Commonwealth English.

# Gallstone

From Wikipedia, the free encyclopedia

A **gallstone** is a stone formed within the gallbladder out of bile components.[1] The term **cholelithiasis** may refer to the presence of stones in the gallbladder or to the diseases caused by gallstones.[2] Most people with gallstones (about 80%) never have symptoms.[1][3] In 1–4% of those with gallstones, a crampy pain in the right upper part of the abdomen, known as biliary colic, occurs each year.[4] Complications of gallstones include inflammation of the gallbladder, inflammation of the pancreas, and liver inflammation.[1][4] Symptoms of these complications may include pain of more than five hours duration, fever, yellowish skin, vomiting, or tea-color urine.[1]

Risk factors for gallstones include birth control pills, pregnancy, a family history of gallstones, obesity, diabetes, liver disease, or rapid weight loss. Gallstones are formed in the gallbladder, typically from either cholesterol or bilirubin.[1] Gallstones may be suspected based on symptoms.[4] Diagnosis is then typically confirmed by ultrasound. Complications may be detected on blood tests.[1]

Prevention is by maintaining a healthy weight and eating a proper diet. If there are no symptoms, treatment is usually not needed. In those who are having gallbladder attacks surgery to remove the gallbladder is typically recommended. This can be either done through several small incisions or through a single larger incision. Surgery is typically done under general anesthesia. In those who are unable to have surgery, medication to try to dissolve the stones or shock wave lithotripsy may be tried.[1]

In the developed world, 10–15% of adults have gallstones.[4] Rates in many parts of Africa, however, are as low as 3%.[5] Gallbladder and biliary related diseases occurred in about 104 million people (1.6%) in 2013 and they resulted in 106,000 deaths.[6][7] Women more commonly have stones than men and they occur more commonly after the age of 40. Certain ethnic groups have gallstones more often than others. For example, 48% of American Indians have gallstones. Once the gallbladder is removed, outcomes are generally good.[1]

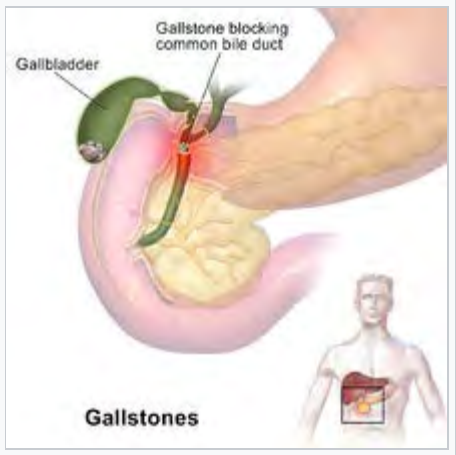
A video explanation of gallstones

## Definitions [edit]

Gallstone disease refers to the condition where gallstones are either in the gallbladder or common bile duct.[1] The presence of stones in the gallbladder is referred to as cholelithiasis, from the Greek *chol-* (bile) + *lith-* (stone) + *iasis-* (process). If gallstones migrate into the ducts of the biliary tract, the condition is referred to as choledocholithiasis, from the Greek *chol-* (bile) + *docho-* (duct) + *lith-* (stone) + *iasis-* (process). Choledocholithiasis is frequently associated with obstruction of the biliary tree, which in turn can lead to acute ascending cholangitis, from the Greek: *chol-* (bile) + *ang-* (vessel) + *itis-* (inflammation), a serious infection of the bile ducts. Gallstones within the ampulla of Vater can obstruct the exocrine system of the pancreas, which in turn can result in pancreatitis.

## Signs and symptoms [edit]



Gallstones

Gallstones may be asymptomatic, even for years. These gallstones are called "silent stones" and do not require treatment.[8][9] The size and number of gallstones present does not appear to influence whether or not people are symptomatic or asymptomatic.[10] A characteristic symptom of gallstones is a gallstone attack, in which a person may experience colicky pain in the upper-right side of the abdomen, often accompanied by nausea and vomiting, that steadily increases for approximately 30 minutes to several hours. A person may also experience referred pain between the shoulder blades or below the right shoulder. These symptoms may resemble those of a "kidney stone attack". Often, attacks occur after a particularly fatty meal and almost always happen at night, and after drinking.

In addition to pain, nausea, and vomiting, a person may experience a fever. If the stones block the duct and cause bilirubin to leak into the bloodstream and surrounding tissue, there may also be jaundice and itching. This can also lead to confusion. If this is the case, the liver enzymes are likely to be raised.[11]

### Other complications [edit]

Rarely, in cases of severe inflammation, gallstones may erode through the gallbladder into adherent bowel potentially causing an obstruction termed gallstone ileus.[12]

Other complications include ascending cholangitis if there is a bacterial infection which can cause purulent inflammation in the biliary tree and liver, and acute pancreatitis as blockage of the bile ducts can prevent

active enzymes being secreted into the bowel, instead damaging the pancreas.[11]

## Risk factors [edit]

Gallstone risk increases for females (especially before menopause) and for people near or above 40 years;[13] the condition is more prevalent among both North and South Americans and among those of European descent than among other ethnicities. A lack of melatonin could significantly contribute to gallbladder stones, as melatonin inhibits cholesterol secretion from the gallbladder, enhances the conversion of cholesterol to bile, and is an antioxidant, which is able to reduce oxidative stress to the gallbladder.[14] Researchers believe that gallstones may be caused by a combination of factors, including inherited body chemistry, body weight, gallbladder motility (movement), and low calorie diet.[*citation needed*] The absence of such risk factors does not, however, preclude the formation of gallstones.

A clear relationship has been proven between diet and gallstone formation. According to a study limited to 80 patients in Nepal, non-vegetarians have 9 times the incidence of gallstones compared to vegetarians.[15] The methodology of the study has been disputed.[16] Nutritional factors that may increase risk of gallstones include constipation; eating fewer meals per day; low intake of the nutrients folate, magnesium, calcium, and vitamin C;[17] and, at least for men, a high intake of carbohydrate, a high glycemic load, and high glycemic index diet.[18] Wine and whole-grained bread may decrease the risk of gallstones.[19]

Rapid weight loss increases risk of gallstones.[20] Patients taking orlistat, a weight loss drug, may already be at increased risk for the formation of gall stones. Weight loss with orlistat can increase the risk of gall stones.[21] On the contrary, ursodeoxycholic acid (UCDA), a bile acid, also a drug marketed as Ursodiol, appears to prevent formation of gallstones during weight loss.[22] A high fat diet during weight loss also appears to prevent gallstones.[22]

Pigment gallstones are most commonly seen in the developing world. Risk factors for pigment stones include hemolytic anemias (such as from sickle-cell disease and hereditary spherocytosis), cirrhosis, and biliary tract infections.[23] People with erythropoietic protoporphyria (EPP) are at increased risk to develop gallstones.[24][25] Additionally, prolonged use of proton pump inhibitors has been shown to decrease gallbladder function, potentially leading to gallstone formation.[26]

## Pathophysiology [edit]

Cholesterol gallstones develop when bile contains too much cholesterol and not enough bile salts. Besides a high concentration of cholesterol, two other factors are important in causing gallstones. The first is how often and how well the gallbladder contracts; incomplete and infrequent emptying of the gallbladder may cause the bile to become overconcentrated and contribute to gallstone formation. This can be caused by high resistance to the flow of bile out of the gallbladder due to the complicated internal geometry of the cystic duct.[27] The second factor is the presence of proteins in the liver and bile that either promote or inhibit cholesterol crystallization into gallstones. In addition, increased levels of the hormone estrogen, as a result of pregnancy or hormone therapy, or the use of combined (estrogen-containing) forms of hormonal contraception, may increase cholesterol levels in bile and also decrease gallbladder movement, resulting in gallstone formation.

### Composition [edit]

Gallstones can vary in size and shape from as small as a grain of sand to as large as a golf ball.[28] The gallbladder may contain a single large stone or many smaller ones. Pseudoliths, sometimes referred to as sludge, are thick secretions that may be present within the gallbladder, either alone or in conjunction with fully formed gallstones. The clinical presentation is similar to that of cholelithiasis.[*citation needed*] The composition of gallstones is affected by age, diet and ethnicity.[29] On the basis of their composition, gallstones can be divided into the following types:

Gallbladder opened to show small cholesterol gallstones

µCT of a gallstone

The large, yellow stone is largely cholesterol, while the green-to-brown stones is mostly bile pigments

Play media

Images of a CT of gallstones

Large gallstone

## Cholesterol stones [edit]

Cholesterol stones vary from light yellow to dark green or brown or chalk white and are oval, usually solitary, between 2 and 3 cm long, each often having a tiny, dark, central spot. To be classified as such, they must be at least 80% cholesterol by weight (or 70%, according to the Japanese- classification system).[30] Between 35% and 90% of stones are cholesterol stones.[3]

## Bilirubin stones [edit]

Bilirubin ("pigment", "black pigment") stones are small, dark (often appearing black), and usually numerous. They are composed primarily of bilirubin (insoluble bilirubin pigment polymer) and calcium (calcium phosphate) salts that are found in bile. They contain less than 20% of cholesterol (or 30%, according to the Japanese-classification system).[30] Between 2% and 30% of stones are bilirubin stones.[3]

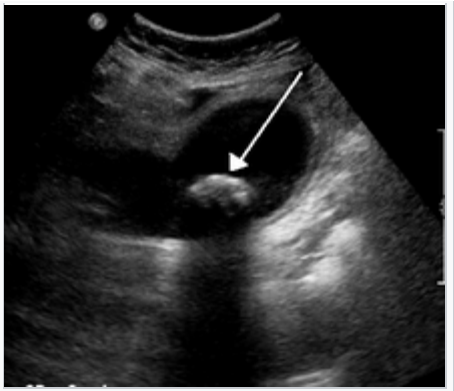
## Mixed stones [edit]

Mixed ("Brown Pigment") stones typically contain 20–80% cholesterol (or 30–70%, according to the Japanese- classification system).[30] Other common constituents are calcium carbonate, palmitate phosphate, bilirubin and other bile pigments (calcium bilirubinate, calcium palmitate and calcium stearate). Because of their calcium content, they are often radiographically visible. They typically arise secondary to infection of the biliary tract which results in the release of β-glucuronidase (by injured hepatocytes and bacteria) which hydrolyzes bilirubin glucuronides and increases the amount of unconjugated bilirubin in bile. Between 4% and 20% of stones are mixed.[3]

# Diagnosis [edit]

Diagnosis is than typically confirmed by ultrasound. Complications may be detected on blood tests.[1]

A positive Murphy's sign is a common finding on physical examination during a gallbladder attack.

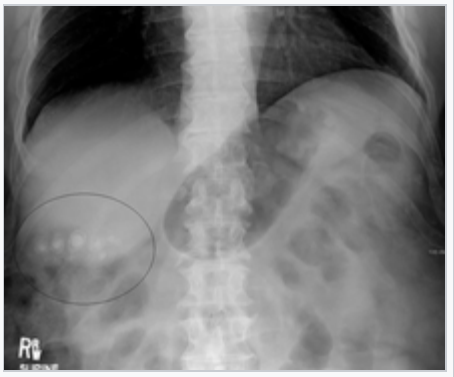


A 1.9 cm gallstone impacted in the neck of the gallbladder and leading to cholecystitis as seen on ultrasound. There is 4 mm gall bladder wall thickening.

## Treatment [edit]

### Surgical [edit]

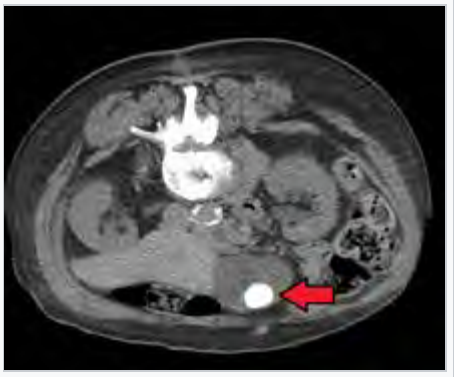
Cholecystectomy (gallbladder removal) has a 99% chance of eliminating the recurrence of cholelithiasis. Surgery is only indicated in symptomatic patients. The lack of a gallbladder may have no negative consequences in many people. However, there is a portion of the population—between 10 and 15%—who develop a condition called postcholecystectomy syndrome[31] which may cause gastrointestinal distress and persistent pain in the upper-right abdomen, as well as a 10% risk of developing chronic diarrhea.[32]



Gallstones as seen on plain X-ray

There are two surgical options for cholecystectomy:

- Open cholecystectomy is performed via an abdominal incision (laparotomy) below the lower right ribs. Recovery typically requires 3–5 days of hospitalization, with a return to normal diet a week after release and to normal activity several weeks after release.[8]
- Laparoscopic cholecystectomy, introduced in the 1980s,[33] is performed via three to four small puncture holes for a camera and instruments. Post-operative care typically includes a same-day release or a one night hospital stay, followed by a few days of home rest and pain medication.[8] Laparoscopic cholecystectomy patients can, in general, resume normal diet and light activity a week after release, with some decreased energy level and minor residual pain continuing for a month or two. Studies have shown that this procedure is as effective as the more invasive open cholecystectomy, provided the stones are accurately located by cholangiogram prior to the procedure so that they can all be removed.[*citation needed*]



Large gallstone as seen on CT

### Medical [edit]

Cholesterol gallstones can sometimes be dissolved with ursodeoxycholic acid taken by mouth, but it may be necessary for the person to take this medication for years.[34] Gallstones may recur, however, once the drug is stopped. Obstruction of the common bile duct with gallstones can sometimes be relieved by endoscopic retrograde sphincterotomy (ERS) following endoscopic retrograde cholangiopancreatography (ERCP). Gallstones can be broken up using a procedure called extracorporeal shock wave lithotripsy (often simply called "lithotripsy"),[34] which is a method of concentrating ultrasonic shock waves onto the stones to break them into tiny pieces. They are then passed safely in the feces. However, this form of treatment is suitable only when there is a small number of gallstones.

## Other animals [edit]

Gallstones are a valuable by-product of animals butchered for meat because their use as a purported antipyretic and antidote in the folk remedies of some cultures, in particular, in China. The finest gallstones

tend to be sourced from old dairy cows, which are called *niuhuang* (yellow thing of cattle) in Chinese. Much as in the manner of diamond mines, slaughterhouses carefully scrutinize workers for gallstone theft.[35]

# Gastritis

From Wikipedia, the free encyclopedia

**Gastritis** is inflammation of the lining of the stomach. It may occur as a short episode or may be of a long duration. There may be no symptoms but, when symptoms are present, the most common is upper abdominal pain.[1] Other possible symptoms include nausea and vomiting, bloating, loss of appetite and heartburn.[1][2] Complications may include bleeding, stomach ulcers, and stomach tumors.[1] When due to autoimmune problems, low red blood cells due to not enough vitamin B12 may occur, a condition known as pernicious anemia.[3]

Common causes include infection with *Helicobacter pylori* and use of NSAIDs. Less common causes include alcohol, smoking, cocaine, severe illness, autoimmune problems, radiation therapy and Crohn's disease, among others.[1][4] Endoscopy, a type of X-ray known as an upper gastrointestinal series, blood tests, and stool tests may help with diagnosis.[1] The symptoms of gastritis may be a presentation of a myocardial infarction. Other conditions with similar symptoms include inflammation of the pancreas, gallbladder problems, and peptic ulcer disease.[2]

Prevention is by avoiding things that cause the disease.[5] Treatment includes medications such as antacids, H2 blockers, or proton pump inhibitors.[1] During an acute attack drinking viscous lidocaine may help.[6] If gastritis is due to NSAIDs these may be stopped. If *H. pylori* is present it may be treated with a combination of antibiotics such as amoxicillin and clarithromycin.[1] For those with pernicious anemia, vitamin B12 supplements are recommended either by mouth or by injection.[3] People are usually advised to avoid foods that bother them.[7]

Gastritis is believed to affect about half of people worldwide.[5] In 2013 there were approximately 90 million new cases of the condition.[8] As people get older the disease becomes more common.[5] It, along with a similar condition in the first part of the intestines known as duodenitis, resulted in 60,000 deaths in 2013.[9] *H. pylori* was first discovered in 1981 by Barry Marshall and Robin Warren.[10]

## Signs and symptoms [edit]

Many people with gastritis experience no symptoms at all. However, upper central abdominal pain is the most common symptom; the pain may be dull, vague, burning, aching, gnawing, sore, or sharp.[11] Pain is usually located in the upper central portion of the abdomen,[12] but it may occur anywhere from the upper left portion of the abdomen around to the back.

A peptic ulcer may accompany gastritis. Endoscopic image.

Other signs and symptoms may include the following:

- Nausea
- Vomiting (if present, may be clear, green or yellow, blood-streaked, or completely bloody, depending on the severity of the stomach inflammation)
- Belching (if present, usually does not relieve the pain much)
- Bloating
- Early satiety[11]
- Loss of appetite
- Unexplained weight loss

## Cause [edit]

Common causes include *Helicobacter pylori* and NSAIDs. Less common causes include alcohol, cocaine, severe illness and Crohn disease, among others.[1]

### *Helicobacter pylori* [edit]

*Helicobacter pylori* colonizes the stomachs of more than half of the world's population, and the infection continues to play a key role in the pathogenesis of a number of gastroduodenal diseases. Colonization of the gastric mucosa with *Helicobacter pylori* results in the development of chronic gastritis in infected individuals, and in a subset of patients chronic gastritis progresses to complications (e.g., ulcer disease, gastric neoplasias, some distinct extragastric disorders).[13] However, over 80 percent of individuals infected with the bacterium are asymptomatic and it has been postulated that it may play an important role in the natural stomach ecology.[14]

### Critical illness [edit]

Gastritis may also develop after major surgery or traumatic injury ("Cushing ulcer"), burns ("Curling ulcer"), or severe infections. Gastritis may also occur in those who have had weight loss surgery resulting in the banding or reconstruction of the digestive tract.

Edit links

### Diet [edit]

Evidence does not support a role for specific foods including spicy foods and coffee in the development of

peptic ulcers.[15] People are usually advised to avoid foods that bother them.[7]

## Pathophysiology [edit]

### Acute [edit]

Acute erosive gastritis typically involves discrete foci of surface necrosis due to damage to mucosal defenses.[16] NSAIDs inhibit cyclooxygenase-1, or COX-1, an enzyme responsible for the biosynthesis of eicosanoids in the stomach, which increases the possibility of peptic ulcers forming.[17] Also, NSAIDs, such as aspirin, reduce a substance that protects the stomach called prostaglandin. These drugs used in a short period are not typically dangerous. However, regular use can lead to gastritis.[18] Additionally, severe physiologic stress ("stress ulcers") from sepsis, hypoxia, trauma, or surgery, is also a common etiology for acute erosive gastritis. This form of gastritis can occur in more than 5% of hospitalized patients.

Also, note that alcohol consumption does not cause chronic gastritis. It does, however, erode the mucosal lining of the stomach; low doses of alcohol stimulate hydrochloric acid secretion. High doses of alcohol do not stimulate secretion of acid.[19]

### Chronic [edit]

Chronic gastritis refers to a wide range of problems of the gastric tissues.[16] The immune system makes proteins and antibodies that fight infections in the body to maintain a homeostatic condition. In some disorders the body targets the stomach as if it were a foreign protein or pathogen; it makes antibodies against, severely damages, and may even destroy the stomach or its lining.[18] In some cases bile, normally used to aid digestion in the small intestine, will enter through the pyloric valve of the stomach if it has been removed during surgery or does not work properly, also leading to gastritis. Gastritis may also be caused by other medical conditions, including HIV/AIDS, Crohn's disease, certain connective tissue disorders, and liver or kidney failure. Since 1992, chronic gastritis lesions are classified according to the Sydney system.[20]

### Metaplasia [edit]

Mucous gland metaplasia, the reversible replacement of differentiated cells, occurs in the setting of severe damage of the gastric glands, which then waste away (atrophic gastritis) and are progressively replaced by mucous glands. Gastric ulcers may develop; it is unclear if they are the causes or the consequences. Intestinal metaplasia typically begins in response to chronic mucosal injury in the antrum, and may extend to the body. Gastric mucosa cells change to resemble intestinal mucosa and may even assume absorptive characteristics. Intestinal metaplasia is classified histologically as complete or incomplete. With complete metaplasia, gastric mucosa is completely transformed into small-bowel mucosa, both histologically and functionally, with the ability to absorb nutrients and secrete peptides. In incomplete metaplasia, the epithelium assumes a histologic appearance closer to that of the large intestine and frequently exhibits dysplasia.[16]

## Diagnosis [edit]

Often, a diagnosis can be made based on the patient's description of their symptoms, but other methods which may be used to verify gastritis include:

- Blood tests:
  - Blood cell count
  - Presence of *H. pylori*
  - Liver, kidney, gallbladder, or pancreas functions
- Urinalysis
- Stool sample, to look for blood in the stool
- X-rays

- ECGs
- Endoscopy, to check for stomach lining inflammation and mucous erosion
- Stomach biopsy, to test for gastritis and other conditions[21]

## Treatment [edit]

Antacids are a common treatment for mild to medium gastritis.[22] When antacids do not provide enough relief, medications such as $H_2$ blockers and proton-pump inhibitors that help reduce the amount of acid are often prescribed.[22][23]

Cytoprotective agents are designed to help protect the tissues that line the stomach and small intestine. They include the medications sucralfate and misoprostol. If NSAIDs are being taken regularly, one of these medications to protect the stomach may also be taken. Another cytoprotective agent is bismuth subsalicylate.

Several regimens are used to treat *H. pylori* infection. Most use a combination of two antibiotics and a proton pump inhibitor. Sometimes bismuth is also added to the regimen.

# Gastrointestinal bleeding

From Wikipedia, the free encyclopedia

**Gastrointestinal bleeding**, **gastrointestinal hemorrhage**, is all forms of bleeding in the gastrointestinal tract, from the mouth to the rectum.[1] When there is significant blood loss over a short time, symptoms may include vomiting red blood, vomiting black blood, bloody stool, or black stool. Small amounts of bleeding over a long time may cause iron-deficiency anemia resulting in feeling tired or heart-related chest pain.[2] Other symptoms may include abdominal pain, shortness of breath, pale skin, or passing out.[1][2] Sometimes in those with small amounts of bleeding no symptoms may be present.[2]

Bleeding is typically divided into two main types: upper gastrointestinal bleeding and lower gastrointestinal bleeding.[3] Causes of upper GI bleeds include: peptic ulcer disease, esophageal varices due to liver cirrhosis and cancer, among others.[4] Causes of lower GI bleeds include: hemorrhoids, cancer, and inflammatory bowel disease among others.[3] Diagnosis typically begins with a medical history and physical examination, along with blood tests. Small amounts of bleeding may be detected by fecal occult blood test. Endoscopy of the lower and upper gastrointestinal track may locate the area of bleeding. Medical imaging may be useful in cases that are not clear.[2]

Initial treatment focuses on resuscitation which may include intravenous fluids and blood transfusions.[5] Often blood transfusions are not recommended unless the hemoglobin is less than 70 or 80 g/L.[6][7] Treatment with proton pump inhibitors, octreotide, and antibiotics may be considered in certain cases.[8][9][10] If other measures are not effective, an esophageal balloon may be attempted in those with persumed esophageal varices.[3] Endoscopy of the esophagus, stomach, and duodenum or endoscopy of the large bowel are generally recommended within 24 hours and may allow treatment as well as diagnosis.[5]

An upper GI bleed is more common than lower GI bleed.[3] An upper GI bleed occurs in 50 to 150 per 100,000 adults per year.[11] A lower GI bleed is estimated to occur in 20 to 30 per 100,000 per year.[3] It results in about 300,000 hospital admissions a year in the United States.[2] Risk of death from a GI bleed is between 5% and 30%.[2][6] Risk of bleeding is more common in males and increases with age.[3]

Contents

## Signs and symptoms [edit]

Gastrointestinal bleeding can range from small non-visible amounts, which are only detected by laboratory testing, to massive bleeding where bright red blood is passed and shock develops. With bleeding that is rapid there may be syncope.[12]

Blood that is digested may appear black rather than red, resulting in "coffee ground" vomit or tar colored stool called melena.[3]

Other signs and symptoms include feeling tired, dizziness, and pale skin color.[12]

## Differential diagnosis [edit]

Gastrointestinal bleeding can be roughly divided into two clinical syndromes: upper gastrointestinal bleeding and lower gastrointestinal bleeding.[3] About 2/3 of all GI bleeds are from upper sources and 1/3 from lower sources.[13] Common causes of gastrointestinal bleeding include infections, cancers, vascular disorders, adverse effects of medications, and blood clotting disorders.[3] Obscure gastrointestinal bleeding (OGIB) is when a source is unclear following investigation.

### Upper gastrointestinal [edit]

*Main article: Upper gastrointestinal bleeding*

Upper gastrointestinal bleeding is from a source between the pharynx and the ligament of Treitz. An upper source is characterised by hematemesis (vomiting up blood) and melena (tarry stool containing altered blood). About half of cases are due to peptic ulcer disease.[4] Esophageal inflammation and erosive disease are the next most common causes.[4] In those with liver cirrhosis, 50–60% of bleeding is due to esophageal varices.[4] Approximately half of those with peptic ulcers have an *H. pylori* infection.[4] Other causes include gastric or duodenal ulcers, Mallory-Weiss tears, cancer, and angiodysplasia.[3]

A number of medications are found to cause upper GI bleeds.[14] NSAIDs or COX-2 inhibitors increase the risk about fourfold.[14] SSRIs, corticosteroids, and anticoagulants may also increase the risk.[14] The risk with dabigatran is 30% greater than that with warfarin.[15]

### Lower gastrointestinal [edit]

*Main article: Lower gastrointestinal bleeding*

Lower gastrointestinal bleeding is typically from the colon, rectum or anus.[3] Common causes of lower gastrointestinal bleeding include hemorrhoids, cancer, angiodysplasia, ulcerative colitis, Crohn's disease, and

aortoenteric fistula.[3] It may be indicated by the passage of fresh red blood rectally, especially in the absence of bloody vomiting. Isolated melena may originate from anywhere between the stomach and the proximal colon.

### Other [edit]

A number of foods and medications can turn the stool either red or black.[3] Bismuth found in many antacids may turn stools black as may activated charcoal.[3] Blood from the vagina or urinary tract may also be confused with blood in the stool.[3]

## Diagnostic approach [edit]

Diagnosis is often based on direct observation of blood in the stool or vomit. This can be confirmed with a fecal occult blood test. Differentiating between upper and lower bleeding in some cases can be difficult. The severity of an upper GI bleed can be judged based on the Blatchford score[5] or Rockall score.[14] The Rockall score is the more accurate of the two.[14] As of 2008 there is no scoring system useful for lower GI bleeds.[14]

### Clinical [edit]

Gastric aspiration and or lavage, where a tube is inserted into the stomach via the nose in an attempt to determine if there is blood in the stomach, if negative does not rule out an upper GI bleed[16] but if positive is useful for ruling one in.[13] Clots in the stool indicate a lower GI source while melana stools an upper one.[13]

### Laboratory testing [edit]

Recommended laboratory blood testing includes: cross matching blood, hemoglobin, hematocrit, platelets, coagulation time, and electrolytes.[5] If the ratio of blood urea nitrogen to creatinine is greater than 30 the source is more likely from the upper GI tract.[13]

### Imaging [edit]

A CT angiography is useful for determining the exact location of the bleeding within the gastrointestinal tract.[17] Nuclear scintigraphy is a sensitive test for detecting occult gastrointestinal bleeding when direct imaging with upper and lower endoscopies are negative. Direct angiography allows for embolization of a bleeding source, but requires a bleeding rate faster than 1mL/minute.[18]

## Prevention [edit]

In those with significant varices or cirrhosis nonselective β-blockers reduce the risk of future bleeding.[9] With a target heart rate of 55 beats per minute they reduce the absolute risk of bleeding by 10%.[9] Endoscopic band ligation (EBL) is also effective at improving outcomes.[9] Either B-blockers or EBL are recommended as initial preventative measures.[9] In those who have had a previous varcial bleed both treatments are recommended.[9] With some evidence supporting the addition of isosorbide mononitrate.[19] Testing for and treating those who are positive for *H. pylori* is recommended.[14] Transjugular intrahepatic portosystemic shunting (TIPS) may be used to prevent bleeding in people who re-bleed despite other measures.[14]

## Treatment [edit]

The initial focus is on resuscitation beginning with airway management and fluid resuscitation using either intravenous fluids and or blood.[5] A number of medications may improve outcomes depending on the source of the bleeding.[5]

## Peptic ulcers [edit]

Based on evidence from people with other health problems crystalloid and colloids are believed to be equivalent for peptic ulcer bleeding.[5] Proton pump inhibitors (PPI) may reduce mortality in those with severe disease as well as the risk of re-bleeding and the need for surgery among this group.[8] Oral and intravenous formulations may be equivalent; however, the evidence to support this is suboptimal.[20] In those with less severe disease and where endoscopy is rapidly available, they are of less immediate clinical importance.[21] There is tentative evidence of benefit for tranexamic acid which inhibits clot breakdown.[22] Somatostatin and octreotide, while recommended for varicial bleeding, have not been found to be of general use for non variceal bleeds.[5] After treatment of a high risk bleeding ulcer endoscopically giving a PPI once or a day rather than as an infusion appears to work just as well and is less expensive (the method may be either by mouth or intravenously).[23]

## Variceal bleeding [edit]

For initial fluid replacement colloids or albumin is preferred in people with cirrhosis.[5] Medications typically include octreotide or, if not available, vasopressin and nitroglycerin to reduce portal venous pressures.[9] Terlipressin appears to be more effective than octreotide, but it is not available in many areas of the world.[14][24] It is the only medication that has been shown to reduce mortality in acute variceal bleeding.[24] This is in addition to endoscopic banding or sclerotherapy for the varices.[9] If this is sufficient then beta blockers and nitrates may be used for the prevention of re-bleeding.[9] If bleeding continues, balloon tamponade with a Sengstaken-Blakemore tube or Minnesota tube may be used in an attempt to mechanically compress the varices.[9] This may then be followed by a transjugular intrahepatic portosystemic shunt.[9] In those with cirrhosis, antibiotics decrease the chance of bleeding again, shorten the length of time spent in hospital, and decrease mortality.[10] Octreotide reduces the need for blood transfusions[25] and may decrease mortality.[26] No trials of vitamin K have been conducted.[27]

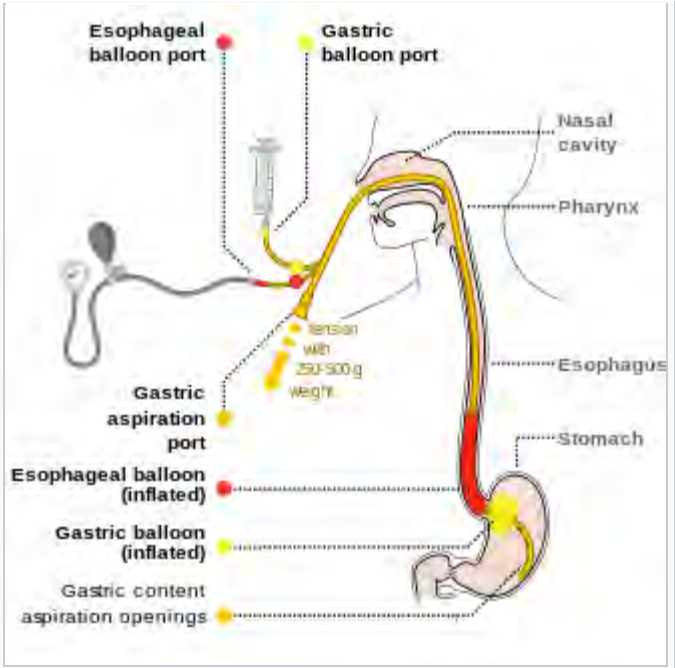
## Blood products [edit]

The evidence for benefit of blood transfusions in GI bleed is poor with some evidence finding harm.[11] In those in shock O-negative packed red blood cells are recommended.[3] If large amounts of pack red blood cells are used additional platelets and fresh frozen plasma (FFP) should be administered to prevent coagulopathies.[5] In alcoholics FFP is suggested before confirmation of a coagulopathy due to presumed blood clotting problems.[3] Evidence supports holding off on blood transfusions in those who have a hemoglobin greater than 7 to 8 g/dL and moderate bleeding, including in those with preexisting coronary artery disease.[6][7]

If the INR is greater than 1.5 to 1.8 correction with fresh frozen plasma or prothrombin complex may decrease mortality.[5] Evidence of a harm or benefit of recombinant activated factor VII in those with liver diseases and gastrointestinal bleeding is not determined.[28] A massive transfusion protocol may be used, but there is a lack of evidence for this indication.[14]

## Procedures [edit]

The benefits versus risks of placing a nasogastric tube in those with upper GI bleeding are not determined.[5] Endoscopy within 24 hours is recommended,[5] in addition to medical management.[29] A number of endoscopic treatments may be used, including:



The Blakemore esophageal balloon used for stopping esophageal bleeds if other measures have failed

epinephrine injection, band ligation, sclerotherapy, and fibrin glue depending on what is found.[3] Prokinetic agents such as erythromycin before endocopy can decrease the amount of blood in the stomach and thus improve the operators view.[5] They also decrease the amount of blood transfusions required.[30] Early endoscopy decreases hospital and the amount of blood transfusions needed.[5] A second endoscopy within a day is routinely recommended by some[14] but by others only in specific situations.[18] Proton pump inhibitors, if they have not been started earlier, are recommended in those in whom high risk signs for bleeding are found.[5] High and low dose PPIs appear equivalent at this point.[31] It is also recommended that people with high risk signs are kept in hospital for at least 72 hours.[5] Those at low risk of re-bleeding may begin eating typically 24 hours following endoscopy.[5] If other measures fail or are not available, esophageal balloon tamponade may be attempted.[3] While there is a success rate up to 90%, there are some potentially significant complications including aspiration and esophageal perforation.[3]

Colonoscopy is useful for the diagnosis and treatment of lower GI bleeding.[3] A number of techniques may be employed including: clipping, cauterizing, and sclerotherapy.[3] Preparation for colonoscopy takes a minimum of six hours which in those bleeding briskly may limit its applicability.[32] Surgery, while rarely used to treat upper GI bleeds, is still commonly used to manage lower GI bleeds by cutting out the part of the intestines that is causing the problem.[3] Angiographic embolization may be used for both upper and lower GI bleeds.[3] Transjugular intrahepatic portosystemic shunting (TIPS) may also be considered.[14]

## Prognosis [edit]

Death in those with a GI bleed is more commonly due to other illnesses (some of which may have contributed to the bleed, such as cancer or cirrhosis), than the bleeding itself.[3] Of those admitted to a hospital because of a GI bleed, death occurs in about 7%.[14] Despite treatment, re-bleeding occurs in about 7–16% of those with upper GI bleeding.[4] In those with esophageal varices, bleeding occurs in about 5–15% a year and if they have bled once, there is a higher risk of further bleeding within six weeks.[9] Testing and treating *H. pylori* if found can prevent re-bleeding in those with peptic ulcers.[5] The benefits versus risks of restarting blood thinners such as aspirin or warfarin and anti-inflammatories such as NSAIDs need to be carefully considered.[5] If aspirin is needed for cardiovascular disease prevention, it is reasonable to restart it within seven days in combination with a PPI for those with nonvariceal upper GI bleeding.[18]

## Epidemiology [edit]

Gastrointestinal bleeding from the upper tract occurs in 50 to 150 per 100,000 adults per year.[11] It is more common than lower gastrointestinal bleeding which is estimated to occur at the rate of 20 to 30 per 100,000 per year.[3] Risk of bleeding is more common in males, and increases with age.[3]

# Gastrointestinal perforation

From Wikipedia, the free encyclopedia

**Gastrointestinal perforation**, also known as **ruptured bowel**, is a hole in the wall of part of the gastrointestinal tract.[2] The gastrointestinal tract includes the esophagus, stomach, small intestine, and large intestine.[2][1] Symptoms include severe abdominal pain and tenderness.[2] When the hole is in the stomach or early part of the small intestine the onset of pain is typically sudden while with a hole in the large intestine onset may be more gradual.[2] The pain is usually constant in nature.[2] Sepsis, with an increased heart rate, increased breathing rate, fever, and confusion may occur.[2]

The cause can include trauma such as from a knife wound, eating a sharp object, or a medical procedure such as colonoscopy, bowel obstruction such as from a volvulus, colon cancer, or diverticulitis, stomach ulcers, ischemic bowel, and a number of infections including *C. difficile*.[2] A hole allows intestinal contents to enter the abdominal cavity.[2] The entry of bacteria results in a condition known as peritonitis or in the formation of an abscess.[2] A hole in the stomach can also lead to a chemical peritonitis due to gastric acid.[2] A CT scan is typically the preferred method of diagnosis; however, free air from a perforation can often be seen on plain X-ray.[2]

Perforation anywhere along the gastrointestinal tract typically requires emergency surgery in the form of an exploratory laparotomy.[2] This is usually carried out along with intravenous fluids and antibiotics.[2] A number of different antibiotics may be used such as piperacillin/tazobactam or the combination of ciprofloxacin and metronidazole.[3][4] Occasionally the hole can be sewn closed while other times a bowel resection is required.[2] Even with maximum treatment the risk of death can be as high as 50%.[2] A hole from a stomach ulcer occurs in about 1 per 10,000 people per year, while one from diverticulitis occurs in about 0.4 per 10,000 people per year.[5][1]

## Signs and symptoms [edit]

Sudden pain in the epigastrium to the right of the midline indicates perforation of a duodenal ulcer. In a gastric ulcer perforation creates a history of burning pain in epigastrium, with flatulence and dyspepsia. A history of drug intake with insufficient food intake may be present.

In intestinal perforation pain starts from the site of perforation and spreads across the abdomen.

Gastrointestinal perforation results in severe abdominal pain intensified by movement, nausea, vomiting and hematemesis. Later symptoms include fever and or chills.[6]

In any case, the abdomen becomes rigid with tenderness and rebound tenderness. After some time the abdomen becomes silent and heart sounds can be heard all over. Patient stops passing flatus and motion, abdomen is distended.

The symptoms of esophageal rupture may include sudden onset chest pain.

## Causes [edit]

Underlying causes include gastric ulcers, duodenal ulcers, appendicitis, gastrointestinal cancer, diverticulitis, inflammatory bowel disease, superior mesenteric artery syndrome, trauma and ascariasis. Typhoid fever,[7] non-steroidal anti-inflammatory drugs,[8][9] ingestion of corrosives may also be responsible.[10]

## Diagnosis [edit]

On x-rays, gas may be visible in the abdominal cavity. Gas is easily visualized on x-ray while the patient is in an upright position. The perforation can often be visualised using computed tomography. White blood cells are often elevated.

## Treatment [edit]

Surgical intervention is nearly always required in form of exploratory laparotomy and closure of perforation with peritoneal wash. Occasionally they may be managed laparoscopically.[11]

Conservative treatment including intravenous fluids, antibiotics, nasogastric aspiration and bowel rest is indicated only if the person is nontoxic and clinically stable.[*citation needed*]

# Hemorrhoid

From Wikipedia, the free encyclopedia

**Hemorrhoids**, (alternative spelling **haemorrhoids**), also called **piles**, are vascular structures in the anal canal.[3][4] In their normal state, they are cushions that help with stool control.[2] They become a disease when swollen or inflamed; the unqualified term "hemorrhoid" is often used to mean the disease.[4] The signs and symptoms of hemorrhoids depend on the type present.[5] Internal hemorrhoids usually present with painless, bright red rectal bleeding when defecating.[6][5] External hemorrhoids often result in pain and swelling in the area of the anus. If bleeding occurs it is usually darker.[5] Symptoms frequently get better after a few days.[6] A skin tag may remain after the healing of an external hemorrhoid.[5]

While the exact cause of hemorrhoids remains unknown, a number of factors which increase pressure in the abdomen are believed to be involved.[5] This may include constipation, diarrhea, and sitting on the toilet for a long time. Hemorrhoids are also more common during pregnancy. Diagnosis is made by looking at the area.[6] Many people incorrectly refer to any symptom occurring around the anal area as "hemorrhoids" and serious causes of the symptoms should be ruled out.[2] Colonoscopy or sigmoidoscopy is reasonable to confirm the diagnosis and rule out more serious causes.[7]

Often, no specific treatment is needed.[7] Initial measures consists of increasing fiber intake, drinking fluids to maintain hydration, NSAIDs to help with pain, and rest.[1] Medicated creams applied to the area are poorly supported by evidence.[7] A number of minor procedures may be performed if symptoms are severe or do not improve with conservative management. Surgery is reserved for those who fail to improve following these measures.[8]

Half to two thirds of people have problems with hemorrhoids at some point in their lives.[1][6] Males and females are affected about equally commonly.[1] Hemorrhoids affect people most often between 45 and 65 years of age.[9] It is more common among the wealthy.[5] Outcomes are usually good.[6][7] The first known mention of the disease is from a 1700 BC Egyptian papyrus.[10]

Contents

# Signs and symptoms

In about 40% of people with pathological hemorrhoids there are no significant symptoms.[5] Internal and external hemorrhoids may present differently; however, many people may have a combination of the two.[4] Bleeding enough to cause anemia is rare,[9] and life-threatening bleeding is even more uncommon.[11] Many people feel embarrassed when facing the problem[9] and often seek medical care only when the case is advanced.[4]

External hemorrhoid as seen around the human anus

## External

If not thrombosed, external hemorrhoids may cause few problems.[12] However, when thrombosed, hemorrhoids may be very painful.[4][1] Nevertheless, this pain typically resolves in two to three days.[9] The swelling may, however, take a few weeks to disappear.[9] A skin tag may remain after healing.[4] If hemorrhoids are large and cause issues with hygiene, they may produce irritation of the surrounding skin, and thus itchiness around the anus.[12]

## Internal

Internal hemorrhoids usually present with painless, bright red rectal bleeding during or following a bowel movement.[4] The blood typically covers the stool (a condition known as hematochezia), is on the toilet paper, or drips into the toilet bowl.[4] The stool itself is usually normally coloured.[4] Other symptoms may include mucous discharge, a perianal mass if they prolapse through the anus, itchiness, and fecal incontinence.[11][13] Internal hemorrhoids are usually only painful if they become thrombosed or necrotic.[4]

# Causes

The exact cause of symptomatic hemorrhoids is unknown.[14] A number of factors are believed to play a

role, including irregular bowel habits (constipation or diarrhea), lack of exercise, nutritional factors (low-fiber diets), increased intra-abdominal pressure (prolonged straining, ascites, an intra-abdominal mass, or pregnancy), genetics, an absence of valves within the hemorrhoidal veins, and aging.[1][9] Other factors believed to increase risk include obesity, prolonged sitting,[4] a chronic cough, and pelvic floor dysfunction.[2] Evidence for these associations, however, is poor.[2]

During pregnancy, pressure from the fetus on the abdomen and hormonal changes cause the hemorrhoidal vessels to enlarge. The birth of the baby also leads to increased intra-abdominal pressures.[15] Pregnant women rarely need surgical treatment, as symptoms usually resolve after delivery.[1]

# Pathophysiology

Hemorrhoid cushions are a part of normal human anatomy and become a pathological disease only when they experience abnormal changes.[4] There are three main cushions present in the normal anal canal.[1] These are located classically at left lateral, right anterior, and right posterior positions.[9] They are composed of neither arteries nor veins, but blood vessels called sinusoids, connective tissue, and smooth muscle.[2]:175 Sinusoids do not have muscle tissue in their walls, as veins do.[4] This set of blood vessels is known as the hemorrhoidal plexus.[2]

Hemorrhoid cushions are important for continence. They contribute to 15–20% of anal closure pressure at rest and protect the internal and external anal sphincter muscles during the passage of stool.[4] When a person bears down, the intra-abdominal pressure grows, and hemorrhoid cushions increase in size, helping maintain anal closure.[9] Hemorrhoid symptoms are believed to result when these vascular structures slide downwards or when venous pressure is excessively increased.[11] Increased internal and external anal sphincter pressure may also be involved in hemorrhoid symptoms.[9] Two types of hemorrhoids occur: internals from the superior hemorrhoidal plexus and externals from the inferior hemorrhoidal plexus.[9] The dentate line divides the two regions.[9]

# Diagnosis

Hemorrhoids are typically diagnosed by physical examination.[8] A visual examination of the anus and surrounding area may diagnose external or prolapsed hemorrhoids.[4] A rectal exam may be performed to detect possible rectal tumors, polyps, an enlarged prostate, or abscesses.[4] This examination may not be possible without appropriate sedation because of pain, although most internal hemorrhoids are not associated with pain.[1] Visual confirmation of internal hemorrhoids may require anoscopy, insertion of a hollow tube device with a light attached at one end.[9] The two types of hemorrhoids are external and internal. These are differentiated by their position with respect to the dentate line.[1] Some persons may concurrently have symptomatic versions of both.[9] If pain is present, the condition is more likely to be an anal fissure or an external hemorrhoid rather than an internal hemorrhoid.[9]

**Internal hemorrhoid grades**

| Grade | Diagram | Picture |
|---|---|---|
| 1 |  |  |
| 2 |  |  |
| 3 |  |  |

## Internal

Internal hemorrhoids originate above the dentate

line.[12] They are covered by columnar epithelium, which lacks pain receptors.[2] They were classified in 1985 into four grades based on the degree of prolapse:[2][1]

| | | |
|---|---|---|
| 4 |  |  |

- Grade I: No prolapse, just prominent blood vessels[8]
- Grade II: Prolapse upon bearing down, but spontaneous reduction
- Grade III: Prolapse upon bearing down requiring manual reduction
- Grade IV: Prolapse with inability to be manually reduced.

### External

A thrombosed external hemorrhoid

External hemorrhoids occur below the dentate or pectinate line.[12] They are covered proximally by anoderm and distally by skin, both of which are sensitive to pain and temperature.[2]

### Differential

Many anorectal problems, including fissures, fistulae, abscesses, colorectal cancer, rectal varices, and itching have similar symptoms and may be incorrectly referred to as hemorrhoids.[1] Rectal bleeding may also occur owing to colorectal cancer, colitis including inflammatory bowel disease, diverticular disease, and angiodysplasia.[8] If anemia is present, other potential causes should be considered.[9]

Other conditions that produce an anal mass include skin tags, anal warts, rectal prolapse, polyps, and enlarged anal papillae.[9] Anorectal varices due to increased portal hypertension (blood pressure in the portal venous system) may present similar to hemorrhoids but are a different condition.[9] Portal hypertension does not increase the risk of hemorrhoids.[5]

## Prevention

A number of preventative measures are recommended, including avoiding straining while attempting to defecate, avoiding constipation and diarrhea either by eating a high-fiber diet and drinking plenty of fluid or by taking fiber supplements, and getting sufficient exercise.[9][16] Spending less time attempting to defecate, avoiding reading while on the toilet,[1] and losing weight for overweight persons and avoiding heavy lifting are also recommended.[17]

## Management

### Conservative

Conservative treatment typically consists of foods rich in dietary fiber, intake of oral fluids to maintain hydration, nonsteroidal anti-inflammatory drugs, sitz baths, and rest.[1] Increased fiber intake has been shown to improve outcomes[18] and may be achieved by dietary alterations or the consumption of fiber supplements.[1][18] Evidence for benefits from sitz baths during any point in treatment, however, is lacking.[19] If they are used, they should be limited to 15 minutes at a time.[2]:182

While many topical agents and suppositories are available for the treatment of hemorrhoids, little evidence supports their use.[1] Steroid-containing agents should not be used for more than 14 days, as they may

cause thinning of the skin.[1] Most agents include a combination of active ingredients.[2] These may include a barrier cream such as petroleum jelly or zinc oxide, an analgesic agent such as lidocaine, and a vasoconstrictor such as epinephrine.[2] Some contain Balsam of Peru to which certain people may be allergic.[20][21]

Flavonoids are of questionable benefit, with potential side effects.[2][22] Symptoms usually resolve following pregnancy; thus active treatment is often delayed until after delivery.[23]

## Procedures

A number of office-based procedures may be performed. While generally safe, rare serious side effects such as perianal sepsis may occur.[8]

- Rubber band ligation is typically recommended as the first-line treatment in those with grade 1 to 3 disease.[8] It is a procedure in which elastic bands are applied onto an internal hemorrhoid at least 1 cm above the dentate line to cut off its blood supply. Within 5–7 days, the withered hemorrhoid falls off. If the band is placed too close to the dentate line, intense pain results immediately afterwards.[1] Cure rate has been found to be about 87%[1] with a complication rate of up to 3%.[8]
- Sclerotherapy involves the injection of a sclerosing agent, such as phenol, into the hemorrhoid. This causes the vein walls to collapse and the hemorrhoids to shrivel up. The success rate four years after treatment is about 70%.[1]
- A number of cauterization methods have been shown to be effective for hemorrhoids, but are usually only used when other methods fail. This procedure can be done using electrocautery, infrared radiation, laser surgery,[1] or cryosurgery.[24] Infrared cauterization may be an option for grade 1 or 2 disease.[8] In those with grade 3 or 4 disease, reoccurrence rates are high.[8]

## Surgery

A number of surgical techniques may be used if conservative management and simple procedures fail.[8] All surgical treatments are associated with some degree of complications including bleeding, infection, anal strictures and urinary retention, due to the close proximity of the rectum to the nerves that supply the bladder.[1] Also, a small risk of fecal incontinence occurs, particularly of liquid,[2][25] with rates reported between 0% and 28%.[26] Mucosal ectropion is another condition which may occur after hemorrhoidectomy (often together with anal stenosis).[27] This is where the anal mucosa becomes everted from the anus, similar to a very mild form of rectal prolapse.[27]

- Excisional hemorrhoidectomy is a surgical excision of the hemorrhoid used primarily only in severe cases.[1] It is associated with significant postoperative pain and usually requires 2–4 weeks for recovery.[1] However, the long-term benefit is greater in those with grade 3 hemorrhoids as compared to rubber band ligation.[28] It is the recommended treatment in those with a thrombosed external hemorrhoid if carried out within 24–72 hours.[12][8] Glyceryl trinitrate ointment after the procedure helps both with pain and healing.[29]
- Doppler-guided, transanal hemorrhoidal dearterialization is a minimally invasive treatment using an ultrasound doppler to accurately locate the arterial blood inflow. These arteries are then "tied off" and the prolapsed tissue is sutured back to its normal position. It has a slightly higher recurrence rate, but fewer complications compared to a hemorrhoidectomy.[1]
- Stapled hemorrhoidectomy, also known as stapled hemorrhoidopexy, involves the removal of much of the abnormally enlarged hemorrhoidal tissue, followed by a repositioning of the remaining hemorrhoidal tissue back to its normal anatomical position. It is generally less painful and is associated with faster healing compared to complete removal of hemorrhoids.[1] However, the chance of symptomatic hemorrhoids returning is greater than for conventional hemorroidectomy,[30] so it is typically only recommended for grade 2 or 3 disease.[8]

# Epidemiology

It is difficult to determine how common hemorrhoids are as many people with the condition do not see a healthcare provider.[11][14] However, symptomatic hemorrhoids are thought to affect at least 50% of the US population at some time during their lives, and around 5% of the population is affected at any given time.[1] Both sexes experience about the same incidence of the condition,[1] with rates peaking between 45 and 65 years.[9] They are more common in Caucasians[31] and those of higher socioeconomic status.[2]

Long-term outcomes are generally good, though some people may have recurrent symptomatic episodes.[11] Only a small proportion of persons end up needing surgery.[2]

## History

The first known mention of this disease is from a 1700 BC Egyptian papyrus, which advises: "... Thou shouldest give a recipe, an ointment of great protection; acacia leaves, ground, titurated and cooked together. Smear a strip of fine linen there-with and place in the anus, that he recovers immediately."[10] In 460 BC, the Hippocratic corpus discusses a treatment similar to modern rubber band ligation: "And hemorrhoids in like manner you may treat by transfixing them with a needle and tying them with very thick and woolen thread, for application, and do not forment until they drop off, and always leave one behind; and when the patient recovers, let him be put on a course of Hellebore."[10] Hemorrhoids may have been described in the Bible, with earlier English translations using the now-obsolete spelling "emerods".[9]

An 11th-century English miniature: On the right is an operation to remove hemorrhoids.

Celsus (25 BC – AD 14) described ligation and excision procedures, and discussed the possible complications.[32] Galen advocated severing the connection of the arteries to veins, claiming it reduced both pain and the spread of gangrene.[32] The Susruta Samhita (4th–5th century AD) is similar to the words of Hippocrates, but emphasizes wound cleanliness.[10] In the 13th century, European surgeons such as Lanfranc of Milan, Guy de Chauliac, Henri de Mondeville, and John of Ardene made great progress and development of the surgical techniques.[32]

In medieval times, hemorrhoids were also known as Saint Fiacre's curse after a sixth-century saint who developed them following tilling the soil.[33] The first use of the word "hemorrhoid" in English occurs in 1398, derived from the Old French "emorroides", from Latin *hæmorrhoida*,[34] in turn from the Greek αἱμορροΐς (*haimorrhois*), "liable to discharge blood", from αἷμα (*haima*), "blood"[35] and ῥόος (*rhoos*), "stream, flow, current",[36] itself from ῥέω (*rheo*), "to flow, to stream".[37]

## Notable cases

Hall-of-Fame baseball player George Brett was removed from a game in the 1980 World Series due to hemorrhoid pain. After undergoing minor surgery, Brett returned to play in the next game, quipping "...my problems are all behind me."[38] Brett underwent further hemorrhoid surgery the following spring.[39] Conservative political commentator Glenn Beck underwent surgery for hemorrhoids, subsequently describing his unpleasant experience in a widely viewed 2008 YouTube video.[40][41] Former U.S. President Jimmy Carter had surgery for hemorrhoids in 1984.[42] Cricketers Matthew Hayden and Viv Richards also had the condition.[43]

[edit on Wikidata]

A **hernia** is the exit of an organ, such as the bowel, through the wall of the cavity in which it normally resides.[1] Hernias come in a number of different types. Most commonly they involve the abdomen, specifically the groin.[2] Groin hernias are most common of the inguinal type but may also be femoral.[1] Other hernias include hiatus, incisional, and umbilical hernias.[2] Symptoms are present in about 66% of people with groin hernias. This may include pain or discomfort especially with coughing, exercise, or going to the bathroom. Often it gets worse throughout the day and improves when lying down. A bulging area may occur that becomes larger when standing. Groin hernias occur more often on the right than left side. The main concern is strangulation, where the blood supply to part of the bowel is blocked. This usually produces severe pain and tenderness of the area.[1] Hiatus or hiatal hernias often result in heartburn but may also cause chest pain or pain with eating.[3]

Risk factors for the development of a hernia include: smoking, chronic obstructive pulmonary disease, obesity, pregnancy, peritoneal dialysis, collagen vascular disease, and previous open appendectomy, among others.[1][3][4] Hernias are partly genetic and occur more often in certain families. It is unclear if groin hernias are associated with heavy lifting. Hernias can often be diagnosed based on signs and symptoms. Occasionally medical imaging is used to confirm the diagnosis or rule out other possible causes.[1] The diagnosis of hiatus hernias is often by endoscopy.[3]

Groin hernias that do not cause symptoms in males do not need to be repaired. Repair, however, is generally recommended in women due to the higher rate of femoral hernias which have more complications. If strangulation occurs immediate surgery is required. Repair may be done by open surgery or by laparoscopic surgery. Open surgery has the benefit of possibly being done under local anesthesia rather than general anesthesia. Laparoscopic surgery generally has less pain following the procedure.[1] A hiatus hernia may be treated with lifestyle changes such as raising the head of the bed, weight loss, and adjusting eating habits. The medications, H2 blockers or proton pump inhibitors may help. If the symptoms do not improve with medications the surgery known as laparoscopic fundoplication may be an option.[3]

About 27% of males and 3% of females develop a groin hernia at some time in their life.[1] Groin hernias occur most often before the age of one and after the age of fifty.[4] Inguinal, femoral and abdominal

hernias resulted in 32,500 deaths in 2013 and 50,500 in 1990.[5] It is not known how commonly hiatus hernias occur with estimates in North America varying from 10 to 80%.[3] The first known description of a hernia dates back to at least 1550 BC in the Ebers Papyrus from Egypt.[6]

## Signs and symptoms [edit]

By far the most common hernias develop in the abdomen, when a weakness in the abdominal wall evolves into a localized hole, or "defect", through which adipose tissue, or abdominal organs covered with peritoneum, may protrude. Another common hernia involves the spinal discs and causes *sciatica*. A hiatus hernia occurs when the stomach protrudes into the *mediastinum* through the esophageal opening in the diaphragm.

Frontal view of an inguinal hernia (right).

Hernias may or may not present with either pain at the site, a visible or palpable lump, or in some cases more vague symptoms resulting from pressure on an organ which has become "stuck" in the hernia, sometimes leading to organ dysfunction. Fatty tissue usually enters a hernia first, but it may be followed or accompanied by an organ.

Hernias are caused by a disruption or opening in the fascia, or fibrous tissue, which forms the abdominal wall. It is possible for the bulge associated with a hernia to come and go, but the defect in the tissue will persist.

Umbilical hernia with surrounding inflammation

Symptoms and signs vary depending on the type of hernia. Symptoms may or may not be present in some inguinal hernias. In the case of reducible hernias, a bulge in the groin or in another abdominal area can often be seen and felt. When standing, such a bulge becomes more obvious. Besides the bulge, other symptoms include pain in the groin that may also include a heavy or dragging sensation, and in men, there is sometimes pain and swelling in the scrotum around the testicular area.[7]

Irreducible abdominal hernias or incarcerated hernias may be painful, but their most relevant symptom is that they cannot return to the abdominal cavity when pushed in. They may be chronic, although painless, and can lead to strangulation (loss of blood supply) and/or

obstruction (kinking of intestine). Strangulated hernias are always painful and pain is followed by tenderness. Nausea, vomiting, or fever may occur in these cases due to bowel obstruction. Also, the hernia bulge in this case may turn red, purple or dark and pink.

In the diagnosis of abdominal hernias, imaging is the principal means of detecting internal diaphragmatic and other nonpalpable or unsuspected hernias. Multidetector CT (MDCT) can show with precision the anatomic site of the hernia sac, the contents of the sac, and any complications. MDCT also offers clear detail of the abdominal wall allowing wall hernias to be identified accurately.[8]

## Causes [edit]

Causes of hiatus hernia vary depending on each individual. Among the multiple causes, however, are the mechanical causes which include: improper heavy weight lifting, hard coughing bouts, sharp blows to the abdomen, and incorrect posture.[9]

Furthermore, conditions that increase the pressure of the abdominal cavity may also cause hernias or worsen the existing ones. Some examples would be: obesity, straining during a bowel movement or urination (constipation, enlarged prostate), chronic lung disease, and also, fluid in the abdominal cavity (ascites).[10]

Also, if muscles are weakened due to poor nutrition, smoking, and overexertion, hernias are more likely to occur.

The physiological school of thought contends that in the case of inguinal hernia, the above-mentioned are only an anatomical symptom of the underlying physiological cause. They contend that the risk of hernia is due to a physiological difference between patients who suffer hernia and those who do not, namely the presence of aponeurotic extensions from the transversus abdominis aponeurotic arch.[11]

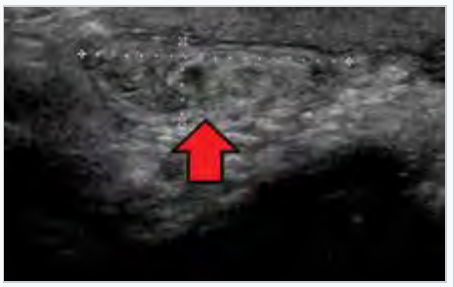
Abdominal wall hernia may occur due to trauma. If this type of hernia is due to blunt trauma it is an emergency condition and could be associated with various solid organs and hollow viscus injuries.

## Diagnosis [edit]

### Inguinal [edit]

*Main article: inguinal hernia*

By far the most common hernias (up to 75% of all abdominal hernias) are the so-called inguinal hernias. Inguinal hernias are further divided into the more common indirect inguinal hernia (2/3, depicted here), in which the inguinal canal is entered via a congenital weakness at its entrance (the internal inguinal ring), and the direct inguinal hernia type (1/3), where the hernia contents push through a weak spot in the back wall of the inguinal canal. Inguinal hernias are the most common type of hernia in both men and women. In some selected cases, they may require surgery.

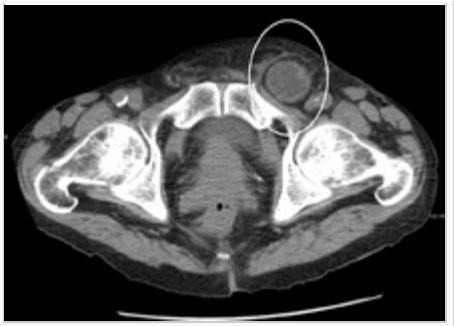


Ultrasound showing an inguinal hernia

### Femoral [edit]

*Main article: femoral hernia*

Femoral hernias occur just below the inguinal ligament, when abdominal contents pass into the weak area at the posterior wall of the femoral canal. They can be hard to distinguish from the inguinal type (especially when ascending cephalad): however, they generally appear more rounded, and, in contrast to inguinal hernias, there is a strong female preponderance in femoral hernias. The incidence of strangulation in femoral hernias is high. Repair techniques are similar for femoral and



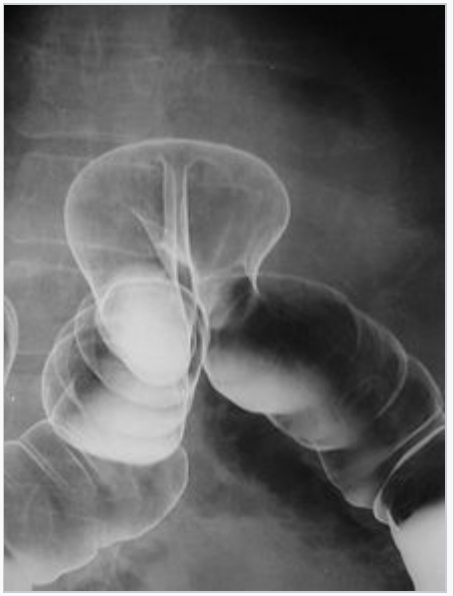
An incarcerated inguinal hernia as seen on CT

inguinal hernia.

## Umbilical [edit]

*Main article: Umbilical hernia*

They involve protrusion of intraabdominal contents through a weakness at the site of passage of the umbilical cord through the abdominal wall. Umbilical hernias in adults are largely acquired, and are more frequent in obese or pregnant women. Abnormal decussation of fibers at the linea alba may contribute.



X-ray of colonic herniation

## Incisional [edit]

*Main article: incisional hernia*

An incisional hernia occurs when the defect is the result of an incompletely healed surgical wound. When these occur in median laparotomy incisions in the linea alba, they are termed ventral hernias. These can be the most frustrating and difficult to treat, as the repair utilizes already attenuated tissue.

## Diaphragmatic [edit]

*Main article: diaphragmatic hernia*

Higher in the abdomen, an (internal) "diaphragmatic hernia" results when part of the stomach or intestine protrudes into the chest cavity through a defect in the diaphragm.

A hiatus hernia is a particular variant of this type, in which the normal passageway through which the esophagus meets the stomach (esophageal hiatus) serves as a functional "defect", allowing part of the stomach to (periodically) "herniate" into the chest. Hiatus hernias may be either "*sliding*", in which the gastroesophageal junction itself slides through the defect into the chest, or non-sliding (also known as *para-esophageal*), in which case the junction remains fixed while another portion of the stomach moves up through the defect. Non-sliding or para-esophageal hernias can be dangerous as they may allow the stomach to rotate and obstruct. Repair is usually advised.

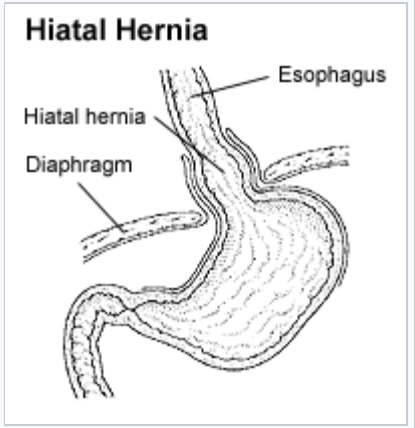


Diagram of a hiatus hernia (coronal section, viewed from the front).

A congenital diaphragmatic hernia is a distinct problem, occurring in up to 1 in 2000 births, and requiring pediatric surgery. Intestinal organs may herniate through several parts of the diaphragm, posterolateral (in Bochdalek's triangle, resulting in *Bochdalek's hernia*), or anteromedial-retrosternal (in the cleft of Larrey/Morgagni's foramen, resulting in *Morgagni-Larrey hernia*, or Morgagni's hernia).[12]

## Other hernias [edit]

Since many organs or parts of organs can herniate through many orifices, it is very difficult to give an exhaustive list of hernias, with all synonyms and eponyms. The above article deals mostly with "visceral hernias", where the herniating tissue arises within the abdominal cavity. Other hernia types and unusual

types of visceral hernias are listed below, in alphabetical order:

- Amyand's hernia: containing the appendix vermiformis within the hernia sac
- Cooper's hernia: a femoral hernia with two sacs, the first being in the femoral canal, and the second passing through a defect in the superficial fascia and appearing almost immediately beneath the skin.
- Brain herniation, sometimes referred to as brain hernia, is a potentially deadly side effect of very high intracranial pressure that occurs when a part of the brain is squeezed across structures within the skull.
- Epigastric hernia: a hernia through the linea alba above the umbilicus.
- Hiatus hernia: a hernia due to "short oesophagus" — insufficient elongation — stomach is displaced into the thorax
- Littre's hernia: a hernia involving a Meckel's diverticulum. It is named after the French anatomist Alexis Littré (1658–1726).
- Lumbar hernia: a hernia in the lumbar region (not to be confused with a lumbar disc hernia), contains the following entities:
  - Petit's hernia: a hernia through Petit's triangle (inferior lumbar triangle). It is named after French surgeon Jean Louis Petit (1674–1750).
  - Grynfeltt's hernia: a hernia through Grynfeltt-Lesshaft triangle (superior lumbar triangle). It is named after physician Joseph Grynfeltt (1840–1913).
- Maydl's hernia: two adjacent loops of small intestine are within a hernial sac with a tight neck. The intervening portion of bowel within the abdomen is deprived of its blood supply and eventually becomes necrotic.
- Morgagni hernia: a type of hernia where abdominal contents pass into the thorax through a weakness in the diaphragm
- Obturator hernia: hernia through obturator canal
- Pantaloon hernia (Saddle Bag hernia): a combined direct and indirect hernia, when the hernial sac protrudes on either side of the inferior epigastric vessels
- Paraesophageal hernia
- Parastomal hernias, which is when tissue protrudes adjacent to a stoma tract.
- Paraumbilical hernia: a type of umbilical hernia occurring in adults
- Perineal hernia: a perineal hernia protrudes through the muscles and fascia of the perineal floor. It may be primary but usually is acquired following perineal prostatectomy, abdominoperineal resection of the rectum, or pelvic exenteration.
- Properitoneal hernia: rare hernia located directly above the peritoneum, for example, when part of an inguinal hernia projects from the deep inguinal ring to the preperitoneal space.
- Richter's hernia: a hernia involving only one sidewall of the bowel, which can result in bowel strangulation leading to perforation through ischaemia without causing bowel obstruction or any of its warning signs. It is named after German surgeon August Gottlieb Richter (1742–1812).
- Sliding hernia: occurs when an organ drags along part of the peritoneum, or, in other words, the organ is part of the hernia sac. The colon and the urinary bladder are often involved. The term also frequently refers to sliding hernias of the stomach.
- Sciatic hernia: this hernia in the greater sciatic foramen most commonly presents as an uncomfortable mass in the gluteal area. Bowel obstruction may also occur. This type of hernia is only a rare cause of sciatic neuralgia.
- Spigelian hernia, also known as spontaneous lateral ventral hernia
- Sports hernia: a hernia characterized by chronic groin pain in athletes and a dilated superficial inguinal ring.
- Velpeau hernia: a hernia in the groin in front of the femoral blood vessels

Patient with a colostomy complicated by a large parastomal hernia.

## Treatment [edit]

*Main articles: Hernia repair and Inguinal hernia surgery*

### Truss [edit]

The benefits of the use of an external device to maintain reduction of the hernia without repairing the underlying defect (such as hernia trusses, trunks, belts, etc.) are unclear.[1]

### Surgery [edit]

Surgery is recommended for some types of hernias to prevent complications like obstruction of the bowel or strangulation of the tissue, although umbilical hernias and hiatus hernias may be watched, or are treated with medication.[13] Most abdominal hernias can be surgically repaired, but surgery has complications. Time needed for recovery after treatment is reduced if hernias are operated on laparoscopically. However, open surgery can be done sometimes without general anesthesia. Uncomplicated hernias are principally repaired by pushing back, or "reducing", the herniated tissue, and then mending the weakness in muscle tissue (an operation called herniorrhaphy). If complications have occurred, the surgeon will check the viability of the herniated organ and remove part of it if necessary.

Hernia repair being performed aboard the amphibious assault ship USS *Bataan*.

Muscle reinforcement techniques often involve synthetic materials (a mesh prosthesis).[14] The mesh is placed either over the defect (anterior repair) or under the defect (posterior repair). At times staples are used to keep the mesh in place. These mesh repair methods are often called "tension free" repairs because, unlike some suture methods (e.g., Shouldice), muscle is not pulled together under tension. However, this widely used terminology is misleading, as there are many tension-free suture methods that do not use mesh (e.g., Desarda, Guarnieri, Lipton-Estrin, etc.).

Evidence suggests that tension-free methods (with or without mesh) often have lower percentage of recurrences and the fastest recovery period compared to tension suture methods. However, among other possible complications, prosthetic mesh usage seems to have a higher incidence of chronic pain and, sometimes, infection.[15]

The frequency of surgical correction ranges from 10 per 100,000 (U.K.) to 28 per 100,000 (U.S.).[1]

### Recovery [edit]

Many people are managed through day surgery centers, and are able to return to work within a week or two, while intense activities are prohibited for a longer period. People who have their hernias repaired with mesh often recover in a number of days, though pain can last longer. Surgical complications include pain that lasts more than three months, surgical site infections, nerve and blood vessel injuries, injury to nearby organs, and hernia recurrence. Pain that lasts more than three months occurs in about 10% of people following hernia repair.[1]

## Complications [edit]

Complications may arise post-operation, including rejection of the mesh that is used to repair the hernia. In the event of a mesh rejection, the mesh will very likely need to be removed. Mesh rejection can be detected by obvious, sometimes localised swelling and pain around the mesh area. Continuous discharge from the scar is likely for a while after the mesh has been removed.

A surgically treated hernia can lead to complications, while an untreated hernia may be complicated by:

- Inflammation
- Irreducibility

- Obstruction of any lumen, such as bowel obstruction in intestinal hernias
- Strangulation
- Hydrocele of the hernial sac
- Haemorrhage
- Autoimmune problems
- Incarceration, which is where it cannot be reduced, or pushed back into place,[16] at least not without very much external effort.[17] In intestinal hernias, this also substantially increases the risk of bowel obstruction and strangulation.

## Epidemiology [edit]

About 27% of males and 3% of females develop a groin hernia at some time in their life.[1] In 2013 about 25 million people had a hernia.[18] Inguinal, femoral and abdominal hernias resulted in 32,500 deaths globally in 2013 and 50,500 in 1990.[5]

# Irritable bowel syndrome

From Wikipedia, the free encyclopedia

*This article is about a functional disorder. For bowel inflammation, see Inflammatory bowel disease.*

**Irritable bowel syndrome** (**IBS**) is a group of symptoms—including abdominal pain and changes in the pattern of bowel movements without any evidence of underlying damage.[1] These symptoms occur over a long time, often years.[1] It has been classified into four main types depending on if diarrhea is common, constipation is common, both are common, or neither occurs very often (IBS-D, IBS-C, IBS-M, or IBS-U respectively).[1] IBS negatively affects quality of life and may result in missed school or work.[3] Disorders such as anxiety, major depression, and chronic fatigue syndrome, are common among people with IBS.[1][4]

The causes of IBS are not clear.[2] Theories include gut–brain axis problems, small intestinal bacterial overgrowth, genetic factors, food sensitivity, and gut motility problems.[2] Onset may be triggered by an intestinal infection,[5] or stressful life event.[6] IBS is a functional gastrointestinal disorder.[1] Diagnosis is based on signs and symptoms in the absence of worrisome features.[7] Worrisome features include onset at greater than 50 years of age, weight loss, blood in the stool, or a family history of inflammatory bowel disease.[7] Other conditions that may present similarly include celiac disease, microscopic colitis, inflammatory bowel disease, bile acid malabsorption, and colon cancer.[7]

There is no cure for IBS.[8] Treatment is carried out to improve symptoms.[8] This may including dietary changes, medication, probiotics, and counselling.[8] Dietary measures include increasing soluble fiber intake, a gluten free diet, or a diet low in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAP).[7][9] The medication loperamide may be used to help with diarrhea while laxatives may be used to help with constipation.[7] Antidepressants may improve overall symptoms and pain.[7] Patient education and a good doctor–patient relationship are an important part of care.[7][10]

About 10 to 15% of people in the developed world are believed to be affected by IBS.[1][11] It is more common in South America and less common in Southeast Asia.[7] It is twice as common in women as men and typically occurs before age 45.[1] The condition appears to become less common with age.[7] IBS does not affect life expectancy or lead to other serious diseases.[12] The first description of the condition was in

## Classification [edit]

IBS can be classified as either diarrhea-predominant (IBS-D), constipation-predominant (IBS-C), or with alternating stool pattern (IBS-A) or pain-predominant.[14] In some individuals, IBS may have an acute onset and develop after an infectious illness characterized by two or more of: fever, vomiting, diarrhea, or positive stool culture. This postinfective syndrome has consequently been termed "postinfectious IBS" (IBS-PI).

## Signs and symptoms [edit]

The primary symptoms of IBS are abdominal pain or discomfort in association with frequent diarrhea or constipation and a change in bowel habits.[15] Symptoms usually are experienced as acute attacks that subside within one day, but recurrent attacks are likely.[16] There may also be urgency for bowel movements, a feeling of incomplete evacuation (tenesmus), bloating, or abdominal distension.[17] In some cases, the symptoms are relieved by bowel movements.[10] People with IBS, more commonly than others, have gastroesophageal reflux, symptoms relating to the genitourinary system, chronic fatigue syndrome, fibromyalgia, headache, backache, and psychiatric symptoms such as depression and anxiety.[4][17] About a third of men and women who have IBS also report sexual dysfunction typically in the form of a reduction in libido.[18]

## Cause [edit]

While the causes of IBS are still unknown, it is believed that the entire gut–brain axis is affected.[19][20]

The risk of developing IBS increases six-fold after acute gastrointestinal infection. Postinfection, further risk factors are young age, prolonged fever, anxiety, and depression.[21] Psychological factors, such as depression or anxiety, have not been shown to cause or influence the onset of IBS, but may play a role in the persistence and perceived severity of symptoms.[22] Nevertheless, they may worsen IBS symptoms and the patient quality of life.[22] Antibiotic use also appears to increase the risk of developing IBS.[23] Research has found that genetic defects in innate immunity and epithelial homeostasis increase the risk of developing both post-infectious as well as other forms of IBS.[24]

## Post-infectious [edit]

Approximately 10 percent of IBS cases are triggered by an acute gastroenteritis infection. Genetic defects relating to the innate immune system and epithelial barrier as well as high stress and anxiety levels appear from evidence to increase the risk of developing post-infectious IBS. Post-infectious IBS usually manifests itself as the diarrhea predominant subtype. Evidence has demonstrated that the release of high levels of proinflammatory cytokines during acute enteric infection causes increased gut permeability leading to translocation of the commensal bacteria across the epithelial barrier resulting in significant damage to local tissues which is likely to result in chronic gut abnormalities in sensitive individuals. However, increased gut permeability is strongly associated with IBS regardless of whether IBS was initiated by an infection or not.[24]

## Stress [edit]

Publications suggesting the role of brain-gut "axis" appeared in the 1990s[25] and childhood physical and psychological abuse is often associated with the development of IBS.[26]

Given the high levels of anxiety seen in IBS patients and the overlap with conditions such as fibromyalgia and chronic fatigue syndrome, a potential model of IBS involves a disruption of the stress system. The stress response in the body involves the HPA axis and the sympathetic nervous system, both of which have been shown to operate abnormally in IBS patients. Psychiatric illness or anxiety precedes IBS symptoms in two-thirds of patients, and psychological traits predispose previously healthy people to developing IBS after gastroenteritis.[27][28]

## Bacteria [edit]

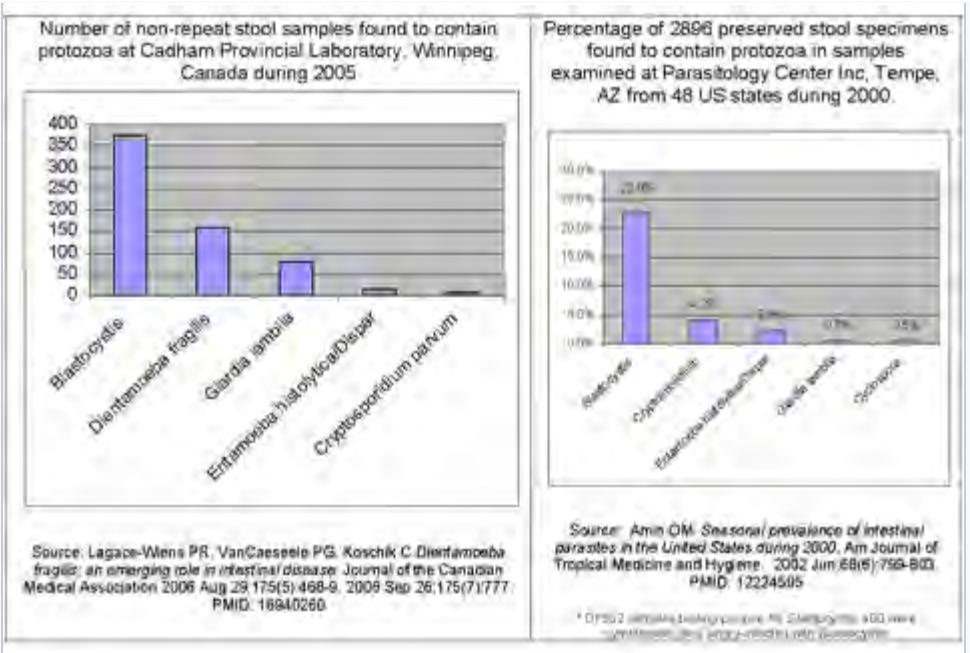
Small intestinal bacterial overgrowth occurs with greater frequency in patients who have been diagnosed with IBS compared to healthy controls. SIBO is most common in diarrhea-predominate IBS but also occurs in constipation-predominant IBS more frequently than healthy controls. Symptoms of SIBO include bloating, abdominal pain, diarrhea or constipation among others. IBS may be the result of the immune system interacting abnormally with gut microbiota resulting in an abnormal cytokine signalling profile.[29]

## Fungus [edit]

There is growing evidence that alterations of gut microbiota (dysbiosis) are associated with the intestinal manifestations of IBS, but also with the psychiatric morbidity that coexists in up to 80% of patients with IBS.[30] The role of the gut mycobiota, and especially of the abnormal proliferation of the yeast *Candida albicans* in some patients with IBS, is under investigation.[31]

## Protozoa [edit]

Protozoal infections can cause symptoms that mirror specific IBS subtypes,[34] e.g., infection by certain substypes of *blastocystis hominis* (blastocystosis) has a



Prevalence of protozoal infections in industrialized countries (United States and Canada) in the 21st century[32][33]

significant (possibly causal) relationship with IBS-D;[35][36] certain protozoal infections also occur more frequently in IBS patients.[37][38] *Dientamoeba fragilis* has also been considered a possible organism to study, though it is also found in people without IBS.[39]

## Mechanism [edit]

There is evidence that abnormalities occur in the gut flora of individuals who have IBS, such as reduced diversity, a decreased abundance of bacteria belonging to the phylum *Bacteroidetes*, and an increased abundance of those belonging to the phylum *Firmicutes*.[40] The changes in gut flora are most profound in individuals who have diarrhoea predominant IBS. Antibodies against common components (namely flagellin) of the commensal gut flora are a common occurrence in IBS affected individuals.[41] Chronic low-grade inflammation commonly occurs in IBS affected individuals with abnormalities found including increased enterochromaffin cells, intraepithelial lymphocytes, and mast cells resulting in chronic immune mediated inflammation of the gut mucosa.[19][42]

Genetic, environmental, and psychological factors seem to be important in the development of IBS. Studies have shown that IBS has a genetic component even though there is a predominant influence of environmental factors.[43] IBS has been reported in greater quantities in multigenerational families with IBS than in the regular population.[44]

## Diagnosis [edit]

No specific laboratory or imaging test can be performed to diagnose irritable bowel syndrome. Diagnosis involves excluding conditions that produce IBS-like symptoms, and then following a procedure to categorize the patient's symptoms. Ruling out parasitic infections, lactose intolerance, small intestinal bacterial overgrowth, and celiac disease is recommended for all patients before a diagnosis of irritable bowel syndrome is made. In patients over 50 years old, they are recommended to undergo a screening colonoscopy.[45] IBS sufferers are at increased risk of being given inappropriate surgeries such as appendectomy, cholecystectomy, and hysterectomy due to their IBS symptoms being misdiagnosed as other medical conditions.[46]

### Differential diagnosis [edit]

Colon cancer, inflammatory bowel disease, thyroid disorders, and giardiasis can all feature abnormal defecation and abdominal pain. Less common causes of this symptom profile are carcinoid syndrome, microscopic colitis, bacterial overgrowth, and eosinophilic gastroenteritis; IBS is, however, a common presentation, and testing for these conditions would yield low numbers of positive results, so it is considered difficult to justify the expense.[47]

[48]

Some people, managed for years for IBS, may have non-celiac gluten sensitivity (NCGS). Gastrointestinal symptoms of IBS are clinically indistinguishable from those of NCGS, but the presence of any of the following non-intestinal manifestations suggest a possible NCGS: headache or migraine, "foggy mind", chronic fatigue,[49] fibromyalgia,[50][51][52] joint and muscle pain,[49][50][53] leg or arm numbness,[49][50][53] tingling of the extremities,[49][53] dermatitis (eczema or skin rash),[49][53] atopic disorders,[49] allergy to one or more inhalants, foods or metals[49][50] (such as mites, graminaceae, parietaria, cat or dog hair, shellfish, or nickel[50]), depression,[49][50][53] anxiety,[50] anemia,[49][53] iron-deficiency anemia, folate deficiency, asthma, rhinitis, eating disorders,[50] neuropsychiatric disorders (such as schizophrenia,[53][54] autism,[50][53][54] peripheral neuropathy,[53][54] ataxia,[54] attention deficit hyperactivity disorder[49]) or autoimmune diseases.[49] An improvement with a gluten-free diet of immune-mediated symptoms, including autoimmune diseases, once having reasonably ruled out coeliac disease and wheat allergy, is another way to realize a differential diagnosis.[49]

Because many causes of diarrhea give IBS-like symptoms, the American Gastroenterological Association published a set of guidelines for tests to be performed to rule out other causes for these symptoms. These include gastrointestinal infections, lactose intolerance, and coeliac disease. Research has suggested these guidelines are not always followed.[45] Once other causes have been excluded, the diagnosis of IBS is performed using a diagnostic algorithm. Well-known algorithms include the Manning criteria, the obsolete Rome I and II criteria, and the Kruis criteria, and studies have compared their reliability.[55] The more recent Rome III process was published in 2006. Physicians may choose to use one of these guidelines or may simply choose to rely on their own anecdotal experience with past patients. The algorithm may include additional tests to guard against misdiagnosis of other diseases as IBS. Such "red flag" symptoms may include weight loss, gastrointestinal bleeding, anemia, or nocturnal symptoms. However, red flag conditions may not always contribute to accuracy in diagnosis; for instance, as many as 31% of IBS patients have blood in their stool, many possibly from hemorrhoidal bleeding.[55]

The diagnostic algorithm identifies a name that can be applied to the patient's condition based on the combination of the patient's symptoms of diarrhea, abdominal pain, and constipation. For example, the statement "50% of returning travelers had developed functional diarrhea while 25% had developed IBS" would mean half the travelers had diarrhea while a quarter had diarrhea with abdominal pain. While some researchers believe this categorization system will help physicians understand IBS, others have questioned the value of the system and suggested all IBS patients have the same underlying disease but with different symptoms.[56]

## Investigations [edit]

Investigations are performed to exclude other conditions:

- Stool microscopy and culture (to exclude infectious conditions)
- Blood tests: Full blood examination, liver function tests, erythrocyte sedimentation rate, and serological testing for coeliac disease
- Abdominal ultrasound (to exclude gallstones and other biliary tract diseases)
- Endoscopy and biopsies (to exclude peptic ulcer disease, coeliac disease, inflammatory bowel disease, and malignancies)
- Hydrogen breath testing (to exclude fructose and lactose malabsorption)

## Misdiagnosis [edit]

Some common examples of misdiagnosis include infectious diseases, coeliac disease,[57] *Helicobacter pylori*,[58][59] parasites (non-protozoal).[34][60][61]

Coeliac disease in particular is often misdiagnosed as IBS. The American College of Gastroenterology recommends all patients with symptoms of IBS be tested for coeliac disease.[62]

Bile acid malabsorption is also sometimes missed in patients with diarrhea-predominant IBS. SeHCAT tests suggest around 30% of D-IBS patients have this condition, and most respond to bile acid sequestrants.[63]

Chronic use of certain sedative-hypnotic drugs, especially the benzodiazepines, may cause irritable bowel-like symptoms that can lead to a misdiagnosis of irritable bowel syndrome.[64]

### Comorbidities [edit]

Several medical conditions, or comorbidities, appear with greater frequency in patients diagnosed with IBS.

- Neurological/Psychiatric: A study of 97,593 individuals with IBS identified comorbidities such as headache, fibromyalgia, and depression.[65] IBS occurs in 51% of chronic fatigue syndrome patients and 49% of fibromyalgia patients, and psychiatric disorders occur in 94% of IBS patients.[4]
- Inflammatory bowel disease: IBS may be a type of low-grade inflammatory bowel disease.[66] Researchers have suggested IBS and IBD are interrelated diseases,[67] noting that patients with IBD experience IBS-like symptoms when their IBD is in remission.[68][69] A three-year study found that patients diagnosed with IBS were 16.3 times more likely to be diagnosed with IBD during the study period.[70] Serum markers associated with inflammation have also been found in patients with IBS.
- Abdominal surgery: IBS patients were at increased risk of having unnecessary gall bladder removal surgery not due to an increased risk of gallstones, but rather to abdominal pain, awareness of having gallstones, and inappropriate surgical indications.[71] These patients also are 87% more likely to undergo abdominal and pelvic surgery and three times more likely to undergo gallbladder surgery.[72] Also, IBS patients were twice as likely to undergo hysterectomy.[73]
- Endometriosis: One study reported a statistically significant link between migraine headaches, IBS, and endometriosis.[74]
- Other chronic disorders: Interstitial cystitis may be associated with other chronic pain syndromes, such as irritable bowel syndrome and fibromyalgia. The connection between these syndromes is unknown.[75]

## Management [edit]

A number of treatments have been found to be effective, including fiber, talk therapy, antispasmodic and antidepressant medication, and peppermint oil.[76][77][78]

### Diet [edit]

Studies have shown that up to 70% of IBS patients benefited from eating a low FODMAP diet. Symptoms most likely to improve from such a diet include urgency, flatulence, bloating, abdominal pain, and altered stool output. One national guideline advises a low FODMAP diet for managing IBS when other dietary and lifestyle measures have been unsuccessful.[79] This diet restricts various carbohydrates which are poorly absorbed in the small intestine, as well as fructose and lactose, which are similarly poorly absorbed in those with intolerances to them. Reduction of fructose and fructan has been shown to reduce IBS symptoms in a dose-dependent manner in patients with fructose malabsorption and IBS.[80]

Some IBS patients believe they have some form of dietary intolerance; however, tests attempting to predict food sensitivity in IBS have proven disappointing. A small study reported that an IgG antibody test was somewhat effective in determining food sensitivity in IBS patients, with patients on the elimination diet experiencing 10% greater symptom-reduction than those on a sham diet.[81] However, more research is necessary before IgG testing can be recommended.[82]

### FODMAPs diet [edit]

A diet restricted in fermentable oligo- di- and monosaccharides and polyols (FODMAPs) now has an evidence base sufficiently strong to recommend its widespread application in conditions such as IBS and IBD.[83] They also state the restriction of FODMAPs globally, rather than individually, controls the symptoms of functional gut disorders (e.g., IBS), and the majority of IBD patients respond just as well. It is more successful than restricting only fructose and fructans, which are also FODMAPs, as is recommended for those with fructose malabsorption. Longer-term compliance with the diet was high.

## Fiber [edit]

Some evidence suggests soluble fiber supplementation (e.g., psyllium/ispagula husk) is effective.[9] It acts as a bulking agent, and for many IBS-D patients, allows for a more consistent stool. For IBS-C patients, it seems to allow for a softer, moister, more easily passable stool.

However, insoluble fiber (e.g., bran) has not been found to be effective for IBS.[84][85] In some people, insoluble fiber supplementation may aggravate symptoms.[86][87]

Fiber might be beneficial in those who have a predominance of constipation. In people who have IBS-C, soluble fiber can reduce overall symptoms, but will not reduce pain. The research supporting dietary fiber contains conflicting, small studies complicated by the heterogeneity of types of fiber and doses used.[88]

One meta-analysis found only soluble fiber improved global symptoms of irritable bowel, but neither type of fiber reduced pain.[88] An updated meta-analysis by the same authors also found soluble fiber reduced symptoms, while insoluble fiber worsened symptoms in some cases.[89] Positive studies have used 10–30 grams per day of psyllium.[90][91] One study specifically examined the effect of dose, and found 20 g of ispaghula husk were better than 10 g and equivalent to 30 g per day.[92]

## Medication [edit]

Medications may consist of stool softeners and laxatives in IBS-C and antidiarrheals (e.g., opiate, opioid, or opioid analogs such as loperamide, codeine, diphenoxylate) in IBS-D for mild symptoms and stronger opiates such as morphine and oxycodone for severe cases.[93][94][95]

Drugs affecting serotonin (5-HT) in the intestines can help reduce symptoms.[96] On the other hand, many IBS-D patients report that SSRI type medications exacerbate spasms and diarrhea. This is thought to be due to the large number of serotonin receptors in the gut. 5HT3 antagonists such as ondansetron are effective in postinfectious IBS and diarrhoea-dominant IBS due to their blockade of serotonin on 5HT3 receptors in the gut; the reason for their benefit is believed to be that excessive serotonin in the gut is thought to play a role in the pathogenesis of some subtypes of IBS. Certain atypical antipsychotic medications, such as clozapine and olanzapine, may also provide relief due to serotonergic properties these agents possess, acting on the same receptors as other medications in this specific category.[97] Benefits may include reduced diarrhoea, reduced abdominal cramps, and improved general well-being. Any nausea present may also respond to 5HT3 antagonists owing to their antiemetic properties.[98] Serotonin stimulates the gut motility and so agonists can help constipation-predominant irritable bowel, while antagonists can help diarrhea-predominant irritable bowel. Selective serotonin reuptake inhibitors, SSRIs, frequently prescribed for panic and/or anxiety disorder and depression, affect serotonin in the gut, as well as the brain. The bowels are highly dependent on serotonin for neural communication. "Selective serotonin reuptake inhibitor antidepressants seem to promote global well-being in some patients with irritable bowel syndrome and, possibly, some improvement in abdominal pain and bowel symptoms, but this effect appears to be independent of improved depression. Further research is required."[99]

Mast cells and the compound that they secrete are central to the pathophysiology and implicated in the treatment of IBS;[19] some of the secreted mast cell mediators (and associated receptors) which have been implicated in symptoms of IBS or specific subtypes include: histamine (HRH1, HRH2, HRH3), tryptase and chymase (PAR2), serotonin (5-HT3), PGD2 (DP1).[19] Histamine also causes epithelial secretion of chloride ions and water (associated with secretory diarrhea) by signaling through a receptor or ligand-gated ion channel that has not been identified as of 2015.[19] A 2015 review noted that both H1-antihistamines and mast cell stabilizers have shown efficacy in reducing pain associated with visceral hypersensitivity in IBS;[19] other lower quality studies have also suggested the benefit of these agents for IBS.[19] In a related review on idiopathic mast cell activation syndromes (including IBS), a combined treatment approach using antileukotrienes, H1/H2-antihistamines, and a mast cell stabilizer are suggested.[100]

## Laxatives [edit]

For patients who do not adequately respond to dietary fiber, osmotic laxatives such as polyethylene glycol, sorbitol, and lactulose can help avoid "cathartic colon" which has been associated with stimulant laxatives.[101] Among the osmotic laxatives, doses of 17–26 g/d of polyethylene glycol have been well studied. Lubiprostone (Amitiza) is a gastrointestinal agent used for the treatment of idiopathic chronic constipation and constipation-predominant IBS. It is well tolerated in adults, including elderly patients. As of July 20, 2006, lubiprostone had not been studied in pediatric patients. Lubiprostone is a bicyclic fatty acid (prostaglandin E1 derivative) that acts by specifically activating ClC-2 chloride channels on the apical aspect of gastrointestinal epithelial cells, producing a chloride-rich fluid secretion. These secretions soften the stool, increase motility, and promote spontaneous bowel movements. Unlike many laxative products, lubiprostone does not show signs of tolerance, dependency, or altered serum electrolyte concentration.

## Antispasmodics [edit]

The use of antispasmodic drugs (e.g., anticholinergics such as hyoscyamine or dicyclomine) may help patients, especially those with cramps or diarrhea. A meta-analysis by the Cochrane Collaboration concludes if seven patients are treated with antispasmodics, one patient will benefit.[93] Antispasmodics can be divided in two groups: neurotropics and musculotropics.

- Neurotropics — for example, phenobarbitals such as Donnatal or atropine — act at the nerve fibre of the parasympathicus, but also affect other nerves, causing side effects in many patients.
- Musculotropics, such as mebeverine, act directly at the smooth muscle of the gastrointestinal tract, relieving spasm without affecting normal gut motility.[*citation needed*] Since this action is not mediated by the autonomic nervous system, the usual anticholinergic side effects are absent.[*citation needed*]

## Discontinuation of proton pump inhibitors [edit]

Proton pump inhibitors (PPIs) used to suppress stomach acid production may cause bacterial overgrowth leading to IBS symptoms. Discontinuation of PPIs in selected individuals has been recommended as it may lead to an improvement or resolution of IBS symptoms.[102]

## Tricyclic antidepressants [edit]

Strong evidence indicates low doses of tricyclic antidepressants can be effective for IBS. However, the evidence is less robust as to the effectiveness of other antidepressant classes such as SSRIs.[85][87]

## Serotonin agonists [edit]

- Tegaserod (Zelnorm), a selective 5-HT4 agonist for IBS-C, is available for relieving IBS constipation in women and chronic idiopathic constipation in men and women. On March 30, 2007, the FDA requested Novartis Pharmaceuticals to voluntarily discontinue marketing of tegaserod based on the recently identified finding of an increased risk of serious cardiovascular adverse events (heart problems) associated with use of the drug. Novartis agreed to voluntarily suspend marketing of the drug in the United States and in many other countries. On July 27, 2007, the FDA approved a limited-treatment IND program for tegaserod in the US to allow restricted access to the medication for patients in need if no comparable alternative drug or therapy is available to treat the disease. The FDA had issued two previous warnings about the serious consequences of tegaserod. In 2005, it was rejected as an IBS medication by the European Union. Tegaserod, marketed as Zelnorm in the United States, was the only agent approved to treat the multiple symptoms of IBS (in women only), including constipation, abdominal pain, and bloating.
- Selective serotonin reuptake inhibitor antidepressants (SSRIs), because of their serotonergic effect, would seem to help IBS, especially patients who are constipation predominant. Initial crossover studies[103] and randomized controlled trials[104][105][106] support this role. Publication bias may play a role in the apparent benefit of SSRIs.[107] One study concludes that tricyclic antidepressants can improve overall symptoms of irritable bowel syndrome; however, there was no strong evidence to confirm the effectiveness of SSRIs.[108]

## Serotonin antagonists [edit]

Alosetron, a selective 5-HT3 antagonist for IBS-D and cilansetron (also a selective 5-HT3 antagonist) were trialed for IBS. Due to severe adverse effects, namely ischemic colitis and severe constipation, they are not available or recommended.[87]

## Other agents [edit]

Magnesium aluminum silicates and alverine citrate drugs can be effective for IBS.[87]

Evidence is conflicting about the benefit of antidepressants in IBS. Some meta-analyses have found a benefit, while others have not.[109] A meta-analysis of randomized controlled trials of mainly TCAs found three patients have to be treated with TCAs for one patient to improve.[110] A separate randomized controlled trial found TCAs are best for patients with IBS-D.[111]

Rifaximin can be used as an effective treatment for abdominal bloating and flatulence,[112][113] giving more credibility to the potential role of bacterial overgrowth in some patients with IBS.[114]

Domperidone, a dopamine receptor blocker and a parasympathomimetic, has been shown to reduce bloating and abdominal pain as a result of an accelerated colon transit time and reduced faecal load, that is, a relief from 'hidden constipation'; defecation was similarly improved.[115]

The use of opioids is controversial due to the potential risk of tolerance, physical dependence, and addiction, but can be the only relief for some diarrhea-predominant cases when other treatment has been ineffective.[116]

## SIBO therapy [edit]

Statistically significant reduction in IBS symptoms occurs following antibiotic therapy for small intestinal bacterial overgrowth.[117] However, recent research has shown that the lactulose hydrogen breath test does not actually measure SIBO, and that SIBO is unlikely to be the cause of IBS.[118]

## Psychological therapies [edit]

The mind-body or brain-gut interactions has been proposed for IBS, and is gaining increasing research attention.[85] Hypnosis can improve mental well-being, and cognitive behavioural therapy can provide psychological coping strategies for dealing with distressing symptoms, as well as help suppress thoughts and behaviours that increase the symptoms of IBS,[85][87] although the evidence base for effectiveness of psychotherapy and hypnosis is weak and such therapies are in general not recommended.[46] However, in treatment resistant cases where pharmacological therapies over a period of at least 12 months have failed to give relief, NICE clinical guidelines recommend that consideration should be given to psychological treatment strategies such as cognitive behavioural therapy [CBT], hypnotherapy and/or psychological therapy.[119]

## Stress relief [edit]

Reducing stress may reduce the frequency and severity of IBS symptoms. Techniques that may be helpful include:

- Relaxation techniques such as meditation
- Physical activities such as yoga or tai chi
- Regular exercise such as swimming, walking, or running[120]

## Probiotics [edit]

Probiotics can be beneficial in the treatment of IBS; taking 10 billion to 100 billion beneficial bacteria per day is recommended for beneficial results. However, further research is needed on individual strains of beneficial bacteria for more refined recommendations.[85][121] Probiotics have positive effects such as enhancing the intestinal mucosal barrier, providing a physical barrier, bacteriocin production (resulting in

reduced numbers of pathogenic and gas-producing bacteria), reducing intestinal permeability and bacterial translocation, and regulating the immune system both locally and systemically among other beneficial effects.[46] Probiotics may also have positive effects on the gut-brain axis by their positive effects countering the effects of stress on gut immunity and gut function.[122]

A number of probiotics have been found to be effective, including *Lactobacillus plantarum*,[46] and *Bifidobacteria infantis*;[123] but one review found only *Bifidobacteria infantis* showed efficacy.[124] *B. infantis* may have effects beyond the gut via it causing a reduction of proinflammatory cytokine activity and elevation of blood tryptophan levels, which may cause an improvement in symptoms of depression.[125] Some yogurt is made using probiotics that may help ease symptoms of IBS.[126] A probiotic yeast called Saccharomyces boulardii has some evidence of effectiveness in the treatment of irritable bowel syndrome.[127]

Certain probiotics have different effects on certain symptoms of IBS. For example, *Bifidobacterium breve*, *B. longum,* and *Lactobacillus acidophilus* have been found to alleviate abdominal pain. *B. breve, B. infantis, L. casei*, or *L. plantarum* species alleviated distension symptoms. *B. breve, B. infantis, L. casei, L. plantarum, B. longum, L. acidophilus, L. bulgaricus*, and *Streptococcus salivarius* ssp. *thermophilus* have all been found to affect flatulence levels. Most clinical studies show probiotics do not improve straining, sense of incomplete evacuation, stool consistency, fecal urgency, or stool frequency, although a few clinical studies did find some benefit of probiotic therapy. The evidence is conflicting for whether probiotics improve overall quality of life scores.[128]

Probiotics may exert their beneficial effects on IBS symptoms via preserving the gut microbiota, normalisation of cytokine blood levels, improving the intestinal transit time, decreasing small intestine permeability, and by treating small intestinal bacterial overgrowth of fermenting bacteria.[128]

### Herbal remedies [edit]

Peppermint oil appears useful.[129] Safety during pregnancy has not been established, however, and caution is required not to chew or break the enteric coating; otherwise, gastroesophageal reflux may occur as a result of lower esophageal sphincter relaxation. Occasionally, nausea and perianal burning occur as side effects.[85] Iberogast, a multi-herbal extract, was found to be superior in efficacy to placebo.[130] Commiphora mukul and Plantago ovata[131]

Only limited evidence exists for the effectiveness of other herbal remedies for IBS. As with all herbs, it is wise to be aware of possible drug interactions and adverse effects.[85]

### Yoga [edit]

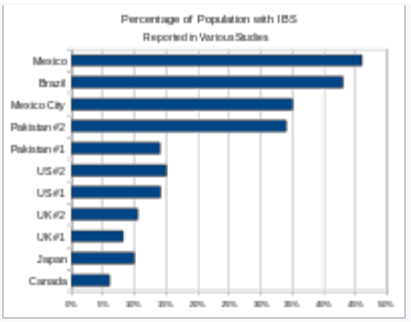
Yoga may be effective for some IBS patients, especially poses which exercise the lower abdomen.[87]

### Acupuncture [edit]

A meta-analysis found no benefits of acupuncture relative to placebo for IBS symptom severity or IBS-related quality of life.[132]

## Epidemiology [edit]

The prevalence of IBS varies by country and by age range examined. The bar graph at right shows the percentage of the population reporting symptoms of IBS in studies from various geographic regions (see table below for references). The following table contains a list of studies performed in different countries that measured the prevalence of IBS and IBS-like symptoms:



Percentage of population with IBS reported in various studies in different countries

**Percentage of population reporting symptoms of IBS in various studies from various geographic areas**

| Country | Prevalence | Author/year | Notes |
|---|---|---|---|
| Canada | 6%[133] | Boivin, 2001 | |
| Japan | 10%[134] | Quigley, 2006 | Study measured prevalence of GI abdominal pain/cramping |
| United Kingdom | 8.2%[135]<br>10.5%[136] | Ehlin, 2003<br>Wilson, 2004 | Prevalence increased substantially 1970–2004 |
| United States | 14.1%[137] | Hungin, 2005 | Most undiagnosed |
| United States | 15%[133] | Boivin, 2001 | Estimate |
| Pakistan | 14%[138] | Jafri, 2007 | Much more common in 16–30 age range. Of IBS patients, 56% male, 44% female |
| Pakistan | 34%[139] | Jafri, 2005 | College students |
| Mexico City | 35%[140] | Schmulson, 2006 | n=324. Also measured functional diarrhea and functional vomiting. High rates attributed to "stress of living in a populated city." |
| Brazil | 43%[134] | Quigley, 2006 | Study measured prevalence of GI abdominal pain/cramping |
| Mexico | 46%[134] | Quigley, 2006 | Study measured prevalence of GI abdominal pain/cramping |

## Gender [edit]

Women are around two to three times more likely to be diagnosed with IBS and four to five times more likely to seek specialty care for it than men.[141] These differences likely reflect a combination of both biological (sex) and social (gender) factors. People diagnosed with IBS are usually younger than 45 years old.[1] Studies of female patients with IBS show symptom severity often fluctuates with the menstrual cycle, suggesting hormonal differences may play a role.[142] Endorsement of gender-related traits has been associated with quality of life and psychological adjustment in IBS.[143] Gender differences in healthcare-seeking may also play a role.[144] Gender differences in trait anxiety may contribute to lower pain thresholds in women, putting them at greater risk for a number of chronic pain disorders.[145] Finally, sexual trauma is a major risk factor for IBS, with as many as 33% of those affected reporting such abuse. Because women are at higher risk of sexual abuse than men, sex-related risk of abuse may contribute to the higher rate of IBS in women.[146]

# History [edit]

One of the first references to the concept of an "irritable bowel" appeared in the *Rocky Mountain Medical Journal* in 1950.[147] The term was used to categorize patients who developed symptoms of diarrhea, abdominal pain, and constipation, but where no well-recognized infective cause could be found. Early theories suggested the irritable bowel was caused by a psychosomatic or mental disorder.

## Economics [edit]

The examples and perspective in this section **may not represent a worldwide view of the subject**. You may improve this article, discuss the issue on the talk page, or create a new article, as appropriate. *(July 2011) (Learn how and when to remove this template message)*

### United States [edit]

The aggregate cost of irritable bowel syndrome in the United States has been estimated at $1.7–10 billion in direct medical costs, with an additional $20 billion in indirect costs, for a total of $21.7–30 billion.[3] A study by a managed care company comparing medical costs of IBS patients to non-IBS controls identified a 49% annual increase in medical costs associated with a diagnosis of IBS.[148] IBS patients incurred average annual direct costs of $5,049 and $406 in out-of-pocket expenses in 2007.[149] A study of workers with IBS found that they reported a 34.6% loss in productivity, corresponding to 13.8 hours lost per 40 hour week.[150] A study of employer-related health costs from a Fortune 100 company conducted with data from the 1990s found IBS patients incurred US $4527 in claims costs vs. $3276 for controls.[151] A study on Medicaid costs conducted in 2003 by the University of Georgia's College of Pharmacy and Novartis found IBS was associated in an increase of $962 in Medicaid costs in California, and $2191 in North Carolina. IBS patients had higher costs for physician visits, outpatients visits, and prescription drugs. The study suggested the costs associated with IBS were comparable to those found in asthma patients.[152]

## Research [edit]

Individuals with IBS have been found to have decreased diversity and numbers of bacteroidetes microbiota. Preliminary research into the effectiveness of fecal microbiota transplant in the treatment of IBS has been very favourable with a 'cure' rate of between 36 percent and 60 percent with remission of core IBS symptoms persisting at 9 and 19 months follow up.[153][154] Treatment with probiotic strains of bacteria has shown to be effective, though not all strains of microorganisms confer the same benefit and adverse side effects have been documented in a minority of cases.[155]

There is increasing evidence for the effectiveness of mesalazine (5-aminosalicylic acid) in the treatment of IBS.[156] Mesalazine is a drug with anti-inflammatory properties that has been reported to significantly reduce immune mediated inflammation in the gut of IBS affected individuals with mesalazine therapy resulting in improved IBS symptoms as well as feelings of general wellness in IBS affected people. It has also been observed that mesalazine therapy helps to normalise the gut flora which is often abnormal in people who have IBS. The therapeutic benefits of mesalazine may be the result of improvements to the epithelial barrier function.[157]

An IgG-mediated food intolerance diet led to a 24% greater deterioration in symptoms compared to those on the elimination diet and food elimination based on IgG antibodies may be effective in reducing IBS symptoms and is worthy of further biomedical research.[81] The main problem with this study was that the differences in symptoms were only observed in exclusion diets is limited, treatment based on "abnormally" high IgG antibodies cannot be recommended.[158]

Differences in visceral sensitivity and intestinal physiology have been noted in IBS. Mucosal barrier reinforcement in response to oral 5-HTP was absent in IBS compared to controls.[159] IBS/IBD individuals are less often HLA DQ2/8 positive than in upper functional gastrointestinal disease and healthy populations.[160]

A questionnaire in 2006 designed to identify patients' perceptions about IBS, their preferences on the type of information they need, and educational media and expectations from health care providers revealed misperceptions about IBS developing into other conditions, including colitis, malnutrition, and cancer. The survey found IBS patients were most interested in learning about foods to avoid (60%), causes of IBS (55%), medications (58%), coping strategies (56%), and psychological factors related to IBS (55%). The respondents indicated they wanted their physicians to be available by phone or e-mail following a visit (80%), have the ability to listen (80%), and provide hope (73%) and support (63%).[161]

"Functional gastrointestinal disorders (FGIDs) are characterized by chronic complaints arising from disorganized brain-gut interactions leading to dysmotility and

hypersensitivity. The two most prevalent FGIDs, affecting up to 16–26% of worldwide population, are functional dyspepsia and irritable bowel syndrome. ... It is well established that mast cell activation can generate epithelial and neuro-muscular dysfunction and promote visceral hypersensitivity and altered motility patterns in FGIDs, postoperative ileus, food allergy and inflammatory bowel disease.

Mast cells play a central pathophysiological role in IBS and possibly in functional dyspepsia, although not well defined.

Increased mast cell activation is a common finding in the mucosa of patients with functional GI disorders. ...

Treatment with mast cell stabilisers offers a reasonably safe and promising option for the management of those patients with IBS non-responding to conventional approaches, though future studies are warranted to evaluate efficacy and indications."

"IBS-like symptoms, such as abdominal pain, gas, distension, and irregular bowel movements, frequently are reported and therefore make it difficult to distinguish NCGS from IBS induced by other causes. The differential diagnosis is facilitated for patients who also experience extraintestinal symptoms, including headache or frank migraine, foggy mind, chronic fatigue, joint and muscle pain, tingling of the extremities, leg or arm numbness, eczema, anemia, depression, or for patients who report a reduction in immune-mediated (including autoimmune) symptoms on a GFD. (...) Therefore, it is possible to consider some subjects with NCGS to be typical IBS patients and vice versa: a subgroup of IBS patients may have NCGS. This last scenario was highlighted in subjects affected by the diarrheapredominant variant of IBS —particularly those with HLA-DQ2 and/or DQ8 genotypes (associated with celiac disease)."

Conditions diagnosed by stool test | Abdominal pain | Chronic pain syndromes

# Pancreatitis

**Pancreatitis** is inflammation of the pancreas. The pancreas is a large organ behind the stomach that produces digestive enzymes. There are two main types, acute pancreatitis and chronic pancreatitis. Signs and symptoms of pancreatitis include pain in the upper abdomen, nausea and vomiting. The pain often goes into the back and is usually severe. In acute pancreatitis a fever may occur and symptoms typically resolve in a few days. In chronic pancreatitis weight loss, fatty stool, and diarrhea may occur. Complications may include infection, bleeding, diabetes mellitus, or problems with other organs.[1]

The most common causes of acute pancreatitis are gallstones and heavy alcohol use. Other causes include direct trauma, certain medications, infections such as mumps, and tumors among others. Chronic pancreatitis may develop as a result of acute pancreatitis. It is most commonly due to many years of heavy alcohol use. Other causes include high levels of blood fats, high blood calcium, some medications, and certain genetic disorders such as cystic fibrosis among others.[1] Smoking increases the risk of both acute and chronic pancreatitis.[2][3] Diagnosis of acute pancreatitis is based on a threefold increase in the blood of either amylase or lipase. In chronic pancreatitis these tests may be normal. Medical imaging such as ultrasound and CT scan may also be useful.[1]

Acute pancreatitis is usually treated with intravenous fluids, pain medication, and sometimes antibiotics. Typically no eating or drinking is allowed and a tube may be placed into the stomach. A procedure known as an endoscopic retrograde cholangiopancreatography (ERCP) may be done to open the pancreatic duct if blocked. In those with gallstones the gallbladder is often also removed. In chronic pancreatitis, in addition to the above, temporary feeding through a nasogastric tube may be used to provide adequate nutrition. Long-term dietary changes and pancreatic enzyme replacement may be required. And occasionally surgery is done to remove parts of the pancreas.[1]

Globally, in 2013 about 17 million cases of pancreatitis occurred.[4] This resulted in 123,000 deaths, up from 83,000 deaths in 1990.[5] Acute pancreatitis occurs in about 30 per 100,000 people a year.[2] New cases of chronic pancreatitis develop in about 8 per 100,000 people a year and currently affect about 50 per 100,000 people in the United States.[6] It is more common in men than women. Often chronic pancreatitis starts between the ages of 30 and 40 while it is rare in children.[1] Acute

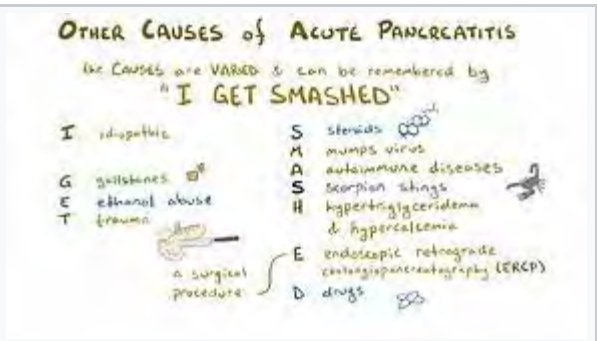
[edit on Wikidata]

pancreatitis was first described on autopsy in 1882 while chronic pancreatitis was first described in 1946.[6]



Play media

Video explanation

## Signs and symptoms [edit]

The most common symptoms of pancreatitis are severe upper abdominal or left upper quadrant burning pain radiating to the back, nausea, and vomiting that is worse with eating. The physical examination will vary depending on severity and presence of internal bleeding. Blood pressure may be elevated by pain or decreased by dehydration or bleeding. Heart and respiratory rates are often elevated. The abdomen is usually tender but to a lesser degree than the pain itself. As is common in abdominal disease, bowel sounds may be reduced from reflex bowel paralysis. Fever or jaundice may be present. Chronic pancreatitis can lead to diabetes or pancreatic cancer. Unexplained weight loss may occur from a lack of pancreatic enzymes hindering digestion.

## Causes [edit]

Eighty percent of cases of pancreatitis are caused by alcohol or gallstones. Gallstones are the single most common cause of acute pancreatitis.[7] Alcohol is the single most common cause of chronic pancreatitis.[8][9][10][11][12]

Some medications are commonly associated with pancreatitis, most commonly corticosteroids such as prednisolone, but also including the HIV drugs didanosine and pentamidine, diuretics, the anticonvulsant valproic acid, the chemotherapeutic agents L-asparaginase and azathioprine, estrogen by way of increased blood triglycerides,[13] and antihyperglycemic agents like metformin,[14] vildagliptin,[15] and sitagliptin.[16] It may be noted here that the drugs used to treat conditions that are themselves associated with increased events of pancreatitis may also be incidentally linked to pancreatitis. Examples include statins in dyslipidemia and gliptins in diabetes. According to the Food and Drug Administration's MedWatch Surveillance System and Published Reports Atypical, atypical antipsychotics such as clozapine, risperidone, and olanzapine can also be responsible for causing pancreatitis.[17]

Edit links

Other common causes include trauma, mumps, autoimmune disease, high blood calcium, hypothermia, and endoscopic retrograde cholangiopancreatography (ERCP). Pancreas divisum is a common congenital malformation of the pancreas that may underlie some recurrent cases. Diabetes mellitus type 2 is associated with a 2.8-fold higher risk.[18]

Less common causes include pancreatic cancer, pancreatic duct stones,[19] vasculitis (inflammation of the small blood vessels in the pancreas), coxsackievirus infection, and porphyria—particularly acute intermittent porphyria and erythropoietic protoporphyria.

There is an inherited form that results in the activation of trypsinogen within the pancreas, leading to autodigestion. Involved genes may include Trypsin 1, which codes for trypsinogen, SPINK1, which codes for

a trypsin inhibitor, or cystic fibrosis transmembrane conductance regulator.[20]

The mnemonic GETSMASHED is often used to remember the common causes of Pancreatitis: G—Gall stones E—Ethanol T—Trauma S—Steroids M—Mumps A—Autoimmune Pancreatitis S—Scorpion sting H—Hyperlipidaemia, Hypothermia, Hyperparathyroidism E—Endoscopic retrograde cholangiopancreatography D—Drugs commonly azathioprine, valproic acid

### Infection [edit]

A number of infectious agents have been recognized as causes of pancreatitis including:[21]

- Viruses
  - Coxsackie virus
  - Cytomegalovirus
  - Hepatitis B
  - Herpes simplex virus
  - Mumps
  - Varicella-zoster virus
- Bacteria
  - Legionella
  - Leptospira
  - Mycoplasma
  - Salmonella
- Fungi
  - Aspergillus
- Parasites
  - Ascaris
  - Cryptosporidium
  - Toxoplasma

## Diagnosis [edit]

The differential diagnosis for pancreatitis includes but is not limited to cholecystitis, choledocholithiasis, perforated peptic ulcer, bowel infarction, small bowel obstruction, hepatitis and mesenteric ischemia .[22]

Diagnosis requires 2 of the 3 following criteria:

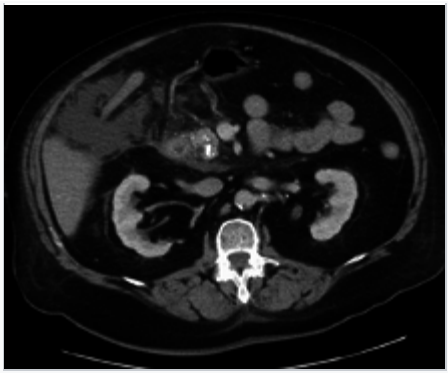
- Characteristic acute onset of epigastric or vague abdominal pain that may radiate to the back (see signs and symptoms above)
- Serum amylase or lipase levels ≥ 3 times the upper limit of normal
- An imaging study with characteristic changes. CT, MRI, abdominal ultrasound or endoscopic ultrasound can be used for diagnosis.

Acute exudative pancreatitis on CT scan

Amylase and lipase are 2 enzymes produced by the pancreas. Elevations in lipase are generally considered a better indicator for pancreatitis as it has greater specificity and has a longer half life.[23]

For imaging, abdominal ultrasound is convenient, simple, non-invasive, and inexpensive.[24] It is more sensitive and specific for pancreatitis from gallstones than other imaging modalities.[23] However, in 25–35% of patients the view of the pancreas can be obstructed by bowel gas making it difficult to evaluate.[22]

A contrast-enhanced CT scan is usually performed more than 48 hours after the onset of pain to evaluate for pancreatic necrosis and



Calcified pancreatic duct stones with some free intraabdominal fluid

extrapancreatic fluid as well as predict the severity of the disease. CT scanning earlier can be falsely reassuring.

ERCP or an endoscopic ultrasound can also be used if a biliary cause for pancreatitis is suspected.

# Treatment [edit]

The treatment of pancreatitis is supportive and depends on severity. Morphine generally is suitable for pain control. There are no clinical studies to suggest that morphine can aggravate or cause pancreatitis or cholecystitis.[25]

The treatment that is received for acute pancreatitis will depend on whether the diagnosis is for the mild form of the condition, which causes no complications, or the severe form, which can cause serious complications.

## Mild acute pancreatitis [edit]

The treatment of mild acute pancreatitis is successfully carried out by admission to a general hospital ward. Traditionally, people were not allowed to eat until the inflammation resolved but more recent evidence suggests early feeding is safe and improves outcomes. Because pancreatitis can cause lung damage and affect normal lung function, oxygen is occasionally delivered through breathing tubes that are connected via the nose. The tubes can then be removed after a few days once it is clear that the condition is improving. Dehydration may result during an episode of acute pancreatitis, so fluids will be provided intravenously. The pain associated with even mild or moderate cases of acute pancreatitis can be severe, which means that a narcotic painkiller may be required.

## Severe acute pancreatitis [edit]

Severe pancreatitis is associated with organ failure, necrosis, infected necrosis, pseudocyst, and abscess. If diagnosed with severe acute pancreatitis, people will need to be admitted to a high dependency unit or intensive care unit. It is likely that the levels of fluids inside the body will have dropped significantly as it diverts bodily fluids and nutrients in an attempt to repair the pancreas. The drop in fluid levels can lead to a reduction in the volume of blood within the body, which is known as hypovolemic shock. Hypovolemic shock can be life-threatening as it can very quickly starve the body of the oxygen-rich blood that it needs to survive. To avoid going into hypovolemic shock, fluids will be pumped intravenously. Oxygen will be supplied through tubes attached to the nose and ventilation equipment may be used to assist with breathing. Feeding tubes may be used to provide nutrients, combined with appropriate analgesia.

As with mild acute pancreatitis, it will be necessary to treat the underlying cause—gallstones, discontinuing medications, cessation of alcohol, etc. If the cause is gallstones, it is likely that an ERCP procedure or removal of the gallbladder will be recommended. The gallbladder should be removed during the same hospital admission or within two weeks of pancreatitis onset so as to limit the risk of recurrent pancreatitis. If the cause of pancreatitis is alcohol, cessation of alcohol consumption and treatment for alcohol dependency may improve pancreatitis. Even if the underlying cause is not related to alcohol consumption, doctors recommend avoiding it for at least six months as this can cause further damage to the pancreas during the recovery process.[26] Oral intake, especially fats, is generally restricted initially but early enteral feeding within 48 hours has been shown to improve clinical outcomes.[27] Fluids and electrolytes are replaced intravenously. Nutritional support is initiated via tube feeding to surpass the portion of the digestive tract most affected by secreted pancreatic enzymes if there is no improvement in the first 72–96 hours of treatment.[28]

## Prognosis [edit]

Severe acute pancreatitis has mortality rates around 2–9%, higher where necrosis of the pancreas has occurred.[29]

Several scoring systems are used to predict the severity of an attack of pancreatitis. They each combine demographic and laboratory data to estimate severity or probability of death. Examples include APACHE II, Ranson, BISAP, and Glasgow. The Modified Glasgow criteria suggests that a case be considered severe if at least three of the following are true:[30]

- Age > 55 years
- Blood levels:
  - PO2 Oxygen < 60mmHg or 7.9kPa
  - White blood cells > 15
  - Calcium < 2 mmol/L
  - Urea > 16 mmol/L
  - Lactate dehydrogenase (LDH) > 600iu/L
  - Aspartate transaminase (AST) > 200iu/L
  - Albumin < 32g/L
  - Glucose > 10 mmol/L

This can be remembered using the mnemonic PANCREAS:

- PO2 Oxygen < 60mmHg or 7.9kPa
- Age > 55
- Neutrophilia White blood cells > 15
- Calcium < 2 mmol/L
- Renal Urea > 16 mmol/L
- Enzymes Lactate dehydrogenase (LDH) > 600iu/L Aspartate transaminase (AST) > 200iu/L
- Albumin < 32g/L
- Sugar Glucose > 10 mmol/L

The BISAP score (Blood urea nitrogen level >25 mg/dL, Impaired mental status, Systemic inflammatory response syndrome, age over 60 years, pleural effusion) has been validated as similar to other prognostic scoring systems.[31]

## Complications [edit]

Early complications include shock, infection, systemic inflammatory response syndrome, low blood calcium, high blood glucose, and dehydration. Blood loss, dehydration, and fluid leaking into the abdominal cavity (ascites) can lead to kidney failure. Respiratory complications are often severe. Pleural effusion is usually present. Shallow breathing from pain can lead to lung collapse. Pancreatic enzymes may attack the lungs, causing inflammation. Severe inflammation can lead to intra-abdominal hypertension and abdominal compartment syndrome, further impairing renal and respiratory function and potentially requiring management with an open abdomen to relieve the pressure.[32]

Late complications include recurrent pancreatitis and the development of pancreatic pseudocysts—collections of pancreatic secretions that have been walled off by scar tissue. These may cause pain, become infected, rupture and bleed, block the bile duct and cause jaundice, or migrate around the abdomen. Acute necrotizing pancreatitis can lead to a pancreatic abscess, a collection of pus caused by necrosis, liquefaction, and infection. This happens in approximately 3% of cases, or almost 60% of cases involving more than two pseudocysts and gas in the pancreas.[33]

## Epidemiology [edit]

Globally the incidence of acute pancreatitis is 5 to 35 cases per 100,000 people. The incidence of chronic pancreatitis is 4–8 per 100,000 with a prevalence of 26–42 cases per 100,000.[34] In 2013 pancreatitis resulted in 123,000 deaths up from 83,000 deaths in 1990.[5]

# Peptic ulcer

From Wikipedia, the free encyclopedia
(Redirected from Peptic ulcer disease)

**Peptic ulcer disease** (**PUD**), also known as a **peptic ulcer** or **stomach ulcer**, is a break in the lining of the stomach, first part of the small intestine, or occasionally the lower esophagus.[1][2] An ulcer in the stomach is known as a **gastric ulcer** while that in the first part of the intestines is known as a **duodenal ulcer**. The most common symptoms of a duodenal ulcer are waking at night with upper abdominal pain or upper abdominal pain that improves with eating.[1] With a gastric ulcer the pain may worsen with eating.[3] The pain is often described as a burning or dull ache. Other symptoms include belching, vomiting, weight loss, or poor appetite. About a third of older people have no symptoms.[1] Complications may include bleeding, perforation, and blockage of the stomach. Bleeding occurs in as many as 15% of people.[4]

Common causes include the bacteria *Helicobacter pylori* and non-steroidal anti-inflammatory drugs (NSAIDs).[1] Other less common causes include tobacco smoking, stress due to serious illness, Behcet disease, Zollinger-Ellison syndrome, Crohn disease and liver cirrhosis, among others.[1][5] Older people are more sensitive to the ulcer causing effects of NSAIDs. The diagnosis is typically suspected due to the presenting symptoms with confirmation by either endoscopy or barium swallow. *H. pylori* can be diagnosed by testing the blood for antibodies, a urea breath test, testing the stool for signs of the bacteria, or a biopsy of the stomach. Other conditions that produce similar symptoms include stomach cancer, coronary heart disease, and inflammation of the stomach lining or gallbladder.[1]

Diet does not play an important role in either causing or preventing ulcers.[6] Treatment includes stopping smoking, stopping NSAIDs, stopping alcohol, and medications to decrease stomach acid. The medication used to decrease acid is usually either a proton pump inhibitor (PPI) or an H2 blocker with four weeks of treatment initially recommended.[1] Ulcers due to *H. pylori* are treated with a combination of medications such as amoxicillin, clarithromycin, and a PPI. Antibiotic resistance is increasing and thus treatment may not always be effective.[7] Bleeding ulcers may be treated by endoscopy, with open surgery typically only used in cases in which it is not successful.[4]

Peptic ulcers are present in around 4% of the population.[1] They newly began in around 53 million people [8] [9]

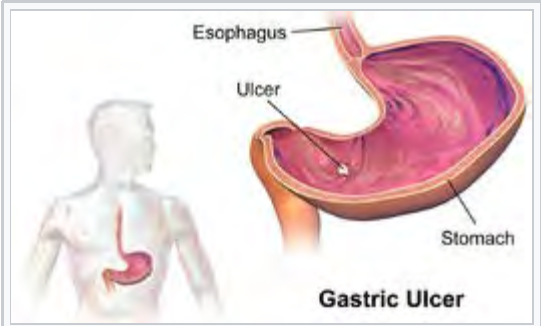
[edit on Wikidata]

in 2013. About 10% of people develop a peptic ulcer at some point in their life. They resulted in 301,000 deaths in 2013 down from 327,000 deaths in 1990.[10] The first description of a perforated peptic ulcer was in 1670 in Princess Henrietta of England.[4] *H. pylori* was first identified as causing peptic ulcers by Barry Marshall and Robin Warren in the late 20th century,[7] a discovery for which they received the Nobel Prize in 2005.[11]

## Signs and symptoms [edit]

Signs and symptoms of a peptic ulcer can include one or more of the following:



Gastric ulcer

- abdominal pain, classically epigastric strongly correlated to mealtimes. In case of duodenal ulcers the pain appears about three hours after taking a meal;
- bloating and abdominal fullness;
- waterbrash (rush of saliva after an episode of regurgitation to dilute the acid in esophagus - although this is more associated with gastroesophageal reflux disease);
- nausea, and copious vomiting;
- loss of appetite and weight loss;
- hematemesis (vomiting of blood); this can occur due to bleeding directly from a gastric ulcer, or from damage to the esophagus from severe/continuing vomiting.
- melena (tarry, foul-smelling feces due to presence of oxidized iron from hemoglobin);
- rarely, an ulcer can lead to a gastric or duodenal perforation, which leads to acute peritonitis, extreme, stabbing pain,[12] and requires immediate surgery.

A history of heartburn, gastroesophageal reflux disease (GERD) and use of certain forms of medication can raise the suspicion for peptic ulcer. Medicines associated with peptic ulcer include NSAIDs (non-steroid anti-inflammatory drugs) that inhibit cyclooxygenase, and most glucocorticoids (e.g. dexamethasone and prednisolone).

In patients over 45 with more than two weeks of the above symptoms, the odds for peptic ulceration are high enough to warrant rapid investigation by esophagogastroduodenoscopy.

The timing of the symptoms in relation to the meal may differentiate between gastric and duodenal ulcers: A gastric ulcer would give epigastric pain during the meal, as gastric acid production is increased as food enters the stomach. Symptoms of duodenal ulcers would initially be relieved by a meal, as the pyloric sphincter closes to concentrate the stomach contents, therefore acid is not reaching the duodenum. Duodenal ulcer pain would manifest mostly 2–3 hours after the meal, when the stomach begins to release digested food and acid into the duodenum.

Also, the symptoms of peptic ulcers may vary with the location of the ulcer and the patient's age. Furthermore, typical ulcers tend to heal and recur and as a result the pain may occur for few days and weeks and then wane or disappear.[13] Usually, children and the elderly do not develop any symptoms unless complications have arisen.

Burning or gnawing feeling in the stomach area lasting between 30 minutes and 3 hours commonly accompanies ulcers. This pain can be misinterpreted as hunger, indigestion or heartburn. Pain is usually caused by the ulcer but it may be aggravated by the stomach acid when it comes into contact with the ulcerated area. The pain caused by peptic ulcers can be felt anywhere from the navel up to the sternum, it may last from few minutes to several hours and it may be worse when the stomach is empty. Also, sometimes the pain may flare at night and it can commonly be temporarily relieved by eating foods that buffer stomach acid or by taking anti-acid medication.[14] However, peptic ulcer disease symptoms may be different for every sufferer.[15]

## Complications [edit]

- Gastrointestinal bleeding is the most common complication. Sudden large bleeding can be life-threatening.[16] It occurs when the ulcer erodes one of the blood vessels, such as the gastroduodenal artery.
- Perforation (a hole in the wall of the gastrointestinal tract) often leads to catastrophic consequences if left untreated. Erosion of the gastro-intestinal wall by the ulcer leads to spillage of stomach or intestinal content into the abdominal cavity. Perforation at the anterior surface of the stomach leads to acute peritonitis, initially chemical and later bacterial peritonitis. The first sign is often sudden intense abdominal pain; an example is Valentino's syndrome, named after the silent-film actor who experienced this pain before his death. Posterior wall perforation leads to bleeding due to the involvement of gastroduodenal artery that lies posterior to the first part of the duodenum.
- Penetration is a form of perforation in which the hole leads to and the ulcer continues into adjacent organs such as the liver and pancreas.[13]
- Gastric outlet obstruction is a narrowing of the pyloric canal by scarring and swelling of the gastric antrum and duodenum due to peptic ulcers. The person often presents with severe vomiting without bile.
- Cancer is included in the differential diagnosis (elucidated by biopsy), *Helicobacter pylori* as the etiological factor making it 3 to 6 times more likely to develop stomach cancer from the ulcer.[13]

# Cause [edit]

## *H. pylori* [edit]

A major causative factor (60% of gastric and up to 50–75%[17] of duodenal ulcers) is chronic inflammation due to *Helicobacter pylori* that colonizes the antral mucosa.[18] The immune system is unable to clear the infection, despite the appearance of antibodies. Thus, the bacterium can cause a chronic active gastritis (type B gastritis). Gastrin stimulates the production of gastric acid by parietal cells. In *H. pylori* colonization responses to increased gastrin, the increase in acid can contribute to the erosion of the mucosa and therefore ulcer formation.

### NSAIDs [edit]

Another major cause is the use of NSAIDs, such as ibuprofen and aspirin.[19] The gastric mucosa protects itself from gastric acid with a layer of mucus, the secretion of which is stimulated by certain prostaglandins. NSAIDs block the function of cyclooxygenase 1 (*cox-1*), which is essential for the production of these prostaglandins. COX-2 selective anti-inflammatories (such as celecoxib or the since withdrawn rofecoxib) preferentially inhibit *cox-2*, which is less essential in the gastric mucosa, and roughly halve the risk of NSAID-related gastric ulceration.

### Stress [edit]

Stress due to serious health problems such as those requiring treatment in an intensive care unit is well described as a cause of peptic ulcers, which are termed stress ulcers.[5]

While chronic life stress was once believed to be the main cause of ulcers, this is no longer the case.[20] It is, however, still occasionally believed to play a role.[20] This may be by increasing the risk in those with other causes such as *H. pylori* or NSAID use.[21]

### Diet [edit]

Dietary factors such as spice consumption, were hypothesized to cause ulcers until late in the 20th century, but have been shown to be of relatively minor importance.[22] Caffeine and coffee, also commonly thought to cause or exacerbate ulcers, appear to have little effect.[23][24] Similarly, while studies have found that alcohol consumption increases risk when associated with *H. pylori* infection, it does not seem to independently increase risk. Even when coupled with *H. pylori* infection, the increase is modest in comparison to the primary risk factor.[25][26][nb 1]

### Other [edit]

Although some studies have found correlations between smoking and ulcer formation,[27] others have been more specific in exploring the risks involved and have found that smoking by itself may not be much of a risk factor unless associated with *H. pylori* infection.[25][28][29][nb 2]

Gastrinomas (Zollinger–Ellison syndrome), rare gastrin-secreting tumors, also cause multiple and difficult-to-heal ulcers.

## Diagnosis [edit]

The diagnosis is mainly established based on the characteristic symptoms. Stomach pain is usually the first signal of a peptic ulcer. In some cases, doctors may treat ulcers without diagnosing them with specific tests and observe whether the symptoms resolve, thus indicating that their primary diagnosis was accurate.

More specifically, peptic ulcers erode the muscularis mucosae, at least to the level of the submucosa (contrast with erosions, which do not involve the muscularis mucosae).[30]

Confirmation of the diagnosis is made with the help of tests such as endoscopies or barium contrast x-rays. The tests are typically ordered if the symptoms do not resolve after a few weeks of treatment, or when they first appear in a person who is over age 45 or who has other symptoms such as weight loss, because stomach cancer can cause similar symptoms. Also, when severe ulcers resist treatment, particularly if a person has several ulcers or the ulcers are in unusual places, a doctor may suspect an

Endoscopic image of gastric ulcer, biopsy proven to be gastric cancer.

underlying condition that causes the stomach to overproduce acid.[13]

An esophagogastroduodenoscopy (EGD), a form of endoscopy, also known as a gastroscopy, is carried out on patients in whom a peptic ulcer is suspected. By direct visual identification, the location and severity of an ulcer can be described. Moreover, if no ulcer is present, EGD can often provide an alternative diagnosis.

One of the reasons that blood tests are not reliable for accurate peptic ulcer diagnosis on their own is their inability to differentiate between past exposure to the bacteria and current infection. Additionally, a false negative result is possible with a blood test if the patient has recently been taking certain drugs, such as antibiotics or proton-pump inhibitors.[31]

The diagnosis of *Helicobacter pylori* can be made by:

- Urea breath test (noninvasive and does not require EGD);
- Direct culture from an EGD biopsy specimen; this is difficult to do, and can be expensive. Most labs are not set up to perform *H. pylori* cultures;
- Direct detection of urease activity in a biopsy specimen by rapid urease test;
- Measurement of antibody levels in the blood (does not require EGD). It is still somewhat controversial whether a positive antibody without EGD is enough to warrant eradication therapy;
- Stool antigen test;
- Histological examination and staining of an EGD biopsy.

The breath test uses radioactive carbon to detect H. pylori.[32] To perform this exam the patient will be asked to drink a tasteless liquid which contains the carbon as part of the substance that the bacteria breaks down. After an hour, the patient will be asked to blow into a bag that is sealed. If the patient is infected with H. pylori, the breath sample will contain radioactive carbon dioxide. This test provides the advantage of being able to monitor the response to treatment used to kill the bacteria.

The possibility of other causes of ulcers, notably malignancy (gastric cancer) needs to be kept in mind. This is especially true in ulcers of the *greater (large) curvature* of the stomach; most are also a consequence of chronic *H. pylori* infection.

If a peptic ulcer perforates, air will leak from the inside of the gastrointestinal tract (which always contains some air) to the peritoneal cavity (which normally never contains air). This leads to "free gas" within the peritoneal cavity. If the patient stands erect, as when having a chest X-ray, the gas will float to a position underneath the diaphragm. Therefore, gas in the peritoneal cavity, shown on an erect chest X-ray or supine lateral abdominal X-ray, is an omen of perforated peptic ulcer disease.

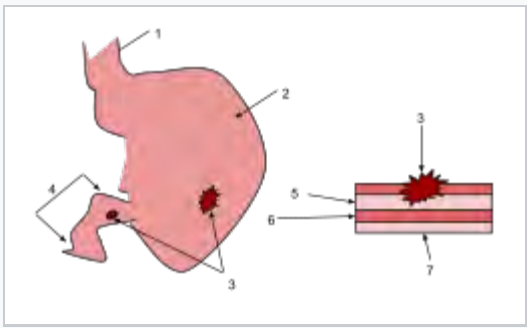
## Classification [edit]

### By area [edit]

- Duodenum (called duodenal ulcer)
- Esophagus (called esophageal ulcer)
- Stomach (called gastric ulcer)
- Meckel's diverticulum (called Meckel's diverticulum ulcer; is very tender with palpation)

### Modified Johnson [edit]

- Type **I**: Ulcer along the body of the stomach, most often along the lesser curve at incisura angularis along the locus minoris resistantiae. Not associated with acid hypersecretion.
- Type **II**: Ulcer in the body in combination with duodenal ulcers. Associated with acid oversecretion.
- Type **III**: In the pyloric channel within 3 cm of pylorus. Associated with acid oversecretion.
- Type **IV**: Proximal gastroesophageal ulcer
- Type **V**: Can occur throughout the stomach. Associated with



1. Esophagus
2. Stomach
3.Ulcers
4.Duodenum
5.Mucosa
6.Submucosa
7.Muscle

the chronic use of NSAIDs (such as ibuprofen).

## Macroscopic appearance [edit]

Gastric ulcers are most often localized on the lesser curvature of the stomach. The ulcer is a round to oval parietal defect ("hole"), 2 to 4 cm diameter, with a smooth base and perpendicular borders. These borders are not elevated or irregular in the acute form of peptic ulcer, regular but with elevated borders and inflammatory surrounding in the chronic form. In the ulcerative form of gastric cancer the borders are irregular. Surrounding mucosa may present radial folds, as a consequence of the parietal scarring.

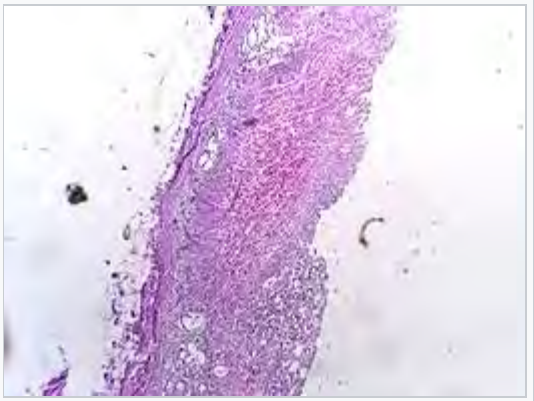
A benign gastric ulcer (from the antrum) of a gastrectomy specimen.

## Microscopic appearance [edit]

A gastric peptic ulcer is a mucosal defect which penetrates the muscularis mucosae and lamina propria, produced by acid-pepsin aggression. Ulcer margins are perpendicular and present chronic gastritis. During the active phase, the base of the ulcer shows 4 zones: inflammatory exudate, fibrinoid necrosis, granulation tissue and fibrous tissue. The fibrous base of the ulcer may contain vessels with thickened wall or with thrombosis.[33]

## Differential diagnosis [edit]

- Gastritis
- Stomach cancer
- Gastroesophageal reflux disease
- Pancreatitis
- Hepatic congestion
- Cholecystitis
- Biliary colic
- Inferior myocardial infarction
- Referred pain (pleurisy, pericarditis)
- Superior mesenteric artery syndrome



Micrograph showing erosive gastric ulcer. (H&E stain)

# Treatment [edit]

Younger patients with ulcer-like symptoms are often treated with antacids or H2 antagonists before endoscopy is undertaken.

People who are taking nonsteroidal anti-inflammatories (NSAIDs) may also be prescribed a prostaglandin analogue (misoprostol) in order to help prevent peptic ulcers.

## Acid reducing medication [edit]

H2 antagonists or proton-pump inhibitors decrease the amount of acid in the stomach, helping with healing of ulcers.[1]

### *H. pylori* [edit]

When *H. pylori* infection is present, the most effective treatments are combinations of 2 antibiotics (e.g. clarithromycin, amoxicillin, tetracycline, metronidazole) and a proton-pump inhibitor (PPI), sometimes together with a bismuth compound. In complicated, treatment-resistant cases, 3 antibiotics (e.g. amoxicillin + clarithromycin + metronidazole) may be used together with a PPI and sometimes with bismuth compound. An effective first-line therapy for uncomplicated cases would be amoxicillin + metronidazole + pantoprazole (a PPI).[1]

## Surgery [edit]

Perforated peptic ulcer is a surgical emergency and requires surgical repair of the perforation. Most bleeding ulcers require endoscopy urgently to stop bleeding with cautery, injection, or clipping.

# Epidemiology [edit]

The lifetime risk for developing a peptic ulcer is approximately 10%.[9] They resulted in 301,000 deaths in 2013 down from 327,000 deaths in 1990.[10]

In Western countries the percentage of people with *Helicobacter pylori* infections roughly matches age (i.e., 20% at age 20, 30% at age 30, 80% at age 80 etc.). Prevalence is higher in third world countries where it is estimated at about 70% of the population, whereas developed countries show a maximum of 40% ratio. Overall, *H. pylori* infections show a worldwide decrease, more so in developed countries. Transmission is by food, contaminated groundwater, and through human saliva (such as from kissing or sharing food utensils).[35]

A minority of cases of *H. pylori* infection will eventually lead to an ulcer and a larger proportion of people will get non-specific discomfort, abdominal pain or gastritis.

Peptic ulcer disease had a tremendous effect on morbidity and mortality until the last decades of the 20th century when epidemiological trends started to point to an impressive fall in its incidence.[36] The reason that the rates of peptic ulcer disease decreased is thought to be the development of new effective medication and acid suppressants and the discovery of the cause of the condition, *H. pylori*.

The incidence of duodenal ulcers has dropped significantly during the last 30 years, while the incidence of gastric ulcers has shown a small increase, mainly caused by the widespread use of NSAIDs. The drop in incidence for duodenal ulcers is considered to be a cohort-phenomenon independent of the progress in the treatment of the disease. The cohort-phenomenon is probably explained by improved standards of living which has lowered the incidence of *H. pylori* infections.[37]

# History [edit]

> *See also: Timeline of peptic ulcer disease and Helicobacter pylori*

John Lykoudis, a general practitioner in Greece, treated patients for peptic ulcer disease with antibiotics, beginning in 1958, long before it was commonly recognized that bacteria were a dominant cause for the disease.[38]

*Helicobacter pylori* was identified in 1982 by two Australian scientists, Robin Warren and Barry J. Marshall as a causative factor for ulcers.[39] In their original paper, Warren and Marshall contended that most gastric ulcers and gastritis were caused by colonization with this bacterium, not by stress or spicy food as had been assumed before.[40]

The *H. pylori* hypothesis was initially poorly received,[41] so in an act of self-experimentation Marshall drank a Petri dish containing a culture of organisms extracted from a patient and five days later developed gastritis. His symptoms disappeared after two weeks, but he took antibiotics to kill the remaining bacteria at the urging of his wife, since halitosis is one of the symptoms of infection.[42] This experiment was published in 1984 in the Australian Medical Journal and is among the most cited articles from the journal.

In 1997, the Centers for Disease Control and Prevention, with other government agencies, academic institutions, and industry, launched a national education campaign to inform health care providers and consumers about the link between *H. pylori* and ulcers. This campaign reinforced the news that ulcers are a curable infection and that health can be greatly improved and money saved by disseminating information about *H. pylori*.[43]

In 2005, the Karolinska Institute in Stockholm awarded the Nobel Prize in Physiology or Medicine to Dr. Marshall and his long-time collaborator Dr. Warren "for their discovery of the bacterium *Helicobacter pylori* and its role in gastritis and peptic ulcer disease." Professor Marshall continues research related to *H. pylori* and runs a molecular biology lab at UWA in Perth, Western Australia.

Some believed that mastic gum, a tree resin extract, actively eliminates the *H. pylori* bacteria.[44] However, multiple subsequent studies have found no effect of using mastic gum on reducing *H. pylori* levels.[45][46]

## Notes [edit]

1. ^ Sonnenberg in his study cautiously concludes that, among other potential factors that were found to correlate to ulcer healing, "moderate alcohol intake might [also] favor ulcer healing." (p. 1066)
2. ^ Kurata 1997 explains that "Data in Fig. 8 indicate that 89% of all serious upper GI disease can be accounted for by NSAIDs and H. pylori, with cigarette smoking acting as a synergistic co-factor."(14)

# Vitamin B12 deficiency anemia

From Wikipedia, the free encyclopedia
(Redirected from Pernicious anemia)

*"Addison's anaemia" redirects here. For the disease affecting the adrenal glands, see Addison's disease.*

**Vitamin $B_{12}$ deficiency anemia**, of which **pernicious anemia** is a type,[4] is a disease in which not enough red blood cells are present due to a lack of vitamin $B_{12}$.[5] The most common initial symptom is feeling tired. Other symptoms may include shortness of breath, pale skin, chest pain, numbness in the hands and feet, poor balance, a smooth, red tongue, poor reflexes, and confusion.[6] If treatment is not provided, some of these problems may become permanent.[5]

Although pernicious anemia technically refers to cases resulting from not enough intrinsic factor, it is often used to describe all cases of anemia due to not enough vitamin $B_{12}$.[5] Lack of intrinsic factor is most commonly due to an autoimmune attack on the cells that make it in the stomach. It can also occur following the surgical removal of part of the stomach or from an inherited disorder. Other causes of low vitamin $B_{12}$ include a poor diet, celiac disease, and a tapeworm infection.[7] When suspected, diagnosis is made by blood and, occasionally, bone marrow tests. Blood tests may show fewer but larger red blood cells, low numbers of young red blood cells, low levels of vitamin $B_{12}$, and antibodies to intrinsic factor.[8]

Pernicious anemia due to lack of intrinsic factor is not preventable. Vitamin $B_{12}$ deficiency due to other causes may be prevented with a balanced diet or with supplements.[9] Pernicious anemia can be easily treated with either injections or pills of vitamin $B_{12}$. If the symptoms are severe, injections are typically recommended initially. For those who have trouble swallowing pills, a nasal spray is available.[10] Often, treatment is lifelong.[11]

Pernicious anemia due to autoimmune problems occurs in about one per 1000 people. Among those over the age of 60, about 2% have the condition.[1] It more commonly affects people of northern European descent.[2] Women are more commonly affected than men.[12] With proper treatment, most people live normal lives.[5] Due to a higher risk of stomach cancer, those with pernicious anemia should be [11]

**Vitamin $B_{12}$ deficiency anemia**

**Synonyms** ... anemia,[2] Addison's anemia,[2] Addison–Biermer anemia[3]

## Signs and symptoms [edit]

A hand of a person with severe anemia compared to one without

The symptoms of pernicious anemia come on slowly. Untreated, it can lead to neurological complications, and in serious cases, death. Many of the signs and symptoms are due to anemia itself, when anemia is present.[16] Symptoms may consist of the triad of tingling or other skin sensations (paresthesia), tongue soreness (glossitis), and fatigue and general weakness.[17][18][19][*page needed*] It presents with a number of further common symptoms,[19][*page needed*][20][*page needed*] including depressive mood, low-grade fevers, diarrhea, dyspepsia, weight loss,[17] neuropathic pain, jaundice, sores at the corner of the mouth (angular cheilitis), a look of exhaustion with pale and dehydrated or cracked lips and dark circles around the eyes, as well as brittle nails,[18] and thinning and early greying of the hair.[18] Because PA may affect the nervous system, symptoms may also include difficulty in proprioception,[21] memory changes,[20][*page needed*] mild cognitive impairment (including difficulty concentrating and sluggish responses, colloquially referred to as brain fog), and even psychoses, impaired urination,[17] loss of sensation in the feet, unsteady gait,[21] difficulty in walking,[18] muscle weakness[19][*page needed*] and clumsiness.[17] Anemia may also lead to tachycardia (rapid heartbeat),[17] cardiac murmurs, a yellow waxy pallor,[18] altered blood pressure (low or high), and a shortness of breath (known as "the sighs").[19][*page needed*] The deficiency also may present with thyroid disorders.[19][*page needed*] In severe cases, the anemia may cause evidence of congestive heart failure.[20][*page needed*] A complication of severe chronic PA is subacute combined degeneration of spinal cord, which leads to distal sensory loss (posterior column), absent ankle reflex, increased knee reflex response, and extensor plantar response.[22] Other than anemia, hematological symptoms may include cytopenias, intramedullary hemolysis, and pseudothrombotic microangiopathy.[1] Pernicious anemia can contribute to a delay in physical growth in children, and may also be a cause for delay in puberty for adolescents.

## Causes [edit]

Vitamin $B_{12}$ cannot be produced by the human body, and must be obtained from the diet. When foods containing $B_{12}$ are eaten, the vitamin is usually bound to protein and is released by stomach acid. Following its release, most $B_{12}$ is absorbed by the body in the small bowel (ileum) after binding to a protein known as intrinsic factor. Intrinsic factor is produced by parietal cells of the gastric mucosa (stomach lining) and the intrinsic factor-$B_{12}$ complex is absorbed by cubilin receptors on the ileum epithelial cells.[23][24] PA is characterised by $B_{12}$ deficiency caused by the absence of intrinsic factor.[25]

PA may be considered as an end stage of immune gastritis, a disease characterised by stomach atrophy and the presence of antibodies to parietal cells and intrinsic factor.[26] A specific form of chronic gastritis, type A gastritis or atrophic body gastritis, is highly associated with PA. This autoimmune disorder is localised to the body of the stomach, where parietal cells are located.[25] Antibodies to intrinsic factor and parietal cells cause the destruction of the oxyntic gastric mucosa, in which the parietal cells are located, leading to the subsequent loss of intrinsic factor synthesis. Without intrinsic factor, the ileum can no longer absorb the $B_{12}$.[27]

Although the exact role of *Helicobacter pylori* infection in PA remains controversial, evidence indicates *H. pylori* is involved in the pathogenesis of the disease. A long-standing *H. pylori* infection may cause gastric autoimmunity by a mechanism known as molecular mimicry. Antibodies produced by the immune system can be cross-reactive and may bind to both *H. pylori* antigens and those found in the gastric mucosa. The antibodies are produced by activated B cells that recognise both pathogen and self-derived peptides. The autoantigens believed to cause the autoreactivity are the alpha and beta subunits of the $H^+/K^+$-ATPase.[27][28]

Less commonly, *H. pylori* and Zollinger-Ellison syndrome may also cause a form of nonautoimmune gastritis that can lead to pernicious anemia.[29]

Impaired $B_{12}$ absorption can also occur following gastric removal (gastrectomy) or gastric bypass surgery. In these surgeries, either the parts of the stomach that produce gastric secretions are removed or they are bypassed. This means intrinsic factor, as well as other factors required for $B_{12}$ absorption, are not available. However, $B_{12}$ deficiency after gastric surgery does not usually become a clinical issue. This is probably because the body stores many years' worth of $B_{12}$ in the liver and gastric surgery patients are adequately supplemented with the vitamin.[30][31]

Although no specific PA susceptibility genes have been identified, a genetic factor likely is involved in the disease. Pernicious anemia is often found in conjunction with other autoimmune disorders, suggesting common autoimmune susceptibility genes may be a causative factor.[25] In spite of that, previous family studies and case reports focusing on PA have suggested that there is a tendency of genetic heritance of PA in particular, and close relatives of the PA patients seem to have higher incidence of PA and associated PA conditions.[32][33][34] Moreover, it was further indicated that the formation of antibodies to gastric cells was autosomal dominant gene determined, and the presence of antibodies to the gastric cells might not be necessarily related to the occurrence of atrophic gastritis related to PA.[32][34]

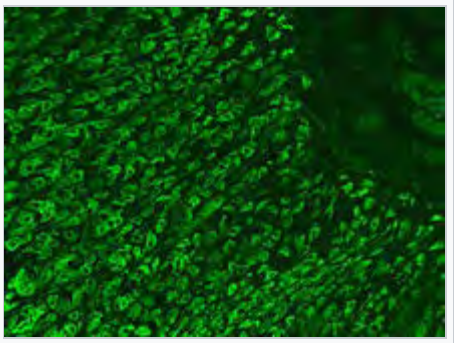
## Pathophysiology [edit]

Although the healthy body stores three to five years' worth of $B_{12}$ in the liver, the usually undetected autoimmune activity in one's gut over a prolonged period of time leads to $B_{12}$ depletion and the resulting anemia. $B_{12}$ is required by enzymes for two reactions: the conversion of methylmalonyl CoA to succinyl CoA, and the conversion of homocysteine to methionine. In the latter reaction, the methyl group of 5-methyltetrahydrofolate is transferred to homocysteine to produce tetrahydrofolate and methionine. This reaction is catalyzed by the enzyme methionine synthase with $B_{12}$ as an essential cofactor. During $B_{12}$ deficiency, this reaction cannot proceed, which leads to the accumulation of 5-methyltetrahydrofolate. This

accumulation depletes the other types of folate required for purine and thymidylate synthesis, which are required for the synthesis of DNA. Inhibition of DNA replication in red blood cells results in the formation of large, fragile megaloblastic erythrocytes. The neurological aspects of the disease are thought to arise from the accumulation of methylmalonyl CoA due to the requirement of $B_{12}$ as a cofactor to the enzyme methylmalonyl CoA mutase.[23][35][36][37]

## Diagnosis [edit]

PA may be suspected when a patient's blood smear shows large, fragile, immature erythrocytes, known as megaloblasts. A diagnosis of PA first requires demonstration of megaloblastic anemia by conducting a full blood count and blood smear, which evaluates the mean corpuscular volume (MCV), as well the mean corpuscular hemoglobin concentration (MCHC). PA is identified with a high MCV (macrocytic anemia) and a normal MCHC (normochromic anemia).[38] Ovalocytes are also typically seen on the blood smear, and a pathognomonic feature of megaloblastic anemias (which include PA and others) is hypersegmented neutrophils.[18]



Immunofluorescence staining pattern of gastric parietal cell antibodies on a stomach section

Serum vitamin $B_{12}$ levels are used to detect its deficiency, but they do not distinguish its causes. Vitamin $B_{12}$ levels can be falsely high or low and data for sensitivity and specificity vary widely. Normal serum levels may be found in cases of deficiency where myeloproliferative disorders, liver disease, transcobalamin II deficiency, or intestinal bacterial overgrowth are present. Low levels of serum vitamin $B_{12}$ may be caused by other factors than $B_{12}$ deficiency, such as folate deficiency, pregnancy, oral contraceptive use, haptocorrin deficiency, and myeloma.[39][40]

The presence of antibodies to gastric parietal cells and intrinsic factor is common in PA. Parietal cell antibodies are found in other autoimmune disorders and also in up to 10% of healthy individuals, making the test nonspecific. However, around 85% of PA patients have parietal cell antibodies, which means they are a sensitive marker for the disease. Intrinsic factor antibodies are much less sensitive than parietal cell antibodies, but they are much more specific. They are found in about half of PA patients and are very rarely found in other disorders. These antibody tests can distinguish between PA and food-$B_{12}$ malabsorption.[40] The combination of both tests of intrinsic factor antibodies and parietal cell antibodies may improve overall sensitivity and specificity of the diagnostic results.[41]

A buildup of certain metabolites occurs in $B_{12}$ deficiency due to its role in cellular physiology. Methylmalonic acid (MMA) can be measured in both the blood and urine, whereas homocysteine is only measured in the blood. An increase in both MMA and homocysteine can distinguish between $B_{12}$ deficiency and folate deficiency because only homocysteine increases in the latter.[40][42]

Elevated gastrin levels can be found in around 80-90% of PA cases, but they may also be found in other forms of gastritis. Decreased pepsinogen I levels or a decreased pepsinogen I to pepsinogen II ratio may also be found, although these findings are less specific to PA and can be found in food-$B_{12}$ malabsorption and other forms of gastritis.[42]

The diagnosis of atrophic gastritis type A should be confirmed by gastroscopy and stepwise biopsy.[43] About 90% of individuals with PA have antibodies for parietal cells; however, only 50% of all individuals in the general population with these antibodies have pernicious anemia.[44]

Forms of vitamin $B_{12}$ deficiency other than PA must be considered in the differential diagnosis of megaloblastic anemia. For example, a $B_{12}$-deficient state which causes megaloblastic anemia and which may be mistaken for classical PA may be caused by infection with the tapeworm *Diphyllobothrium latum*, possibly due to the parasite's competition with host for vitamin $B_{12}$.[45]

The classic test for PA, the Schilling test, is no longer widely used, as more efficient methods are available. This historic test consisted, in its first step, of taking an oral dose of radiolabelled vitamin $B_{12}$, followed by quantitation of the vitamin in the patient's urine over a 24-hour period via measurement of the radioactivity. A second step of the test repeats the regimen and procedure of the first step, with the addition of oral intrinsic factor. A patient with PA presents lower than normal amounts of intrinsic factor; hence, addition of intrinsic factor in the second step results in an increase in vitamin $B_{12}$ absorption (over the baseline established in the first). The Schilling test distinguished PA from other forms of $B_{12}$ deficiency,[23] specifically, from Imerslund-Grasbeck Syndrome (IGS), a vitamin B12-deficiency caused by mutations in the cobalamin receptor.[46]

## Treatment [edit]

The treatment of PA varies by country and area. Opinions vary over the efficacy of administration (parenteral/oral), the amount and time interval of the doses, or the forms of vitamin $B_{12}$ (e.g. cyanocobalamin/hydroxocobalamin). More comprehensive studies are still needed in order to validate the feasibility of a particular therapeutic method for PA in clinical practices. A permanent cure for PA is lacking, although repletion of $B_{12}$ should be expected to result in cessation of anemia-related symptoms, a halt in neurological deterioration, and in cases where neurological problems are not advanced, neurological recovery and a complete and permanent remission of all symptoms, so long as $B_{12}$ is supplemented. Repletion of $B_{12}$ can be accomplished in a variety of ways.

Hydroxocobalamin injection usp(1000 mcg/ml) is a clear red liquid solution of hydoxocobalamin which is available in a 30-ml brown glass multidose vial packaged in a paper box. Shown is 500 mcg B-12 (as 1/2 cc) drawn up in a 0.5-cc U-100 27 gauge x 1/2" insulin syringe, as prepared for subcutaneous injection.

### Intramuscular injections [edit]

The standard treatment for PA has been intramuscular injections of cobalamin in the form of cyanocobalamin (CN-Cbl) and hydroxocobalamin (OH-Cbl).[47]

### Oral doses [edit]

Treatment with high-dose vitamin $B_{12}$ by mouth also appears effective.[47][48][49]

## Prognosis [edit]

A person with well-treated PA can live a healthy life. Failure to diagnose and treat in time, however, may result in permanent neurological damage, excessive fatigue, depression, memory loss, and other complications. In severe cases, the neurological complications of pernicious anemia can lead to death - hence the name, "pernicious", meaning deadly.

An association has been observed between pernicious anemia and certain types of gastric cancer, but a causal link has not been established.[27]

## Epidemiology [edit]

PA is estimated to affect 0.1% of the general population and 1.9% of those over 60, accounting for 20–50% of $B_{12}$ deficiency in adults.[1] A review of literature shows that the prevalence of PA is higher in Northern Europe, especially in Scandinavian countries, and among people of African descent, and that

increased awareness of the disease and better diagnostic tools might play a role in apparently higher rates of incidence.[50]

## History [edit]

The symptoms are first described in 1822 by Dr James Scarth Combe in the *Transactions of the Medico-Chirurgical Society of Edinburgh*, under the title of *History of a Case of Anaemia*.[51]

However, this was not investigated in more depth until 1849, by British physician Thomas Addison, from which it acquired the common name of Addison's anemia. In 1871, German physician Michael Anton Biermer (1827–1892) noticed the particular characteristic of the anemia in one of his patients; he later coined the term "progressive pernicious anemia".[52][*better source needed*] In 1907, Richard Clarke Cabot reported on a series of 1200 patients with PA; their average survival was between one and three years.[*citation needed*] William Bosworth Castle performed an experiment whereby he ingested raw hamburger meat and regurgitated it after an hour, and subsequently fed it to a group of 10 patients.[53][*full citation needed*] Untreated raw hamburger meat was fed to the control group. The former group showed a disease response, whereas the latter group did not. This was not a sustainable practice, but it demonstrated the existence of an 'intrinsic factor' from gastric juice.

Pernicious anemia was a fatal disease before about the year 1920, when George Whipple suggested raw liver as a treatment.[*citation needed*] The first workable treatment for pernicious anemia began when Whipple made a discovery in the course of experiments in which he bled dogs to make them anemic, then fed them various foods to see which would make them recover most rapidly (he was looking for treatments for anemia from bleeding, not pernicious anemia). Whipple discovered ingesting large amounts of liver seemed to cure anemia from blood loss, and tried liver ingestion as a treatment for pernicious anemia, reporting improvement there, also, in a paper in 1920.[*citation needed*] George Minot and William Murphy then set about to partly isolate the curative property in liver, and in 1926 showed it was contained in raw liver juice (in the process also showing it was the iron in liver tissue, not the soluble factor in liver juice, which cured the anemia from bleeding in dogs); thus, the discovery of the liver juice factor as a treatment for pernicious anemia had been by coincidence.[*citation needed*] Frieda Robscheit-Robbins worked closely with Whipple, co-authoring 21 papers from 1925-30.[*citation needed*] For the discovery of the cure of a previously fatal disease of unknown etiology, Whipple, Minot, and Murphy shared the 1934 Nobel Prize in Medicine.[54][*full citation needed*]

After Minot and Murphy's verification of Whipple's results in 1926, pernicious anemia victims ate or drank at least one-half pound of raw liver, or drank raw liver juice, every day.[*citation needed*] This continued for several years, until a concentrate of liver juice became available. In 1928, chemist Edwin Cohn prepared a liver extract that was 50 to 100 times more potent than the natural food (liver).[*citation needed*] The extract could even be injected into muscle, which meant patients no longer needed to eat large amounts of liver or juice. This also reduced the cost of treatment considerably.[*citation needed*]

The active ingredient in liver remained unknown until 1948, when it was isolated by two chemists, Karl A. Folkers of the United States and Alexander R. Todd of Great Britain.[*citation needed*] The substance was a cobalamin, which the discoverers named vitamin $B_{12}$. The new vitamin in liver juice was eventually completely purified and characterized in the 1950s, and other methods of producing it from bacteria were developed.[*citation needed*] It could be injected into muscle with even less irritation, making it possible to treat PA with even more ease.[*citation needed*] Pernicious anemia was eventually treated with either injections or large oral doses of $B_{12}$, typically between 1 and 4 mg daily.[*citation needed*]

One writer has hypothesized that Mary Todd Lincoln, the wife of American President Abraham Lincoln, had pernicious anemia for decades and died from it.[55][56]

## Research [edit]

## SNAC complex [edit]

Although oral megadoses and intramuscular injections are the most common methods of treatment currently available, several novel methods are being tested, with high promise for future incorporation into mainstream treatment methods. As injections are unfavourable vehicles for drug delivery, current research involves improving the passive diffusion across the ileum upon oral ingestion of cobalamin derivatives. Researchers have recently taken advantage of the novel compound sodium N-[8-(2-hydroxybenzoyl)amino]caprylate (SNAC), which greatly enhances both bioavailability and metabolic stability.[57] SNAC is able to form a noncovalent complex with cobalamin while preserving its chemical integrity.[*citation needed*] This complex is much more lipophilic than the water-soluble vitamin $B_{12}$, so is able to pass through cellular membranes with greater ease.

## Recombinant intrinsic factor [edit]

Another method for increasing absorption through the ileum is to ingest a Cbl complex to which IF is already bound. The lack of intrinsic factor produced by the patient's body can be supplemented by using synthetic human IF produced from pea plant recombinants.[58] However, in cases where IF-antibodies are the reason for malabsorption across the ileum, this treatment would be ineffective.

## Sublingual/intranasal delivery [edit]

Sublingual treatments have also been postulated to be more effective than oral treatments alone. A 2003 study[59] found, while this method is effective, a dose of 500 µg of cyanocobalamin given either orally or sublingually, is equally efficacious in restoring normal physiological concentrations of cobalamin. Intranasal methods have also been studied as a vehicle for the delivery of cobalamin. A 1997 study[60] monitored the plasma cobalamin concentration of six patients with pernicious anemia over a period of 35 days while being treated with 1500 µg of intranasal hydroxocobalamin. One hour after administration, all patients showed on average an immediate eight-fold increase in plasma cobalamin concentration and a two-fold increase after 35 days with three 1500 µg treatments. However, further studies are needed to investigate the long-term effectiveness of this delivery method.

## Exploratory treatments [edit]

One exploratory, and potential alternative method for the treatment of pernicious anemia is the use of transdermal patches. In one such system, the patches are composed of cyanocobalamin, its stabilizers, and epidermal penetration enhancers.[61][*self-published source?*][*better source needed*] The transdermal route allows the cobalamin derivative to passively diffuse through the stratum corneum, epidermis, and dermis, and ultimately entering the bloodstream; hence, the cobalamin avoids the hepatic first pass effect, and so offers the potential for improved bioavailability and efficacy.[*according to whom?*][*citation needed*] Slow release increases cobalamin half-life, offering the potential of decreases in required dosage required relative to oral delivery methods.[*according to whom?*][*citation needed*] In one such system, a drug-loaded polycaprolactone fiber that is prepared as a electrospun nanofiber can release hundreds of micrograms of cobabalmin per day.[62][*non-primary source needed*]

# Ulcerative colitis

From Wikipedia, the free encyclopedia

**Ulcerative colitis** (**UC**) is a long-term condition that results in inflammation and ulcers of the colon and rectum.[1][2] The primary symptom of active disease is abdominal pain and diarrhea, mixed with blood. Weight loss, fever, and anemia may also occur. Often symptoms come on slowly and can range from mild to severe. Symptoms typically occur intermittently with periods of no symptoms between flares.[1] Complications may include megacolon, inflammation of the eye, joints, or liver, and colon cancer.[1][3]

The cause of UC is unknown.[1] Theories involve immune system dysfunction, genetics, changes in the normal gut bacteria, and environmental factors.[1][4] Rates tend to be higher in the developed world with some proposing this to be the result of less exposure to intestinal infections, or a Western diet and lifestyle.[2][5] The removal of the appendix at an early age may be protective.[5] Diagnosis is typically by colonoscopy with tissue biopsies. It is a kind of inflammatory bowel disease (IBD) along with Crohn's disease and microscopic colitis.[1]

Dietary changes may improve symptoms. A number of medications are used to treat symptoms and bring about and maintain remission. These include aminosalicylates such as sulfasalazine, steroids, immunosuppressants such as azathioprine, and biological therapy. Removal of the colon by surgery may be necessary if the disease is severe, does not respond to treatment, or if complications such as colon cancer develop.[1] Removal of the colon and rectum can cure the disease.[1][5]

The first description of ulcerative colitis occurred around the 1850s.[5] Each year it newly occurs in 1 to 20 people per 100,000 and 5 to 500 per 100,000 individuals are affected.[2][5] The disease is more common in North America and Europe.[5] Often it begins between 15 and 30 years of age or among those over 60.[1] Males and females appear to be affected equally.[2] It has also become more common since the 1950s.[2][5] Together, ulcerative colitis and Crohn's disease affect approximately 500,000 to 2 million people in the United States.[6] With appropriate treatment the risk of death appears the same as that of the general population.[3]

## Variants

# Signs and symptoms [edit]

## Gastrointestinal [edit]

**Signs and symptoms**

| | Crohn's disease | Ulcerative colitis |
|---|---|---|
| Defecation | Often porridge-like,[7] sometimes steatorrhea | Often mucus-like and with blood[7] |
| Tenesmus | Less common[7] | More common[7] |
| Fever | Common[7] | Indicates severe disease[7] |
| Fistulae | Common[8] | Seldom |
| Weight loss | Often | More seldom |

The clinical presentation[9] of ulcerative colitis depends on the extent of the disease process. Patients usually present with diarrhea mixed with blood and mucus, of gradual onset that persists for an extended period (weeks). They may also have weight loss and blood on rectal examination. The inflammation caused by the disease along with the chronic blood from the GI tract leads to increased rates of anemia. The disease may be accompanied by different degrees of abdominal pain, from mild discomfort to painful bowel movements or painful abdominal cramping with bowel movements.

Ulcerative colitis is associated with a general inflammatory process that affects many parts of the body. Sometimes these associated extra-intestinal symptoms are the initial signs of the disease, such as painful arthritic knees in a teenager and may be seen in adults also. The presence of the disease may not be confirmed immediately, however, until the onset of intestinal manifestations.

## Extent of involvement [edit]

Ulcerative colitis is normally continuous from the rectum up the colon. The disease is classified by the extent of involvement, depending on how far up the colon the disease extends:

- *Distal colitis*, potentially treatable with enemas:[10]
  - *Proctitis*: Involvement limited to the rectum.
  - *Proctosigmoiditis*: Involvement of the rectosigmoid colon, the portion of the colon adjacent to the rectum.
  - *Left-sided colitis*: Involvement of the descending colon, which runs along the patient's left side, up to the splenic flexure and the beginning of the transverse colon.
- *Extensive colitis*, inflammation extending beyond the reach of enemas:
  - *Pancolitis*: Involvement of the entire colon, extending from the rectum to the cecum, beyond which the small intestine begins.

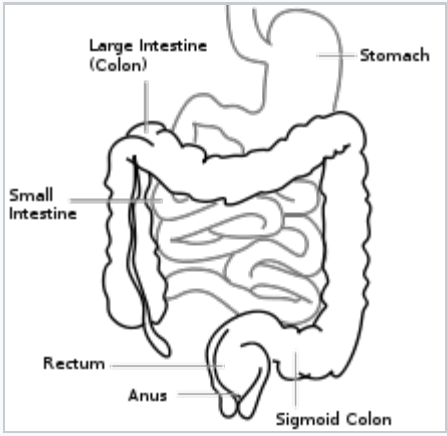

Diagram of the human intestine

## Severity of disease [edit]

In addition to the extent of involvement, people may also be characterized by the severity of their disease.[10]

Colonic pseudopolyps of a patient with intractable ulcerative colitis. Colectomy specimen.

- *Mild disease* correlates with fewer than four stools daily, with or without blood, no systemic signs of toxicity, and a normal erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP). There may be mild abdominal pain or cramping. Patients may believe they are constipated when in fact they are experiencing tenesmus, which is a constant feeling of the need to empty the bowel accompanied by involuntary straining efforts, pain, and cramping with little or no fecal output. Rectal pain is uncommon.
- *Moderate disease* correlates with more than four stools daily, but with minimal signs of toxicity. Patients may display anemia (not requiring transfusions), moderate abdominal pain, and low grade fever, 38 to 39 °C (100 to 102 °F).
- *Severe disease*, correlates with more than six bloody stools a day or observable massive and significant bloody bowel movement, and evidence of toxicity as demonstrated by fever, tachycardia, anemia or an elevated ESR or CRP.
- *Fulminant disease* correlates with more than ten bowel movements daily, continuous bleeding, toxicity, abdominal tenderness and distension, blood transfusion requirement and colonic dilation (expansion). Patients in this category may have inflammation extending beyond just the mucosal layer, causing impaired colonic motility and leading to toxic megacolon. If the serous membrane is involved, a colonic perforation may ensue. Unless treated, the fulminant disease will soon lead to death.

## Extraintestinal features [edit]

As ulcerative colitis is believed to have a systemic (i.e., autoimmune) origin, patients may present with comorbidities leading to symptoms and complications outside the colon. The frequency of such extraintestinal manifestations has been reported as anywhere between 6 and 47 percent.[11] These include the following:

- Aphthous ulcer of the mouth
- Ophthalmic
  - Iritis or uveitis, which is inflammation of the eye's iris
  - Episcleritis
- Musculoskeletal:
  - Seronegative arthritis, which can be a large-joint oligoarthritis (affecting one or two joints), or may affect many small joints of

Patients with ulcerative colitis can occasionally have aphthous ulcers involving the tongue, lips, palate and pharynx

the hands and feet
    - Ankylosing spondylitis, arthritis of the spine
    - Sacroiliitis, arthritis of the lower spine
- Cutaneous (related to the skin):
    - Erythema nodosum, which is a panniculitis, or inflammation of subcutaneous tissue involving the lower extremities
    - Pyoderma gangrenosum, which is a painful ulcerating lesion involving the skin
- Deep venous thrombosis and pulmonary embolism
- Autoimmune hemolytic anemia
- Clubbing, a deformity of the ends of the fingers.
- Primary sclerosing cholangitis, a distinct disease that causes inflammation of the bile ducts

## Causes [edit]

There are no direct known causes for ulcerative colitis, but there are many possible factors such as genetics and stress.

### Genetic factors [edit]

A genetic component to the etiology of ulcerative colitis can be hypothesized based on the following:[12]

- Aggregation of ulcerative colitis in families.
- Identical twin concordance rate of 10% and dizygotic twin concordance rate of 3%[13]
- Ethnic differences in incidence
- Genetic markers and linkages

There are 12 regions of the genome that may be linked to ulcerative colitis, including, in the order of their discovery, chromosomes 16, 12, 6, 14, 5, 19, 1, and 3,[14] but none of these loci have been consistently shown to be at fault, suggesting that the disorder arises from the combination of multiple genes. For example, chromosome band 1p36 is one such region thought to be linked to inflammatory bowel disease.[15]

Some of the putative regions encode transporter proteins such as OCTN1 and OCTN2. Other potential regions involve cell scaffolding proteins such as the MAGUK family. There may even be human leukocyte antigen associations at work. In fact, this linkage on chromosome 6 may be the most convincing and consistent of the genetic candidates.[14]

Multiple autoimmune disorders have been recorded with the neurovisceral and cutaneous genetic porphyrias including ulcerative colitis, Crohn's disease, celiac disease, dermatitis herpetiformis, diabetes, systemic and discoid lupus, rheumatoid arthritis, ankylosing spondylitis, scleroderma, Sjogren's disease and scleritis. Physicians should be on high alert for porphyrias in families with autoimmune disorders and care must be taken with potential porphyrinogenic drugs, including sulfasalazine.

## Environmental factors [edit]

Many hypotheses have been raised for environmental contributants to the pathogenesis of ulcerative colitis. They include the following:

- Diet: as the colon is exposed to many dietary substances which may encourage inflammation, dietary factors have been hypothesized to play a role in the pathogenesis of both ulcerative colitis and Crohn's disease. There have been few studies to investigate such an association, one study showed no association of refined sugar on the prevalence of ulcerative colitis.[16] High intake of unsaturated fat and vitamin B6 may enhance the risk of developing ulcerative colitis.[17] Other identified dietary factors that may influence the development and/or relapse of the disease include meat protein and alcoholic beverages.[18][19] Specifically, sulfur has been investigated as being involved in the etiology of ulcerative colitis, but this is controversial.[20] Sulfur restricted diets have been investigated in patients with UC and animal models of the disease. The theory of sulfur as an etiological factor is related to the gut microbiota and mucosal sulfide detoxification in addition to the diet.[21][22][23]
- Breastfeeding: There have been conflicting reports of the protection of breastfeeding in the development of inflammatory bowel disease. One Italian study showed a potential protective effect.[24]
- One study of isotretinoin found a small increased in the rate of ulcerative colitis.[25]

## Autoimmune disease [edit]

Ulcerative colitis is an autoimmune disease characterized by T-cells infiltrating the colon.[26] In contrast to Crohn's disease, which can affect areas of the gastrointestinal tract outside of the colon, ulcerative colitis usually involves the rectum and is confined to the colon, with occasional involvement of the ileum. This so-called "backwash ileitis" can occur in 10–20% of patients with pancolitis and is believed to be of little clinical significance.[27] Ulcerative colitis can also be associated with comorbidities that produce symptoms in many areas of the body outside the digestive system. Surgical removal of the large intestine often cures the disease.[10]

## Alternative theories [edit]

Levels of sulfate-reducing bacteria tend to be higher in persons with ulcerative colitis. This could mean that there are higher levels of hydrogen sulfide in the intestine. An alternative theory suggests that the symptoms of the disease may be caused by toxic effects of the hydrogen sulfide on the cells lining the intestine.[30]

**Risk factors**

| | Crohn's disease | Ulcerative colitis |
|---|---|---|
| Smoking | Higher risk for smokers | Lower risk for smokers[28] |
| Age | Usual onset between 15 and 30 years[29] | Peak incidence between 15 and 25 years |

# Pathophysiology [edit]

An increased amount of colonic sulfate-reducing bacteria has been observed in some patients with ulcerative colitis, resulting in higher concentrations of the toxic gas hydrogen sulfide. Human colonic mucosa is maintained by the colonic epithelial barrier and immune cells in the lamina propria (see intestinal mucosal barrier). N-butyrate, a short-chain fatty acid, gets oxidized through the beta oxidation pathway into carbon dioxide and ketone bodies. It has been shown that N-butyrate helps supply nutrients to this epithelial barrier. Studies have proposed that hydrogen sulfide plays a role in impairing this beta-oxidation pathway by interrupting the short chain acetyl-CoA dehydrogenase, an enzyme within the

**Pathophysiology**

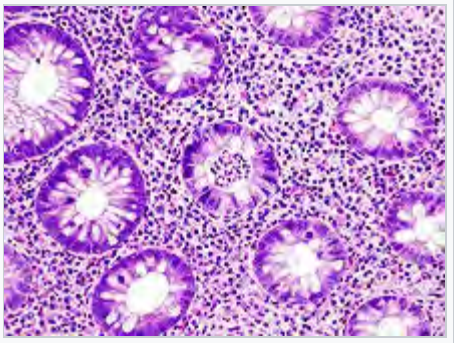
| | Crohn's disease | Ulcerative colitis |
|---|---|---|
| Cytokine response | Associated with $T_h17$[31] | Vaguely associated with $T_h2$ |

pathway. Furthermore, it has been suggested that the protective benefit of smoking in ulcerative colitis is due to the hydrogen cyanide from cigarette smoke reacting with hydrogen sulfide to produce the non-toxic isothiocyanate, thereby inhibiting sulfides from interrupting the pathway.[32] An unrelated study suggested that the sulfur contained in red meats and alcohol may lead to an increased risk of relapse for patients in remission.[30]

Ulcerative colitis patients typically present with rectal bleeding, diarrhea, tenesmus (urgent desire to evacuate the bowels but with the passage of little stool), and lower abdominal pain. The severity of disease at clinical presentation is important in determining the appropriate therapy. Patients with mildly active disease will have fewer than 4 bowel movements daily and no signs of toxicity. Individuals with moderate-severity UC have more frequent bowel movements with bleeding. Approximately 70% of patients with ulcerative colitis will have moderately active disease at presentation. Patients with severely active disease will have signs of toxicity with fever, tachycardia, and anemia. Patients with fulminant or toxic colitis or toxic megacolon often have more than 10 bowel movements in a day, continuous bleeding, abdominal distention and tenderness, and radiologic evidence of edema and, in some cases, bowel dilation. These people most often require immediate colectomy because 10% have perforated colon at the time of surgery.

## Diagnosis [edit]

The initial diagnostic workup for ulcerative colitis includes the following:[10][33]



H&E stain of a colonic biopsy showing a crypt abscess, a classic finding in ulcerative colitis

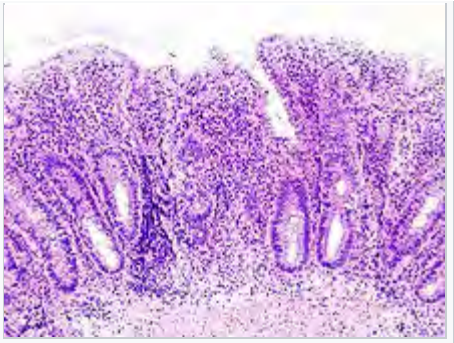
- A complete blood count is done to check for anemia; thrombocytosis, a high platelet count, is occasionally seen
- Electrolyte studies and renal function tests are done, as chronic diarrhea may be associated with hypokalemia, hypomagnesemia and pre-renal failure.
- Liver function tests are performed to screen for bile duct involvement: primary sclerosing cholangitis.
- X-ray
- Urinalysis
- Stool culture, to rule out parasites and infectious causes.
- Erythrocyte sedimentation rate can be measured, with an elevated sedimentation rate indicating that an inflammatory process is present.
- C-reactive protein can be measured, with an elevated level being another indication of inflammation.
- sigmoidoscopy a type of endoscopy which can detect the presence of ulcers in the large intestine after a trial of an enema.

Although ulcerative colitis is a disease of unknown causation, inquiry should be made as to unusual factors believed to trigger the disease.[10] Factors may include: recent cessation of tobacco smoking; recent administration of large doses of iron or vitamin B6; hydrogen peroxide in enemas or other procedures.[*citation needed*]

The simple clinical colitis activity index was created in 1998 and is used to assess the severity of symptoms.[34][35]

### Endoscopic [edit]

The best test for diagnosis of ulcerative colitis remains endoscopy. Full colonoscopy to the cecum and entry into the terminal ileum is attempted only if the diagnosis of UC is unclear. Otherwise, a flexible sigmoidoscopy is sufficient to support the diagnosis. The physician may elect to limit the extent of the exam if severe colitis is encountered to minimize the risk of perforation of the colon. Endoscopic findings in ulcerative colitis include the following:



Biopsy sample (H&E stain) that demonstrates marked lymphocytic infiltration (blue/purple) of the intestinal mucosa and architectural distortion of the crypts.

- Loss of the vascular appearance of the colon
- Erythema (or redness of the mucosa) and friability of the mucosa
- Superficial ulceration, which may be confluent, and
- Pseudopolyps.

Ulcerative colitis is usually continuous from the rectum, with the rectum almost universally being involved. There is rarely perianal disease, but cases have been reported. The degree of involvement endoscopically ranges from proctitis or inflammation of the rectum, to left sided colitis, to pancolitis, which is inflammation involving the ascending colon.

## Histologic [edit]

Biopsies of the mucosa are taken to definitively diagnose UC and differentiate it from Crohn's disease, which is managed differently clinically. Microbiological samples are typically taken at the time of endoscopy. The pathology in ulcerative colitis typically involves distortion of crypt architecture, inflammation of crypts (cryptitis), frank crypt abscesses, and hemorrhage or inflammatory cells in the lamina propria. In cases where the clinical picture is unclear, the histomorphologic analysis often plays a pivotal role in determining the diagnosis and thus the management. By contrast, a biopsy analysis may be indeterminate, and thus the clinical progression of the disease must inform its treatment.

## Differential diagnosis [edit]

The following conditions may present in a similar manner as ulcerative colitis, and should be excluded:

- Crohn's disease
- Infectious colitis, which is typically detected on stool cultures
  - Pseudomembranous colitis, or *Clostridium difficile*-associated colitis, bacterial upsets often seen following administration of antibiotics
- Ischemic colitis, inadequate blood supply to the intestine, which typically affects the elderly
- Radiation colitis in patients with previous pelvic radiotherapy
- Chemical colitis resulting from the introduction of harsh chemicals into the colon from an enema or other procedure.

The most common disease that mimics the symptoms of ulcerative colitis is Crohn's disease, as both are inflammatory bowel diseases that can affect the colon with similar symptoms. It is important to differentiate these diseases since the course of the diseases and treatments may be different. In some cases, however, it may not be possible to tell the difference, in which case the disease is classified as indeterminate colitis.

Endoscopic image of ulcerative colitis affecting the left side of the colon. The image shows confluent superficial ulceration and loss of mucosal architecture. Crohn's disease may be similar in appearance, a fact that can make diagnosing UC a challenge.

**Diagnostic findings**

| | Crohn's disease | Ulcerative colitis |
|---|---|---|
| Terminal ileum involvement | Commonly | Seldom |
| Colon involvement | Usually | Always |

| | | |
|---|---|---|
| Rectum involvement | Seldom | Usually[28] |
| Involvement around the anus | Common[8] | Seldom |
| Bile duct involvement | No increase in rate of primary sclerosing cholangitis | Higher rate[36] |
| Distribution of disease | Patchy areas of inflammation (skip lesions) | Continuous area of inflammation[28] |
| Endoscopy | Deep geographic and serpiginous (snake-like) ulcers | Continuous ulcer |
| Depth of inflammation | May be transmural, deep into tissues[8][14] | Shallow, mucosal |
| Stenosis | Common | Seldom |
| Granulomas on biopsy | May have non-necrotizing non-peri-intestinal crypt granulomas[8][37][38] | Non-peri-intestinal crypt granulomas not seen[28] |

## Management [edit]

*Main article: Management of ulcerative colitis*

Standard treatment for ulcerative colitis depends on the extent of involvement and disease severity. The goal is to induce remission initially with medications, followed by the administration of maintenance medications to prevent a relapse of the disease. The concept of induction of remission and maintenance of remission is very important. The medications used to induce and maintain a remission somewhat overlap, but the treatments are different. Physicians first direct treatment to inducing a remission which involves relief of symptoms and mucosal healing of the lining of the colon and then longer term treatment to maintain the remission and prevent complications. Acute severe ulcerative colitis requires hospitalisation, exclusion of infections, and corticosteroids.[39]

### Medication [edit]

Ulcerative colitis can be treated with a number of medications, including 5-ASA drugs such as sulfasalazine and mesalazine. Corticosteroids such as prednisone can also be used due to their immunosuppressing and short-term healing properties, but because their risks outweigh their benefits, they are not used long-term in treatment. Immunosuppressive medications such as azathioprine and biological agents such as infliximab and adalimumab are given only if people cannot achieve remission with 5-ASA and corticosteroids. This is because of their possible risk factors, including but not limited to increased risk of cancers in teenagers and adults,[40] tuberculosis, and new or worsening heart failure (these side effects are rare). A formulation of budesonide was approved by the FDA for treatment of active ulcerative colitis in January 2013.[41] The evidence on methotrexate does not show a benefit in producing remission in people with ulcerative colitis.[42] Off-label use of drugs such as ciclosporin and tacrolimus has shown some benefits.[43][44] Fexofenadine, an antihistamine drug used in treatment of allergies, has shown promise in a combination therapy in some studies.[45][46] Opportunely, low gastrointestinal absorption (or high absorbed drug gastrointestinal secretion) of fexofenadine results in higher concentration at the site of inflammation. Thus, the drug may locally decrease histamine secretion by involved gastrointestinal mast cells and alleviate the inflammation.

### Aminosalicylates [edit]

Sulfasalazine has been a major agent in the therapy of mild to moderate ulcerative colitis for over 50 years. In 1977, Mastan S. Kalsi *et al.* determined that 5-aminosalicylic acid (5-ASA and mesalazine) was the therapeutically active component in sulfasalazine.[47] Since then, many 5-ASA compounds have been developed with the aim of maintaining efficacy but reducing the common side effects associated with the sulfapyridine moiety in sulfasalazine.[48]

## Biologics [edit]

Biologic treatments such as the TNF inhibitors infliximab, adalimumab, and golimumab are commonly used to treat people with UC who are no longer responding to corticosteroids. Tofacitinib, vedolizumab, and etrolizumab can also produce good clinical remission and response rates in UC.[4] Usually, these medications are only used if other options have been exhausted (i.e., the person has received and not responded favorably to high-dose corticosteroids and immunomodulators such as azathioprine and mesalazine).

Unlike aminosalicylates, biologics can cause serious side effects such as an increased risk of developing extra-intestinal cancers,[40] heart failure; and weakening of the immune system, resulting in a decreased ability of the immune system to clear infections and reactivation of latent infections such as tuberculosis. For this reason, patients on these treatments are closely monitored and are often given tests for hepatitis and tuberculosis at least once a year.

## Nicotine [edit]

Unlike Crohn's disease, ulcerative colitis has a lesser prevalence in smokers than non-smokers.[49][50] Studies using a transdermal nicotine patch have shown clinical and histological improvement.[51]

In one double-blind, placebo-controlled study conducted in the United Kingdom, 48.6% of patients who used the nicotine patch, in conjunction with their standard treatment, showed complete resolution of symptoms. Another randomized, double-blind, placebo-controlled, single-center clinical trial conducted in the United States showed that 39% of patients who used the patch showed significant improvement, versus 9% of those given a placebo.[52] Use of a transdermal nicotine patch without the addition of other standard treatments such as mesalazine has relapse occurrence rates similar to standard treatment without the use of nicotine.

## Iron supplementation [edit]

The gradual loss of blood from the gastrointestinal tract, as well as chronic inflammation, often leads to anemia, and professional guidelines suggest routinely monitoring for this with blood tests repeated every three months in active disease and annually in quiescent disease.[53] Adequate disease control usually improves anemia of chronic disease, but iron deficiency anemia should be treated with iron supplements. The form in which treatment is administered depends both on the severity of the anemia and on the guidelines that are followed. Some advise that parenteral iron be used first because patients respond to it more quickly, it is associated with fewer gastrointestinal side effects, and it is not associated with compliance issues.[54] Others require oral iron to be used first, as patients eventually respond and many will tolerate the side effects.[53][55] All guidelines advise that parenteral iron should be administered in cases of severe anemia (a hemoglobin level less than 10).

## Treatments in development [edit]

This section **may be too technical for most readers to understand**. Please help improve this section to make it understandable to non-experts, without removing the technical details. The talk page may contain suggestions. *(May 2013) (Learn how and when to remove this template message)*

Inflammation of the colon is a characteristic symptom of ulcerative colitis, and a new series of drugs in

development looks to disrupt the inflammation process by selectively targeting an ion channel. A crucial step involved in the inflammation signaling cascade involves an intermediate conductance calcium activated potassium channel (IK channel) known as KCa3.1;[56][*non-primary source needed*] a protein coded for in the human gene KCNN4.[57] Ongoing research seeks to prevent T-cell activation and inflammation by inhibiting the KCa3.1 channel, selectively.[58][*non-primary source needed*] Since there is an upregulation of IK channel activity during T cell activation,[56][*non-primary source needed*] inhibition of the KCa3.1 is able to disrupt the production of Th1 cytokines IL-2 and TNF- . Production of these cytokines decreases because inhibition of KCa3.1 reduces the efflux of $K^+$, which in turn diminishes the influx of $Ca^{2+}$. By lowering elevated intracellular $Ca^{2+}$ in patients with ulcerative colitis, these novel drug candidates can inhibit the signaling cascade involved in the inflammation process[58][*non-primary source needed*] and help relieve many of the symptoms associated with ulcerative colitis.

Preclinical study results in 2012 indicated that these selective inhibitors decreased colon inflammation in mice and rats cloned with the human KCa3.1 protein as effectively as the standard inflammatory bowel disease treatment of sulfasalazine. However, these novel selective IK channel blockers are significantly more potent and theoretically would be able to be taken at a much more manageable dosage.[58][*non-primary source needed*]

Benzothiazinone, NS6180, is a novel class KCa3.1 channel inhibitor in development. Through a number of in vitro experiments, NS6180 was qualified for KCa3.1 channel inhibition. In vivo experiment of DNBS (2,4 - dinitrobenzene sulfonic acid) induced rat colitis, a frequently used animal model for inflammatory bowel disease, showed comparable efficacy and greater potency than sulfasalazine.[58][*non-primary source needed*]

## Surgery [edit]

Unlike in Crohn's disease, the gastrointestinal aspects of ulcerative colitis can generally be cured by surgical removal of the large intestine, though extraintestinal symptoms may persist. This procedure is necessary in the event of: exsanguinating hemorrhage, frank perforation, or documented or strongly suspected carcinoma. Surgery is also indicated for patients with severe colitis or toxic megacolon. Patients with symptoms that are disabling and do not respond to drugs may wish to consider whether surgery would improve the quality of life.

**Management**

| | Crohn's disease | Ulcerative colitis |
|---|---|---|
| Mesalazine | Less useful[59] | More useful[59] |
| Antibiotics | Effective in long-term[60] | Generally not useful[61] |
| Surgery | Often returns following removal of affected part | Usually cured by removal of colon |

Ulcerative colitis affects many parts of the body outside the intestinal tract. In rare cases, the extra-intestinal manifestations of the disease may require removal of the colon.[10]

Another surgical option for ulcerative colitis that is affecting most of the large bowel is called the ileo-anal pouch procedure. This is a two- to three-step procedure in which the large bowel is removed, except for the rectal stump and anus, and a temporary ileostomy is made. The next part of the surgery can be done in one or two steps and is usually done at six- to twelve-month intervals from each prior surgery.

In the next step of the surgery, an internal pouch is made of the patient's own small bowel, and this pouch is then hooked back up internally to the rectal stump so that the patient can once again have a reasonably functioning bowel system, all internal. The temporary ileostomy can be reversed at this time so that the patient is internalized for bowel functions, or, in another step to the procedure, the pouch, and rectal stump anastamosis can be left inside the patient to heal for some time while the patient still uses the ileostomy for bowel function. Then, on a subsequent surgery, the ileostomy is reversed and the patient has internalized bowel function again.

## Leukocyte apheresis [edit]

A type of leukocyte apheresis, known as granulocyte and monocyte adsorptive apheresis, still requires [62]

large-scale trials to determine whether or not it is effective. Results from small trials have been tentatively positive.[63]

## Bacterial recolonization [edit]

- In a number of randomized clinical trials, probiotics have demonstrated the potential to be helpful in the treatment of ulcerative colitis. Specific types of probiotics such as Escherichia coli Nissle have been shown to induce remission in some patients for up to a year.[64] Another type of probiotic that is said to have a similar effect is *Lactobacillus acidophilus*.[*citation needed*] The probiotics are said to work by calming some of the ongoing inflammation that causes the disease, which in turn allows the body to mobilize dendritic cells, otherwise known as messenger immune cells. These cells then are able to produce other T-cells that further aid in restoring balance in the intestines by rebalancing systematic inflammation.[65]
- Fecal bacteriotherapy involves the infusion of human probiotics through fecal enemas. Ulcerative colitis typically requires a more prolonged bacteriotherapy treatment than *Clostridium difficile* infection to be successful, possibly due to the time needed to heal the ulcerated epithelium. The response of ulcerative colitis is potentially very favorable with one study reporting 67.7% of sufferers experiencing complete remission.[66] It suggests that the cause of ulcerative colitis may be a previous infection by a still unknown pathogen. This initial infection resolves itself naturally, but somehow causes an imbalance in the colonic bacterial flora, leading to a cycle of inflammation which can be broken by "recolonizing" the colon with bacteria from a healthy bowel. There have been several reported cases of patients who have remained in remission for up to 13 years.[67]

## Alternative medicine [edit]

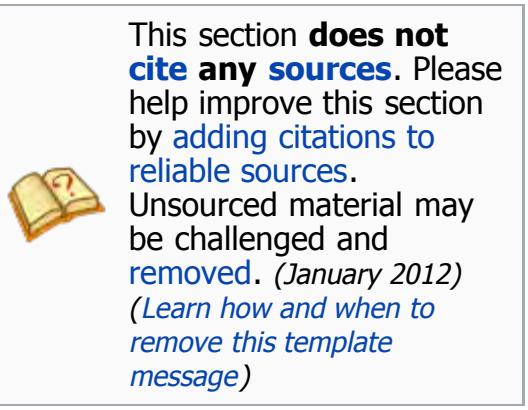
About 21% of inflammatory bowel disease patients use alternative treatments.[68] A variety of dietary treatments show promise, but they require further research before they can be recommended.[69]

- Melatonin may be beneficial according to *in vitro* research, animal studies, and a preliminary human study.[70]
- Dietary fiber, meaning indigestible plant matter, has been recommended for decades in the maintenance of bowel function. Of peculiar note is fiber from brassica, which seems to contain soluble constituents capable of reversing ulcers along the entire human digestive tract before it is cooked.[71]
- Fish oil, and eicosapentaenoic acid (EPA) derived from fish oil, inhibits leukotriene activity, the latter which may be a key factor of inflammation. As an IBD therapy, there are no conclusive studies in support and no recommended dosage. But dosages of EPA between 180 and 1500 mg/day are recommended for other conditions, most commonly cardiac.[72] Fish oil also contains vitamin D, of which the many people with IBD are deficient.[73]
- Short chain fatty acid (butyrate) enema. The epithelial cells in the colon uses butyrate from the contents of the intestine as an energy source. The amount of butyrate available decreases toward the rectum. Inadequate butyrate levels in the lower intestine have been suggested as a contributing factor for the disease. This might be addressed through butyrate enemas.[74] The results however are not conclusive.[*citation needed*]
- Herbal medications are used by patients with ulcerative colitis. Compounds that contain sulfhydryl may have an effect in ulcerative colitis (under a similar hypothesis that the sulfa moiety of sulfasalazine may have activity in addition to the active 5-ASA component).[75] One randomized control trial evaluated the over-the-counter medication *S*-methylmethionine and found a significant decreased rate of relapse when the medication was used in conjunction with oral sulfasalazine.[76]
- Helminthic therapy is the use of intestinal parasitic nematodes to treat ulcerative colitis, and is based on the premises of the hygiene hypothesis. Studies have shown that helminths ameliorate and are more effective than daily corticosteroids at blocking chemically induced colitis in mice,[77][78] and a trial of intentional helminth infection of rhesus monkeys with idiopathic chronic diarrhea (a condition similar to ulcerative colitis in humans) resulted in remission of symptoms in 4 out of 5 of the animals treated.[79] A randomised controlled trial of Trichuris suis ova in humans found the therapy to be safe and

effective,[80] and further human trials are ongoing.
- Curcumin (tumeric) therapy, in conjunction with taking the medications mesalamine or sulfasalazine, may be effective and safe for maintaining remission in people with quiescent ulcerative colitis. The effect of curcumin therapy alone on quiescent ulcerative colitis is unknown.[81]

# Prognosis [edit]

## Progression or remission [edit]



Patients with ulcerative colitis usually have an intermittent course, with periods of disease inactivity alternating with "flares" of disease. Patients with proctitis or left-sided colitis usually have a more benign course: only 15% progress proximally with their disease, and up to 20% can have sustained remission in the absence of any therapy. Patients with more extensive disease are less likely to sustain remission, but the rate of remission is independent of the severity of the disease.

**Complications**

| | | Crohn's disease | Ulcerative colitis |
|---|---|---|---|
| Nutrient deficiency | | Higher risk | |
| Colon cancer risk | | Slight | Considerable |
| Prevalence of **extraintestinal complications**[82] | | | |
| Iritis/uveitis | Females | 2.2% | 3.2% |
| | Males | 1.3% | 0.9% |
| Primary sclerosing cholangitis | Females | 0.3% | 1% |
| | Males | 0.4% | 3% |
| Ankylosing spondylitis | Females | 0.7% | 0.8% |
| | Males | 2.7% | 1.5% |
| Pyoderma gangrenosum | Females | 1.2% | 0.8% |
| | Males | 1.3% | 0.7% |
| Erythema nodosum | Females | 1.9% | 2% |
| | Males | 0.6% | 0.7% |

## Colorectal cancer [edit]

There is a significantly increased risk of colorectal cancer in patients with ulcerative colitis after ten years if involvement is beyond the splenic flexure. Those with only proctitis or rectosigmoiditis usually have no increased risk.[10] It is recommended that patients have screening colonoscopies with random biopsies to look for dysplasia after eight years of disease activity, at one to two year intervals.[83]

## Primary sclerosing cholangitis [edit]

Ulcerative colitis has a significant association with primary sclerosing cholangitis (PSC), a progressive inflammatory disorder of small and large bile ducts. As many as 5% of patients with ulcerative colitis may progress to develop primary sclerosing cholangitis.[84]

## Mortality [edit]

Research has not revealed any difference in overall risk of dying in patients with Ulcerative colitis from that of the background population. The cause-of-death distribution may be different from that of the background population.[85] It is thought that the disease primarily affects quality of life, and not lifespan.

## Other long-term features [edit]

Changes that can be seen in chronic ulcerative colitis include granularity, loss of the vascular pattern of the mucosa, loss of haustra, effacement of the ileocecal valve, mucosal bridging, strictures and pseudopolyps.[86]

## Epidemiology [edit]

The number of new cases per year of ulcerative colitis in North America is 10–12 per 100,000 per year. It begins most commonly between the ages of 15 and 25. The number of people affected is 1–3 per 1000.[87] Another frequent age of onset is the 6th decade of life.

The geographic distribution of ulcerative colitis and Crohn's disease is similar worldwide,[88] with highest incidences in the United States, Canada, the United Kingdom, and Scandinavia. Higher incidences are seen in northern locations compared to southern locations in Europe[89] and the United States.[90]

As with Crohn's disease, the prevalence of ulcerative colitis is greater among Ashkenazi Jews and decreases progressively in other persons of Jewish descent, non-Jewish Caucasians, Africans, Hispanics, and Asians.[27] Appendectomy prior to age 20 for appendicitis[91] and current tobacco use[92] are protective against development of ulcerative colitis (although former tobacco use is associated with a higher risk of developing ulcerative colitis.[92])

## Research [edit]

Helminthic therapy using the whipworm *Trichuris suis* has been shown in a randomized control trial from Iowa to show benefit in patients with ulcerative colitis.[93] The therapy tests the hygiene hypothesis which argues that the absence of helminths in the colons of patients in the developed world may lead to inflammation. Both helminthic therapy and fecal bacteriotherapy induce a characteristic Th2 white cell response in the diseased areas, which was unexpected given that ulcerative colitis was thought to involve Th2 overproduction.[94]

Alicaforsen is a first generation antisense oligodeoxynucleotide designed to bind specifically to the human ICAM-1 messenger RNA through Watson-Crick base pair interactions in order to subdue expression of ICAM-1.[95] ICAM-1 propagates an inflammatory response promoting the extravasation and activation of leukocytes (white blood cells) into inflamed tissue.[95] Increased expression of ICAM-1 has been observed within the inflamed intestinal mucosa of ulcerative colitis sufferers, where ICAM-1 over production correlated with disease activity.[96] This suggests that ICAM-1 is a potential therapeutic target in the treatment of ulcerative colitis.[97]

Gram positive bacteria present in the lumen could be associated with extending the time of relapse for ulcerative colitis.[98]

# Volvulus

From Wikipedia, the free encyclopedia

It has been suggested that *Sigmoid colon volvulus* be merged into this article (Discuss) *Proposed since November 2016.*

## Variants

A **volvulus** is when a loop of intestine twists around itself and the mesentery that supports it, resulting in a bowel obstruction.[1] Symptoms include abdominal pain, abdominal bloating, vomiting, constipation, and bloody stool.[1][2] Onset of symptoms may be rapid or more gradual.[2] The mesentery may become so tightly twisted that blood flow to part of the intestine is cut off, resulting in ischemic bowel.[1] In this situation there may be fever or significant pain when the abdomen is touched.[2]

Risk factors include a birth defect known as intestinal malrotation, an enlarged colon, Hirschsprung disease, pregnancy, and abdominal adhesions.[1] Long term constipation and a high fiber diet may also increase the risk.[3] The most commonly affected part of the intestines in adults is the sigmoid colon with the cecum being second most affected.[1] In children the small intestine is more often involved.[4] The stomach can also be affected.[5] Diagnosis is typically with medical imaging such as plain X-rays, a GI series, or CT scan.[1]

Initial treatment for sigmoid volvulus may occasionally occur via sigmoidoscopy or with a barium enema. Due to the high risk of recurrence, a bowel resection within the next two days is generally recommended.[3] If the bowel is severely twisted or the blood supply is cut off, immediate surgery is required.[1] In a cecal volvulus, often part of the bowel needs to be surgically removed.[3] If the cecum is still healthy, it may occasionally be returned to a normal position and sutured in place.[1][3]

Cases of volvulus were described in ancient Egypt as early as 1550 BC. It occurs most frequently in Africa, the Middle East, and India.[3] Rates of volvulus in the United States are about 2-3 per 100,000 people per year.[6][2] Sigmoid and cecal volvulus typically occurs between the ages of 30 and 70.[1][7] Outcomes are related to whether or not the bowel tissue has died.[1] The term volvulus is from the Latin "volvere"; which means "to roll".[3]

## Signs and symptoms [edit]

Regardless of cause, volvulus causes symptoms by two mechanisms:[*citation needed*]

- Bowel obstruction manifested as abdominal distension and bilious vomiting.
- Ischemia (loss of blood flow) to the affected portion of intestine.

Depending on the location of the volvulus, symptoms may vary. For example, in patients with a cecal volvulus, the predominant symptoms may be those of a small bowel obstruction (nausea, vomiting and lack of stool or flatus), because the obstructing point is close to the ileocecal valve and small intestine. In patients with a sigmoid volvulus, although abdominal pain may be present, symptoms of constipation may be more prominent.

Volvulus causes severe pain and progressive injury to the intestinal wall, with accumulation of gas and fluid in the portion of the bowel obstructed.[8] Ultimately, this can result in necrosis of the affected intestinal wall, acidosis, and death. This is known as a closed loop obstruction because there exists an isolated ("closed") loop of bowel. Acute volvulus often requires immediate surgical intervention to untwist the affected segment of bowel and possibly resect any unsalvageable portion.[8]

Volvulus occurs most frequently in middle-aged and elderly men.[8] Volvulus can also arise as a rare complication in persons with redundant colon, a normal anatomic variation resulting in extra colonic loops.[9]

Sigmoid volvulus is the most-common form of volvulus of the gastrointestinal tract.[10] and is responsible for 8% of all intestinal obstructions.[*citation needed*] Sigmoid volvulus is particularly common in elderly persons and constipated patients. Patients experience abdominal pain, distension, and absolute constipation.

Cecal volvulus is slightly less common than sigmoid volvulus and is associated with symptoms of abdominal pain and small bowel obstruction.

Volvulus can also occur in patients with Duchenne muscular dystrophy due to the smooth muscle dysfunction.[*citation needed*]

## Causes [edit]

This section **does not cite any sources**. Please help improve this section by adding citations to reliable sources. Unsourced material may be challenged and removed. *(April 2012) (Learn how and when to remove this template message)*

Midgut volvulus occurs in people (usually babies) that are predisposed because of congenital intestinal malrotation. Segmental volvulus occurs in people of any age, usually with a predisposition because of abnormal intestinal contents (e.g. meconium ileus) or adhesions. Volvulus of the cecum, transverse colon,

or sigmoid colon occurs, usually in adults, with only minor predisposing factors such as redundant (excess, inadequately supported) intestinal tissue and constipation.

### Types [edit]

- volvulus neonatorum
- volvulus of the small intestine
- volvulus of the caecum (cecum), also cecal volvulus
- sigmoid colon volvulus (sigmoid volvulus)
- volvulus of the transverse colon
- volvulus of the splenic flexure, the rarest
- gastric volvulus
- ileosigmoid knotting

## Diagnosis [edit]

After taking a thorough history, the diagnosis of colonic volvulus is usually easily included in the differential diagnosis. Abdominal plain x-rays are commonly confirmatory for a volvulus, especially if a "bent inner tube" sign or a "coffee bean" sign are seen. These refer to the shape of the air filled closed loop of colon which forms the volvulus. Should the diagnosis be in doubt, a barium enema may be used to demonstrate a "bird's beak" at the point where the segment of proximal bowel and distal bowel rotate to form the volvulus. This area shows an acute and sharp tapering and looks like a bird's beak. If a perforation is suspected, barium should not be used due to its potentially lethal effects when distributed throughout the free infraperitoneal cavity. Gastrografin, which is safer, can be substituted for barium.

Coffee bean sign in a patient with sigmoid volvulus

The differential diagnosis includes the much more common constricting or obstructing carcinoma. In approximately 80 percent of colonic obstructions, an invasive carcinoma is found to be the cause of the obstruction. This is usually easily diagnosed with endoscopic biopsies.

Diverticulitis is a common condition with different presentations. Although diverticulitis may be the source of a colonic obstruction, it more commonly causes an ileus, which appears to be a colonic obstruction.[11] Endoscopic means can be used to secure a diagnosis although this may cause a perforation of the inflamed diverticular area. CT scanning is the more common method to diagnose diverticulitis. The scan will show mesenteric stranding in the involved segment of edematous colon which is usually in the sigmoid region. Micro perforations with free air may be seen.

An x-ray of a person with a small bowel volvulus.

Ulcerative colitis or Crohn's disease may cause colonic obstruction. The obstruction may be acute or chronic after years of uncontrolled disease leads to the formation of strictures and fistulas . The medical history is helpful in that most cases of inflammatory bowel disease are well known to both patient and doctor.

Other rare syndromes, including Ogilvie's syndrome, chronic constipation and impaction may cause a pseudo obstruction.[12]

- Abdominal x-ray – tire-like shadow arising from right iliac fossa and passing to left
- Upper GI series

## Treatment [edit]

### Sigmoid volvulus [edit]

Treatment for sigmoid volvulus may include sigmoidoscopy. If the mucosa of the sigmoid looks normal and pink, place a rectal tube for decompression, correct any fluid, electrolyte, cardiac, renal or pulmonary abnormalities and then take the person to the operating room for repair. If surgery is not performed, there is a high rate of recurrence.[*citation needed*]

For people with signs of sepsis or an abdominal catastrophe, immediate surgery and resection is advised.

Volvulus with gangrene of the sigmoid

### Cecal volvulus [edit]

In a cecal volvulus, the cecum may be returned to a normal position and sutured in place, a procedure known as cecopexy.[1]

### Other [edit]

Laparotomy for other forms of volvulus, especially anal volvulus.

## Complications [edit]

- Strangulation
- Gangrene
- Perforation
- Faecal peritonitis
- Recurrent volvulus

# African trypanosomiasis

From Wikipedia, the free encyclopedia

*For other uses, see Sleeping sickness (disambiguation).*
*For "Sleepy sickness", see Encephalitis lethargica.*

**African trypanosomiasis**, also known as **sleeping sickness**,[1] is a parasitic disease of humans and other animals. It is caused by protozoa of the species *Trypanosoma brucei*. There are two types that infect humans, *Trypanosoma brucei gambiense* (T.b.g) and *Trypanosoma brucei rhodesiense* (T.b.r.).[1] T.b.g causes over 98% of reported cases.[1] Both are usually transmitted by the bite of an infected tsetse fly and are most common in rural areas.[1]

Initially, in the first stage of the disease, there are fevers, headaches, itchiness, and joint pains.[1] This begins one to three weeks after the bite. Weeks to months later the second stage begins with confusion, poor coordination, numbness and trouble sleeping. Diagnosis is via finding the parasite in a blood smear or in the fluid of a lymph node. A lumbar puncture is often needed to tell the difference between first and second stage disease.[3]

Prevention of severe disease involves screening the population at risk with blood tests for T.b.g.[1] Treatment is easier when the disease is detected early and before neurological symptoms occur.[1] Treatment of the first stage is with the medications pentamidine or suramin.[1] Treatment of the second stage involves: eflornithine or a combination of nifurtimox and eflornithine for T.b.g.[3] While melarsoprol works for both stages, it is typically only used for T.b.r., due to serious side effects.[1] Without treatment it typically results in death.[1]

The disease occurs regularly in some regions of sub-Saharan Africa with the population at risk being about 70 million in 36 countries.[4] As of 2010 it caused around 9,000 deaths per year, down from 34,000 in 1990.[5] An estimated 30,000 people are currently infected with 7,000 new infections in 2012.[1] More than 80% of these cases are in the Democratic Republic of the Congo.[1] Three major outbreaks have occurred in recent history: one from 1896 to 1906 primarily in Uganda and the Congo Basin and two in 1920 and 1970 in several African countries.[1] Other animals, such as cows, may carry the disease and become infected in which case it is known as Nagana.[1]

1 Signs and symptoms

## Signs and symptoms [edit]

African trypanosomiasis symptoms occur in two stages. The first stage, known as the hemolymphatic phase, is characterized by fever, headaches, joint pains, and itching. Fever is intermittent, with attacks lasting from a day to a week, separated by intervals of a few days to a month or longer. Invasion of the circulatory and lymphatic systems by the parasites is associated with severe swelling of lymph nodes, often to tremendous sizes. Winterbottom's sign, the tell-tale swollen lymph nodes along the back of the neck, may appear.[6]

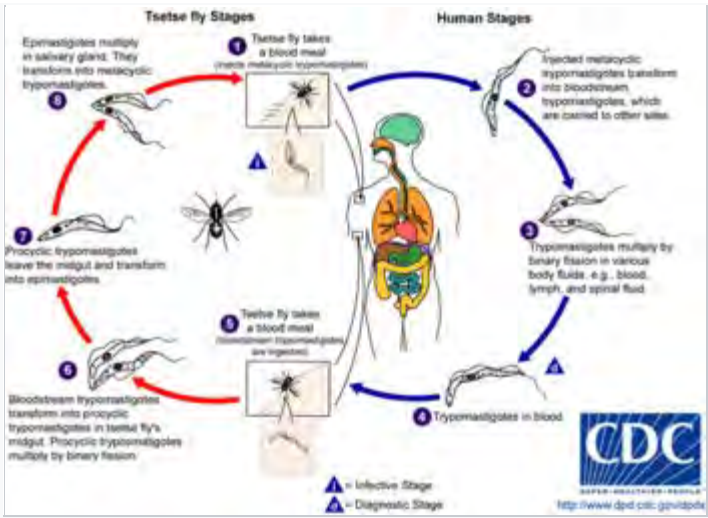
Occasionally, a chancre (red sore) will develop at the location of the tsetse fly bite. If left untreated, the disease overcomes the host's defenses and can cause more extensive damage, broadening symptoms to include anemia, endocrine, cardiac, and kidney dysfunctions. The second, neurological phase, begins when the parasite invades the central nervous system by passing through the blood–brain barrier. Disruption of the sleep cycle is a leading symptom of this stage and is the one that gave the disease the name 'sleeping sickness.' Infected individuals experience a disorganized and fragmented 24-hour rhythm of the sleep-wake cycle, resulting in daytime sleep episodes and nighttime periods of wakefulness.[6]

Other neurological symptoms include confusion, tremor, general muscle weakness, hemiparesis and paralysis of a limb. Parkinson-like movements might arise due to non-specific movement disorders and speech disorders. Individuals may also exhibit psychiatric symptoms such as irritability, psychotic reactions, aggressive behaviour, or apathy which can sometimes dominate the clinical diagnosis.[7] Without treatment, the disease is invariably fatal, with progressive mental deterioration leading to coma, systemic organ failure, and death. An untreated infection with *T. b. rhodesiense* will cause death within months[8] whereas an untreated infection with *T. b. gambiense* will cause death after several years.[9] Damage caused in the neurological phase is irreversible.[10]

## Cause [edit]

### *Trypanosoma brucei* [edit]

There are two subspecies of the parasite that are responsible for starting the disease in humans. *Trypanosoma brucei gambiense* causes the diseases in west and central Africa, whereas *Trypanosoma brucei rhodesiense* has a limited geographical range and is responsible for causing the disease in east and



The life cycle of the *Trypanosoma brucei* parasites.

southern Africa. In addition, a third subspecies of the parasite known as *Trypanosoma brucei brucei* is responsible for affecting animals but not humans.[7]

Humans are the main reservoir for *T. b. gambiense* but this species can also be found in pigs and other animals. Wild game animals and cattle are the main reservoir of *T. b. rhodesiense*. These parasites primarily infect individuals in sub-Saharan Africa because that is where the vector (tsetse fly) is located. The two human forms of the disease also vary greatly in intensity. *T. b. gambiense* causes a chronic condition that can remain in a passive phase for months or years before symptoms emerge and the infection can last about 3 years before death occurs.[7]

*T. b. rhodesiense* is the acute form of the disease and death can occur within months since the symptoms emerge within weeks and it is more virulent and faster developing than *T. b. gambiense*. Furthermore, trypanosomes are surrounded by a coat that is composed of variant surface glycoproteins (VSG). These proteins act to protect the parasite from any lytic factors that are present in human plasma. The host's immune system recognizes the glycoproteins present on the coat of the parasite leading to the production of different antibodies (IgM and IgG).[7]

These antibodies will then act to destroy the parasites that circulate around the blood. However, from the several parasites present in the plasma, a small number of them will experience changes in their surface coats resulting in the formation of new VSGs. Thus, the antibodies produced by the immune system will no longer recognize the parasite leading to proliferation until new antibodies are created to combat the novel VSGs. Eventually the immune system will no longer be able to fight off the parasite due to the constant changes in VSGs and infection will arise.[7]

## Vector [edit]

The tsetse fly (genus *Glossina*) is a large, brown, biting fly that serves as both a host and vector for the trypanosome parasites. While taking blood from a mammalian host, an infected tsetse fly injects metacyclic trypomastigotes into skin tissue. From the bite, parasites first enter the lymphatic system and then pass into the bloodstream. Inside the mammalian host, they transform into bloodstream trypomastigotes, and are carried to other sites throughout the body, reach other body fluids (e.g., lymph, spinal fluid), and continue to replicate by binary fission.

The entire life cycle of African trypanosomes is represented by extracellular stages. A tsetse fly becomes infected with bloodstream trypomastigotes when taking a blood meal on an infected mammalian host. In the fly's midgut, the parasites transform into procyclic trypomastigotes, multiply by binary fission, leave the midgut, and transform into epimastigotes. The epimastigotes reach the fly's salivary glands and continue multiplication by binary fission.

The entire life cycle of the fly takes about three weeks. In addition to the bite of the tsetse fly, the disease can be transmitted by:

- Mother-to-child infection: the trypanosome can sometimes cross the placenta and infect the fetus.[11]
- Laboratories: accidental infections, for example, through the handling of blood of an infected person and organ transplantation, although this is uncommon.
- Blood transfusion
- Sexual contact (This may be possible)[12]

Horse-flies (Tabanidae) and stable flies (Muscidae) possibly play a role in transmission of nagana (the animal form of sleeping sickness) and the human disease form.[13]

## Mechanism [edit]

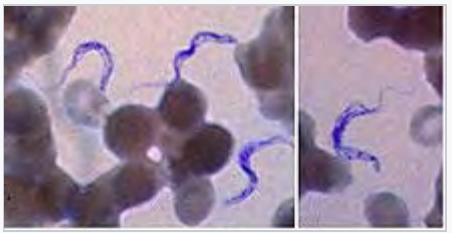
Tryptophol is a chemical compound that induces sleep in humans. It is produced by the trypanosomal parasite in sleeping sickness.[14]

## Diagnosis [edit]

The gold standard for diagnosis is identification of trypanosomes in a patient sample by microscopic examination. Patient samples that can be used for diagnosis include chancre fluid, lymph node aspirates, blood, bone marrow, and, during the neurological stage, cerebrospinal fluid. Detection of trypanosome-specific antibodies can be used for diagnosis, but the sensitivity and specificity of these methods are too variable to be used alone for clinical diagnosis. Further, seroconversion occurs after the onset of clinical symptoms during a *T. b. rhodesiense* infection, so is of limited diagnostic use.[*citation needed*]

Trypanosomes can be detected from patient samples using two different preparations. A wet preparation can be used to look for the motile trypanosomes. Alternatively, a fixed (dried) smear can be stained using Giemsa's or Field's technique and examined under a microscope. Often, the parasite is in relatively low abundance in the sample, so techniques to concentrate the parasites can be used prior to microscopic examination. For blood samples, these include centrifugation followed by examination of the buffy coat; mini anion-exchange/centrifugation; and the quantitative buffy coat (QBC) technique. For other samples, such as spinal fluid, concentration techniques include centrifugation followed by examination of the sediment.[*citation needed*]

Three serological tests are also available for detection of the parasite: the micro-CATT, wb-CATT, and wb-LATEX. The first uses dried blood, while the other two use whole blood samples. A 2002 study found the wb-CATT to be the most efficient for diagnosis, while the wb-LATEX is a better exam for situations where greater sensitivity is required.[15]



Two areas from a blood smear from a patient with African trypanosomiasis, thin blood smear stained with Giemsa: Typical trypomastigote stages (the only stages found in patients), with a posterior kinetoplast, a centrally located nucleus, an undulating membrane, and an anterior flagellum. The two *Trypanosoma brucei* subspecies that cause human trypanosomiasis, *T. b. gambiense* and *T. b. rhodesiense*, are indistinguishable morphologically. The trypanosomes' length range is 14 to 33 μm, Source: CDC

## Prevention [edit]

*See also: Tsetse fly § Control techniques*

Currently there are few medically related prevention options for African Trypanosomiasis (i.e. no vaccine exists for immunity). Although the risk of infection from a tsetse fly bite is minor (estimated at less than 0.1%), the use of insect repellants, wearing long-sleeved clothing, avoiding tsetse-dense areas, implementing bush clearance methods and wild game culling are the best options to avoid infection available for local residents of affected areas.[16]

At the 25th ISCTRC (International Scientific Council for Trypanosomiasis Research and Control) in Mombasa, Kenya, in October 1999, the idea of an African-wide initiative to control tsetse and trypanosomiasis populations was discussed. During the 36th summit of the Organization for African Unity in Lome, Togo, in July 2000, a resolution was passed to form the Pan African Tsetse and Trypanosomiasis Eradication Campaign (PATTEC). The campaign works to eradicate the tsetse vector population levels and subsequently the protozoan disease, by use of insecticide-impregnated targets, fly traps, insecticide-treated cattle, ultra-low dose aerial/ground spraying (SAT) of tsetse resting sites and the sterile insect technique (SIT).[17] The

use of SIT in Zanzibar proved effective in eliminating the entire population of tsetse flies but was expensive and is relatively impractical to use in many of the endemic countries afflicted with African trypanosomiasis.[16]

Regular active surveillance, involving detection and prompt treatment of new infections, and tsetse fly control is the backbone of the strategy used to control sleeping sickness. Systematic screening of at-risk communities is the best approach, because case-by-case screening is not practical in endemic regions. Systematic screening may be in the form of mobile clinics or fixed screening centres where teams travel daily to areas of high infection rates. Such screening efforts are important because early symptoms are not evident or serious enough to warrant patients with gambiense disease to seek medical attention, particularly in very remote areas. Also, diagnosis of the disease is difficult and health workers may not associate such general symptoms with trypanosomiasis. Systematic screening allows early-stage disease to be detected and treated before the disease progresses, and removes the potential human reservoir.[18] A single case of sexual transmission of West African sleeping sickness has been reported.[12]

# Treatment [edit]

## First stage [edit]

The current treatment for first-stage disease is intravenous or intramuscular pentamidine for *T. b. gambiense* or intravenous suramin for *T. b. rhodesiense*.[1]

## Second stage [edit]

For *T. b. gambiense* the combination of nifurtimox and eflornithine (NECT) or eflornithine alone appear to be more effective and result in fewer side effects.[19] These treatments may replace melarsoprol when available[19] with the combination being first line.[3] NECT has the benefit of requiring less injections of eflornithine.[19]

Intravenous melarsoprol was previously the standard treatment for second-stage (neurological phase) disease and is effective for both types.[3] Melarsoprol is the only treatment for second stage *T. b. rhodesiense*; however, it causes death in 5% of people who take it.[3] Resistance to melarsoprol can occur.[3]

# Epidemiology [edit]

As of 2010 it caused around 9,000 deaths, down from 34,000 in 1990.[5] As of 2000, the disability-adjusted life-years (9 to 10 years) lost due to sleeping sickness are 2.0 million.[21] Over 60 million people living in some 250 locations are at risk of contracting the disease, and under 10,000 new cases were reported in 2009.[22]

The disease has been recorded as occurring in 37 countries, all in sub-Saharan Africa. It occurs regularly in southeast Uganda and western Kenya, and killed more than 48,000 Africans in 2008.[10] The population at risk being about 69 million with one third of this number being at a 'very high' to 'moderate' risk and the remaining two thirds at a 'low' to 'very low' risk.[4]

Deaths per 100,000 population due to African trypanosomiasis by country in 2002.[20]

# Prognosis [edit]

If untreated, *T. b. gambiense* almost always results in death, with only a few individuals shown in a long-term 15 year follow-up to have survived after refusing treatment. *T. b. rhodesiense*, being a more acute and severe form of the disease, is consistently fatal if not treated.[3] Disease progression greatly varies depending on disease form. For individuals which are infected by *T. b. gambiense*, which accounts for 98% of all of the reported cases, a person can be infected for months or even years without signs or symptoms until the advanced disease stage, where it is too late to be treated successfully. For individuals affected by *T. b. rhodesiense*, which accounts for 2% of all reported cases, symptoms appear within weeks or months of the infection. Disease progression is rapid and invades the central nervous system, causing death within a short amount of time.[23]

## History [edit]

The condition has been present in Africa for thousands of years.[24] Because of a lack of travel between indigenous people, sleeping sickness in humans had been limited to isolated pockets. This changed once Arab slave traders entered central Africa from the east, following the Congo River, bringing parasites along. Gambian sleeping sickness travelled up the Congo River, then further eastwards.[25]

An Arab writer of the 14th century left the following description in the case of a sultan of the Malli [*sic*] Kingdom: "His end was to be overtaken by the sleeping sickness (*illat an-nawm*) which is a disease that frequently befalls the inhabitants of these countries especially their chieftains. Sleep overtakes one of them in such a manner that it is hardly possible to awake him."[25]

British naval surgeon John Atkins described the disease on his return from West Africa in 1734:

> "The Sleepy Distemper (common among the Negroes) gives no other previous Notice, than a want of Appetite 2 or 3 days before; their sleeps are sound, and Sense and Feeling very little; for pulling, drubbing or whipping will scarce stir up Sense and Power enough to move; and the Moment you cease beating the smart is forgot, and down they fall again into a state of Insensibility, drivling constantly from the Mouth as in deep salivation; breathe slowly, but not unequally nor snort. Young people are more subject to it than the old; and the Judgement generally pronounced is Death, the Prognostik seldom failing. If now and then one of them recovers, he certainly loses the little Reason he had, and turns Ideot..."[25]

In 1903, David Bruce recognized the tsetse fly as the arthropod vector.

In 1901, a devastating epidemic erupted in Uganda, killing more than 250,000 people,[26] including about two-thirds of the population in the affected lakeshore areas. According to *The Cambridge History of Africa*, "It has been estimated that up to half the people died of sleeping-sickness and smallpox in the lands on either bank of the lower river Congo."[27]

The causative agent and vector were identified in 1903 by David Bruce, and the differentiation between the subspecies of the protozoa made in 1910. Bruce had earlier shown that *T. brucei* was the cause of a similar disease in horses and cattle that was transmitted by the tse-tse fly (*Glossina morsitans*).[25]

The first effective treatment, atoxyl, an arsenic-based drug developed by Paul Ehrlich and Kiyoshi Shiga, was introduced in 1910, but blindness was a serious side effect.

Collecting Tsetse flies with the British led *Sleeping Sickness Commission*, Uganda and Nyasaland, 1908-1913.

Suramin was first synthesized by Oskar Dressel and Richard Kothe in 1916 for Bayer. It was introduced in 1920 to treat the first stage of the disease. By 1922, Suramin was generally combined with tryparsamide (another pentavalent organoarsenic drug), the first drug to enter the nervous system and be useful in the treatment of the second stage of the gambiense form. Tryparsamide was announced in the *Journal of Experimental Medicine* in 1919 and tested in the Belgian Congo by Louise Pearce of the Rockefeller Institute in 1920. It was used during the grand epidemic in West and Central Africa on millions of people and was the mainstay of therapy until the 1960s.[28] American medical missionary Arthur Lewis Piper was active in using tryparsamide to treat sleeping sickness in the Belgian Congo in 1925.[29]

Pentamidine, a highly effective drug for the first stage of the disease, has been used since 1939. During the 1950s, it was widely used as a prophylactic agent in western Africa, leading to a sharp decline in infection rates. At the time, eradication of the disease was thought to be at hand.[*citation needed*]

The organoarsenical melarsoprol (Arsobal) developed in the 1940s is effective for patients with second-stage sleeping sickness. However, 3–10% of those injected have reactive encephalopathy (convulsions, progressive coma, or psychotic reactions), and 10–70% of such cases result in death; it can cause brain damage in those who survive the encephalopathy. However, due to its effectiveness, melarsoprol is still used today. Resistance to melarsoprol is increasing, and combination therapy with nifurtimox is currently under research.[*citation needed*]

Eflornithine (difluoromethylornithine or DFMO), the most modern treatment, was developed in the 1970s by Albert Sjoerdsma and underwent clinical trials in the 1980s. The drug was approved by the United States Food and Drug Administration in 1990.[30] Aventis, the company responsible for its manufacture, halted production in 1999. In 2001, Aventis, in association with Médecins Sans Frontières and the World Health Organization, signed a long-term agreement to manufacture and donate the drug.[*citation needed*]

In addition to sleeping sickness, previous names have included negro lethargy, maladie du sommeil (Fr), Schlafkrankheit (Gr), African lethargy,[31] and Congo trypanosomiasis.[31][32]

## Research [edit]

The genome of the parasite has been sequenced and several proteins have been identified as potential targets for drug treatment. Analysis of the genome also revealed the reason why generating a vaccine for this disease has been so difficult. *T. brucei* has over 800 genes that make proteins the parasite "mixes and matches" to evade immune system detection.[33]

Using a genetically modified form of a bacterium that occurs naturally in the gut of the vectors is being studied as a method of controlling the disease.[34]

Recent findings indicate the parasite is unable to survive in the bloodstream without its flagellum. This insight gives researchers a new angle with which to attack the parasite.[35]

Trypanosomiasis vaccines are undergoing research.

Additionally, the Drugs for Neglected Disease Initiative has contributed to the African sleeping sickness research effort by developing a compound called fexinidazole. This project was originally started in April 2007 and is currently in a pivotal study in clinical phase II/III.36 The goal is to have the drug succeed and be proven effective again stage one and stage two HAT caused by *T. b. gambiense*, as well HAT caused by *T. b. rhodesiense*.[36]

### Funding [edit]

For current funding statistics, human African trypanosomiasis is grouped with kinetoplastid infections. Kinetoplastids refer to a group of flagellate protozoa.[37] Kinetoplastid infections include African sleeping sickness, Chagas' disease, and Leishmaniasis. All together, these three diseases accounted for 4.4 million disability adjusted life years (DALYs) and an additional 70,075 recorded deaths yearly.[37] For kinetoplastid infections, the total global research and development funding was approximately $136.3 million in 2012.

Each of the three diseases, African sleeping sickness, Chagas' disease, and Leishmaniasis each received approximately a third of the funding, which was about $36.8 million US dollars, $38.7 million US dollars, and $31.7 million US dollars, respectively.[37]

For sleeping sickness, funding was split into basic research, drug discovery, vaccines, and diagnostics. The greatest amount of funding was directed towards basic research of the disease; approximately $21.6 million US dollars were directed towards that effort. As for therapeutic development, approximately $10.9 billion were invested.[37]

The top funder for kinetoplastid infection research and development are public sources. About 62% of the funding comes from high-income countries while 9% comes from low- and middle-income countries. High-income countries public funding is largest contributors to the neglected disease research effort. However, in recent years, funding from high-income countries has been steadily decreasing; in 2007, high-income countries provided 67.5% of the total funding whereas, in 2012, high-income countries public funds only provided 60% of the total funding for kinetoplastid infections. This downwards trend leaves a gap for other funders, such as philanthropic foundations and private pharmaceutical companies to fill.[37]

Much of the progress that has been made in African sleeping sickness and neglected disease research as a whole is a result of the other non-public funders. One of these major sources of funding has come from foundations, which have increasingly become more committed to neglected disease drug discovery in the 21st century. In 2012, philanthropic sources provided 15.9% of the total funding.[37] The Bill and Melinda Gates Foundation has been a leader in providing funding for neglected disease drug development. They have provided $444.1 million US dollars towards neglected disease research in 2012. To date, they have donated over $1.02 billion US dollars towards the neglected disease discovery efforts.[38]

For kinetoplastid infections specifically, they have donated an average of $28.15 million US dollars annually between the years 2007 to 2011.[37] They have labeled human African trypanosomiasis a high-opportunity target meaning it is a disease that presents the greatest opportunity for control, elimination, and eradication, through the development on new drugs, vaccines, public-health programs, and diagnostics. They are the second highest funding source for neglected diseases, immediately behind the US National Institutes of Health.[37] At a time where public funding is decreasing and government grants for scientific research are harder to obtain, the philanthropic world has stepped in to push the research forward.

Another important component of increased interest and funding has come from industry. In 2012, they contributed 13.1% total to the kinetoplastid research and development effort, and have additionally played an important role by contributing to public-private partnerships (PPP) as well as product-development partnerships (PDP).[37] A public-private partnership is an arrangement between one or more public entities and one or more private entities that exists to achieve a specific health outcome or to produce a health product. The partnership can exist in numerous ways; they may share and exchange funds, property, equipment, human resources, and intellectual property. These public-private partnerships and product-development partnerships have been established to address challenges in pharmaceutical industry, especially related to neglected disease research. These partnerships can help increase the scale of the effort towards therapeutic development by using different knowledge, skills, and expertise from different sources. These types of partnerships have been shown to be more effective than industry or public groups working independently.[39]

## Other animals [edit]

*Trypanosoma* of both the *rhodesiense* and *gambiense* types can affect other animals such as cattle and wild animals.[1] In animals it is known as nagana (animal African trypanosomiasis)

# Ascariasis

From Wikipedia, the free encyclopedia

*This article is about the infection. For the organism, see Ascaris.*

**Ascariasis** is a disease caused by the parasitic roundworm *Ascaris lumbricoides*.[1] Infections have no symptoms in more than 85% of cases, especially if the number of worms is small.[1] Symptoms increase with the number of worms present and may include shortness of breath and fever in the beginning of the disease.[1] These may be followed by symptoms of abdominal swelling, abdominal pain, and diarrhea.[1] Children are most commonly affected, and in this age group the infection may also cause poor weight gain, malnutrition, and learning problems.[1][2][3]

Infection occurs by eating food or drink contaminated with *Ascaris* eggs from feces.[2] The eggs hatch in the intestines, burrow through the gut wall, and migrate to the lungs via the blood.[2] There they break into the alveoli and pass up the trachea, where they are coughed up and swallowed.[2] The larvae then pass through the stomach for a second time into the intestine, where they become adult worms.[2] Ascariasis is classified as a neglected tropical disease as it is a type of soil-transmitted helminthiasis. These diseases are in turn part of a group of diseases called helminthiases.[4]

Prevention is by improved sanitation, which includes improving access to toilets and proper disposal of feces.[1][5] Handwashing with soap appears protective.[6] In areas where more than 20% of the population is affected, treating everyone at regular intervals is recommended.[1] Reoccurring infections are common.[2][7] There is no vaccine.[2] Treatments recommended by the World Health Organization are the medications albendazole, mebendazole, levamisole, or pyrantel pamoate.[2] Other effective agents include tribendimidine and nitazoxanide.[2]

About 0.8 to 1.2 billion people globally have ascariasis, with the most heavily affected populations being in sub-Saharan Africa, Latin America, and Asia.[1][8][9] This makes ascariasis the most common form of soil-transmitted helminthiasis.[8] As of 2010 it caused about 2,700 deaths a year, down from 3,400 in 1990.[10] Another type of *Ascaris* infects pigs.[1]

## Signs and symptoms [edit]

*Further information: Helminthiasis § Signs and symptoms*

Most people who are infected with only a small number of worms have no symptoms. It is common to find that most people are infected by a small number of worms, while a small number of people are heavily infected, something that is characteristic of many worm infections.[1][11] Clinical features depend on the affected body site.

### Migrating larvae [edit]

As larval stages travel through the body, they may cause visceral damage, peritonitis and inflammation, enlargement of the liver or spleen, and an inflammation of the lungs. Pulmonary manifestations take place during larval migration and may present as Loeffler's syndrome, a transient respiratory illness associated with blood eosinophilia and pulmonary infiltrates with radiographic shadowing.[12]

### Intestinal blockage [edit]

The worms can occasionally cause intestinal blockage when large numbers get tangled into a bolus or they may migrate from the small intestine, which may require surgery. More than 796 *A. lumbricoides* worms weighing up to 550 g [19 ounces] were recovered at autopsy from a 2-year-old South African girl. The worms had caused torsion and gangrene of the ileum, which was interpreted as the cause of death.[14]

Piece of intestine, blocked by worms, surgically removed from a 3-year-old boy in South Africa.[13]

### Bowel obstruction [edit]

Bowel obstruction may occur in up to 0.2 per 1000 per year.[1] A worm may block the ampulla of Vater, or go into the main pancreatic duct, resulting in acute pancreatitis with raised serum levels of amylase and lipase. Occasionally, a worm can travel through the biliary tree and even into the gallbladder, causing acute cholangitis or acute cholecystitis.

### Allergies [edit]

Ascariasis may result in allergies to shrimp and dustmites due to the shared antigen, tropomyosin; this has not been confirmed in the laboratory.[15][16]

### Malnutrition [edit]

The worms in the intestine may cause malabsorption and anorexia which contribute to malnutrition.[17] The malabsorption may be due to a loss of brush border enzymes, erosion and flattening of the villi, and inflammation of the lamina propria.[18]

### Others [edit]

*Ascaris* have an aversion to some general anesthetics and may exit the body, sometimes through the mouth, when an infected individual is put under general anesthesia.[19]

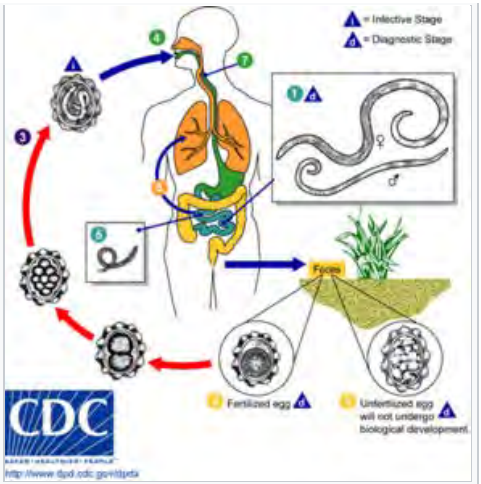
## Cause [edit]

### Transmission [edit]

The source of infection is from objects which have been contaminated with fecal matter containing eggs.[2] Ingestion of infective eggs from soil contaminated with human feces or contaminated vegetables and water is the primary route of infection. Infectious eggs may occur on other objects such as hands, money and furniture.[2] Transmission from human to human by direct contact is impossible.[20]

Transmission comes through municipal recycling of wastewater into crop fields. This is quite common in emerging industrial economies and poses serious risks for local crop sales and exports of contaminated vegetables. A 1986 outbreak of ascariasis in Italy was traced to irresponsible wastewater recycling used to grow Balkan vegetable exports.[21]

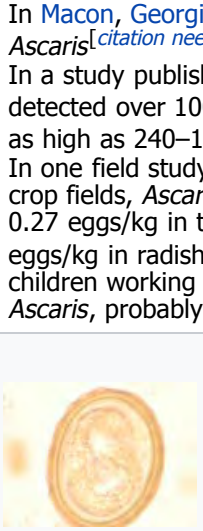
The number of ova (eggs) in sewage or in crops that were irrigated with raw or



Ascaris life cycle: Adult worms (1) live in the lumen of the small intestine. A female may produce approximately 200,000 eggs per day, which are passed with the feces (2). Unfertilized eggs may be ingested but are not infective. Fertile eggs embryonate and become infective after 18 days to several weeks (3), depending on the environmental conditions (optimum: moist, warm, shaded soil). After infective eggs are swallowed (4), the larvae hatch (5), invade the intestinal mucosa and are carried via the portal, then systemic circulation and/or lymphatics to the lungs . The larvae mature further in the lungs (6) (10 to 14 days), penetrate the alveolar walls, ascend the bronchial tree to the throat, and are swallowed (7). Upon reaching the small intestine, they develop into adult worms (8). Between 2 and 3 months are required from ingestion of the infective eggs to oviposition by the adult female. Adult worms can live 1 to 2 years.

partially treated sewage, is a measure of the degree of ascariasis incidence. For example:

- A 1978 study showed about 75% of all sewage sludge samples sampled in United States urban catchments contained *Ascaris* ova, with rates as high as 5 to 100 eggs per litre[*citation needed*].
- In Frankfort, Indiana, 87.5% of the sludge samples were positive with *Ascaris*, *Toxocara*, *Trichuris*, and hookworm[*citation needed*].
- In Macon, Georgia, one of the 13 soil samples tested positive for *Ascaris*[*citation needed*].
- In a study published in 1992, municipal wastewater in Riyadh, Saudi Arabia detected over 100 eggs per litre of wastewater[22] and in Czechoslovakia was as high as 240–1050 eggs per litre.[23]
- In one field study in Marrakech, Morocco, where raw sewage is used to fertilize crop fields, *Ascaris* eggs were detected at the rate of 0.18 eggs/kg in potatoes, 0.27 eggs/kg in turnip, 4.63 eggs/kg in mint, 0.7 eggs/kg in carrots, and 1.64 eggs/kg in radish.[24] A similar study in the same area showed that 73% of children working on these farms were infected with helminths, particularly *Ascaris*, probably as a result of exposure to the raw sewage.



The larva of Ascaris lumbricoides developing in the egg

Ascaris lumbricoides adult worms (with measuring tape for scale)

Ascaris lumbricoides adult worms

Ascaris egg, incubation process: The Ascaris egg incubation process consists in placing the egg in a controlled environment, at 26°C during 28 days, in acidic conditions. This process allows for evaluation of an egg

to determine if it is viable or not, by watching the bipartition of the nucleus, and the growth of the larva.

### Lifecycle [edit]

The first appearance of eggs in stools is 60–70 days. In larval ascariasis, symptoms occur 4–16 days after infection. The final symptoms are gastrointestinal discomfort, colic and vomiting, fever, and observation of live worms in stools. Some patients may have pulmonary symptoms or neurological disorders during migration of the larvae. There are generally few or no symptoms. A bolus of worms may obstruct the intestine; migrating larvae may cause pneumonitis and eosinophilia. Adult worms have a lifespan of 1–2 years which means that individuals may be infected all their lives as worms die and new worms are acquired.[11]

Eggs can survive potentially for 15 years and a single worm may produce 200 thousand eggs a day.[2] They maintain their position by swimming against the intestinal flow.[25]

## Diagnosis [edit]

Most diagnoses are made by identifying the appearance of the worm or eggs in feces. Due to the large quantity of eggs laid, physicians can diagnose using only one or two fecal smears.[*citation needed*]

The diagnosis is usually incidental when the host passes a worm in the stool or vomit. The eggs can be seen in a smear of fresh feces examined on a glass slide under a microscope and there are various techniques to concentrate them first or increase their visibility, such as the ether sedimentation method or the Kato technique. The eggs have a characteristic shape: they are oval with a thick, mamillated shell (covered with rounded mounds or lumps), measuring 35-50 micrometer in diameter and 40-70 in length. During pulmonary disease, larvae may be found in fluids aspirated from the lungs. White blood cells counts may demonstrate peripheral eosinophilia; this is common in many parasitic infections and is not specific to ascariasis. On X-ray, 15–35 cm long filling defects, sometimes with whirled appearance (bolus of worms).

## Mechanism [edit]

*Ascaris* takes most of its nutrients from the partially digested host food in the intestine. There is some evidence that it can secrete anti-enzymes, presumably to protect itself from digestion by the hosts' enzymes. Children are often more severely affected.[1]

## Prevention [edit]

Prevention is by improved access to sanitation which includes the use of properly functioning and clean toilets by all community members as one important aspect.[1] Handwashing with soap may be protective; however, there is no evidence it affects the severity of disease.[6] Eliminating the use of untreated human faeces as fertilizer is also important.

In areas where more than 20% of the population is affected treating everyone is recommended.[1] This has a cost of about 2 to 3 cents per person per treatment.[1] This is known as mass drug administration and is often carried out among school-age children.[26] For this purpose, broad-spectrum benzimidazoles such as mebendazole and albendazole are the drugs of choice recommended by WHO.[27]

## Treatment [edit]

*Further information: Helminthiasis § Treatment*

### Medications [edit]

Medications that are used to kill roundworms are called ascaricides. Those recommended by the World Health Organization for ascariasis are: albendazole, mebendazole, levamisole and pyrantel pamoate.[2] Other effective agents include tribendimidine and nitazoxanide.[2] Pyrantel pamoate may induce intestinal obstruction in a heavy worm load. Albendazole is contraindicated during pregnancy and children under two years of age. Thiabendazole may cause migration of the worm into the esophagus, so it is usually combined with piperazine.

Piperazine is a flaccid paralyzing agent that blocks the response of Ascaris muscle to acetylcholine, which immobilizes the worm. It prevents migration when treatment is accomplished with weak drugs such as thiabendazole. If used by itself, it causes the worm to be passed out in the feces and may be used when worms have caused blockage of the intestine or the biliary duct.

Corticosteroids can treat some of the symptoms, such as inflammation.

## Surgical intervention [edit]

In some cases with severe infestation the worms may cause bowel obstruction, requiring emergency surgery.[28] The bowel obstruction may be due to all the worms or twisting of the bowel.[28] During the surgery the worms may be manually removed.[28]

## Alternative medicine [edit]

- Hexylresorcinol effective in single dose[29]
- Santonin, more toxic than hexylresorcinol[29]
- Oil of chenopodium, more toxic than hexylresorcinol[29]

Santonin is often only partly effective.[30]

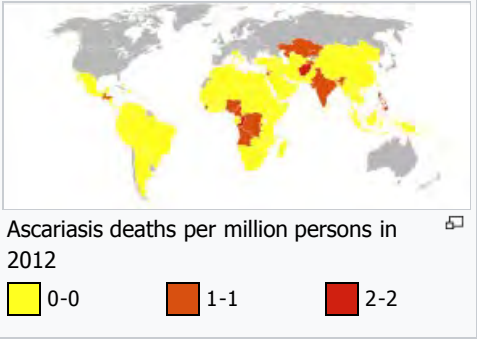
# Prognosis [edit]

It is rare for the infections to be life-threatening.[1]

# Epidemiology [edit]

## Regions [edit]

Ascariasis is common in Africa and in Southeast Asia. It also occurs in the United States including Gulf Coast.[*citation needed*]

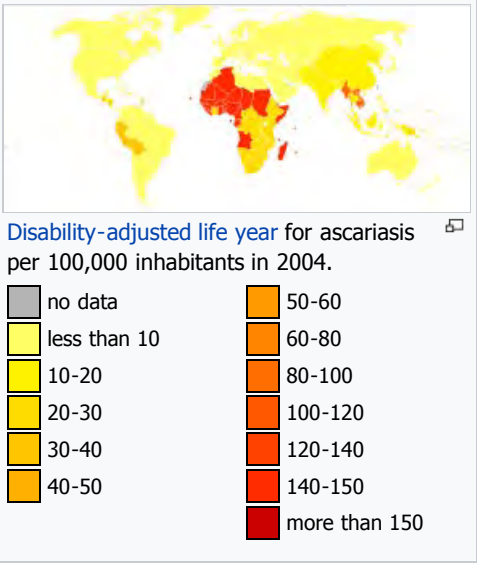


## Infection estimates [edit]

Roughly 0.8-1.3 billion individuals are infected with this intestinal worm, primarily in Africa and Asia.[1][2][9] About 120 to 220 million of these cases are symptomatic.[1] One study indicated that the prevalence of ascariasis in the United States at about 4 million (2%).[*citation needed*]

## Deaths [edit]

As of 2010 Ascariasis caused about 2,700 directly attributable deaths, down from 3,400 in 1990.[10] The indirectly attributable deaths due to the malnutrition link may be much higher.



# Research [edit]

There are two animal models, the mouse and pig, used in studying *Ascaris* infection.[31][32]

# Other animals [edit]

Infections in pigs leads to poor weight gain and thus financial losses for the farmer.[1] In pigs the infection is due to *Ascaris suum*.[1] In horses and other equines, the equine roundworm is *Parascaris equorum* and the parasites are colloquially called Ascarids. A problem for young animals more than for mature ones, clinical signs include unthriftiness, potbelly, rough hair coat, and slow growth.[33]

# Buruli ulcer

From Wikipedia, the free encyclopedia

**Buruli ulcer** (also known as the **Bairnsdale ulcer**, **Searls ulcer**, or **Daintree ulcer**[1][2][3]) is an infectious disease caused by *Mycobacterium ulcerans*.[4] The early stage of the infection is characterised by a painless nodule or area of swelling.[4] This nodule can turn into an ulcer.[4] The ulcer may be larger inside than at the surface of the skin,[5] and can be surrounded by swelling.[5] As the disease worsens, bone can be infected.[4] Buruli ulcers most commonly affect the arms or legs.[4] Fever is uncommon.[4]

*M. ulcerans* releases a toxin known as mycolactone, which decreases immune system function and results in tissue death.[4] Bacteria from the same family also cause tuberculosis and leprosy (*M. tuberculosis* and *M. leprae*, respectively).[4] How the disease is spread is not known.[4] Sources of water may be involved in the spread.[5] As of 2013 there is no effective vaccine.[4][6]

If people are treated early, antibiotics for eight weeks are effective in 80%.[4] The treatment often includes the medications rifampicin and streptomycin.[4] Clarithromycin or moxifloxacin are sometimes used instead of streptomycin.[4] Other treatments may include cutting out the ulcer.[4][7] After the infection heals, the area typically has a scar.[6]

Buruli ulcers occurs most commonly in rural sub-Saharan Africa especially Cote d'Ivoire, but can also occur in Asia, the Western Pacific and the Americas.[4] Cases have occurred in more than 32 countries.[5] About five to six thousand cases occur every year.[4] The disease also occurs in a number of animals other than humans.[4] Albert Ruskin Cook was the first to describe buruli ulcers in 1897.[5]

## Signs and symptoms [edit]

The infection in most instances presents as a painless lump just under the skin. In southern Australia, the presentation is more often as a pimple in the skin (dermis) rather than under it. The infection is mostly in the limbs, most often in exposed areas, but not on the hands or feet. In children, all areas may be involved, including the face or abdomen. A more severe form of infection produces diffuse swelling of a limb, which, unlike the papule or nodule, can be painful and accompanied by fever. Infection may frequently follow physical trauma, often minor trauma such as a small scratch.

## Cause [edit]

The disease is caused by *Mycobacterium ulcerans*.[4] It often occurs in close proximity to water bodies, but no specific activities that bring people into contact with water have been identified (i.e. fetching of water, fishing, washing, bathing, etc.). The mode of transmission of Buruli ulcer is not entirely known. Recent evidence suggests insects may be involved in the transmission of the infection.[8] These insects are aquatic bugs belonging to the genus Naucoris (family Naucoridae) and Diplonychus (family Belostomatidae). Trauma is probably the most frequent means by which *M. ulcerans* is introduced into the skin from surface contamination.[9] The initial trauma can be as slight as a hypodermic needle puncture or as severe as gunshot or exploding land mine wounds.[10] Other studies have suggested aerosol spread but these are not proven.[11] In Australia, animals such as koalas and possums are naturally infected.[12][13] Epidemiological evidence has not clearly supported person-to-person transmission. However, Muelder & Nourou found that 10 out of 28 patients had relatives who had also had the disease, and cautioned against the dismissal of person-to-person transmission.[14] Given the number of patients who shed large numbers of bacilli from their wounds and live in very close contact with relatives, more cases should have been observed. The cases reported by Muelder & Nourou could perhaps have been exposed to a common source of infection, and there might also be genetic component to sensitivity to the disease.

After considering the various suspected agents, Portaels *et al.* proposed the hypothesis that human beings, as well as domestic and wild animals, could be contaminated or infected by biting insects such as water bugs.[15] Aquatic bugs are cosmopolite insects found throughout temperate and tropical regions especially rich in freshwater. They represent about 10% of all species of Hemiptera associated with water and belong to two series of the suborder Heteroptera: the Nepomorpha, which include four superfamilies whose members spend most of their time under water, and the Naucoridae, which include a single family, the Naucoridae, whose members are commonly termed creeping water bugs.

Whether found in temperate countries like France or tropical ones like Ivory Coast, aquatic bugs exhibit the same way of life, preying, according to their size, on mollusks, snails, young fish, and the adults and larvae of other insects that they capture with their raptorial front legs and bite with their rostrum. These insects can inflict painful bites on humans as well. In the Ivory Coast, where Buruli ulcer is endemic, the water bugs are present in swamps and rivers, where human activities such as farming, fishing, and bathing take place. Present findings[16] describing the experimental transmission of *M. ulcerans* from water bugs to mice are in good agreement with the possibility of this mode of transmission to humans by bites.

Also in strong support of this hypothesis was the localization of *M. ulcerans* within the salivary glands of Naucoridae.[16] Local physiological conditions of this niche appear to fit the survival and the replication needs of *M. ulcerans* but not those of other mycobacteria. Surprisingly, infiltration of the salivary glands of Naucoridae by *M. ulcerans* does not seem to be accompanied by any tissue damage similar to the ulcerative skin lesions developed by bitten individuals and mediated by the cytotoxic activity of the mycolactone[17] and other toxins produced by *M. ulcerans*.[18] The inactivation of the latter toxins could be the result of salivary enzymatic activities, which remain to be determined.

Mycobacterium ulcerans was first cultivated and characterized from the environment in 2008.[19]

## Pathology [edit]

The disease is primarily an infection of subcutaneous fat, resulting in a focus of necrotic (dead) fat containing myriads of the mycobacteria in characteristic spherules formed within the dead fat cells. Skin ulceration is a secondary event.

*M. ulcerans* releases a lipid toxin, mycolactone, which functions as an immune suppressant, necrotising agent and activator of cellular death.[20][21]

Healing may occur spontaneously but more often the disease is slowly progressive with further ulceration, granulation, scarring, and contractures. Satellite infection may occur with other nodules developing and infection may occur into bone. Although seldom fatal, the disease results in considerable morbidity and deformity.

Th1-mediated immune responses are protective against *M. ulcerans* infection, whereas Th2-mediated responses are not.

## Diagnosis [edit]

The diagnosis of Buruli ulcer is usually based on the characteristic appearance of the ulcer in an endemic area. If there is any doubt about the diagnosis, then PCR using the IS2404 target is helpful, but this is not specific for *M. ulcerans*. The Ziehl-Neelsen stain is only 40–80% sensitive, and culture is 20–60% sensitive. Simultaneous use of multiple methods may be necessary to make the diagnosis.[22]

## Prevention [edit]

There is no specific vaccine for *Myocobacterium ulcerans*.[6] The Bacillus Calmette-Guérin vaccine may offer temporary protection.[4]

## Treatment [edit]

If treated early antibiotics for eight weeks are effective in 80% of people.[4] This often includes the medications rifampicin and streptomycin.[4] Clarithromycin or moxifloxacin are sometimes used instead of streptomycin.[4]

Treatment may also include cutting out the ulcer.[7] This may be a minor operation and very successful if undertaken early. Advanced disease may require prolonged treatment with extensive skin grafting. Surgical practice can be dangerous in the developing countries where the disease is common.

## Epidemiology [edit]

The infection occurs in well-defined areas throughout the world, mostly tropical areas — in several areas in Australia, in Uganda, in several countries in West Africa, in Central and South America, in southeast Asia and New Guinea. It is steadily rising as a serious disease, especially in West Africa and underdeveloped countries, where it is the third leading cause of mycobacterial infection in healthy people, after tuberculosis and leprosy.

The disease is more likely to occur where there have been environmental changes such as the development of water storages, sand mining, and irrigation.

Buruli ulcer is currently endemic in Benin, Côte d'Ivoire, Ghana, Guinea, Liberia, Nigeria, Sierra Leone and Togo.[23] In Ghana, 1999 data indicated that the prevalence rate of the disease in the Ga West District was 87.7 per 100,000, higher than the estimated national prevalence rate at 20.7 per 100,000 generally, and 150.8 per 100,000 in the most disease-endemic districts.[24]

Map with number of reported cases of Buruli ulcer in 2009.

## Geographical distribution [edit]

Buruli ulcer has been reported from at least 32 countries around the world, mostly in tropical areas:

- West Africa: Benin, Burkina Faso, Côte d'Ivoire, Ghana, Liberia, Nigeria, Togo, Guinea, Sierra Leone.
- Other African Countries: Angola, Cameroon, Congo, Democratic Republic of Congo, Equatorial Guinea, Gabon, Sudan, Uganda.
- Western Pacific: Australia, Papua New Guinea, Kiribati.
- Americas: French Guyana, Mexico, Peru, Surinam.
- Asia: China, Malaysia, Japan.

In several of these countries, the disease is not considered to be a public health problem, hence the current distribution and the number of cases are not known. Possible reasons include:

- the distribution of the disease is often localized in certain parts of endemic countries;
- Buruli ulcer is not a notifiable disease
- In most places where the disease occurs, patients receive care from private sources such as voluntary mission hospitals and traditional healers. Hence the existence of the disease may not come to the attention of the ministries of health.

It most commonly occurs in Africa: Congo and Cameroon in Central Africa, Côte d'Ivoire, Ghana and Benin in West Africa. Some Southeast Asian countries (Papua New Guinea) and Australia have major foci, and there have been a few patients reported from South America (French Guyana and Surinam) and Mexico. Focal outbreaks have followed flooding, human migrations,[25] and man-made topographic modifications such as dams and resorts. Deforestation and increased basic agricultural activities may significantly contribute to the recent marked increases in the incidence of *M. ulcerans* infections, especially in West Africa, where the disease is rapidly emerging.

## Race, age and sex [edit]

Buruli ulcer commonly affects poor people in remote rural areas with limited access to health care. The disease can affect all age groups, although children under the age of 15 years (range 2–14 years) are predominantly affected. There are no sex differences in the distribution of cases among children. Among adults, some studies have reported higher rates among women than males (Debacker *et al.* accepted for publication). No racial or socio-economic group is exempt from the disease. Most ulcers occur on the extremities; lesions on the lower extremities are almost twice as common as those on the upper extremities. Ulcers on the head and trunk accounted for less than 8% of cases in one large series.[26]

# History [edit]

James Augustus Grant, in his book *A Walk across Africa* (1864), describes how his leg became grossly swollen and stiff with later a copious discharge. This was almost certainly the severe edematous form of the disease, and is the first known description of the infection[*citation needed*]. Buruli ulcer disease was identified in 1897 by Sir Albert Cook, a British physician, at Mengo Hospital in Kampala, Uganda. A detailed description of the disease was written in 1948 by Professor Peter MacCallum and his colleagues, who were treating patients from the Bairnsdale district, near Melbourne, Australia. They were the first to identify *Mycobacterium ulcerans* as the pathogen causing it. The disease was so named after Buruli County in Uganda (now called Nakasongola District), because of the many cases that occurred there in the 1960s.[27] The incidence of the disease has recently been rising in tropical Africa.

In March 2008, researchers announced the first isolation of *M. ulcerans* from the environment.[19] This suggested that the disease might be transmitted via contact with the environment rather than person to person.[19] The entire genome of *M. ulcerans* has been sequenced.[*citation needed*]

## Other names [edit]

Other names include Bairnsdale ulcer, Searls ulcer, Daintree ulcer,[1][2][3] Kumusi ulcer,[28] and mycoburuli ulcers.[29] Searls was one of the first physician who first described it.[30]

# Chagas disease

From Wikipedia, the free encyclopedia

**Chagas disease**, also known as **American trypanosomiasis**, is a tropical parasitic disease caused by the protozoan *Trypanosoma cruzi*.[1] It is spread mostly by insects known as Triatominae or kissing bugs.[1] The symptoms change over the course of the infection. In the early stage, symptoms are typically either not present or mild, and may include fever, swollen lymph nodes, headaches, or local swelling at the site of the bite.[1] After 8–12 weeks, individuals enter the chronic phase of disease and in 60–70% it never produces further symptoms.[2][3] The other 30 to 40% of people develop further symptoms 10 to 30 years after the initial infection,[3] including enlargement of the ventricles of the heart in 20 to 30%, leading to heart failure.[1] An enlarged esophagus or an enlarged colon may also occur in 10% of people.[1]

*T. cruzi* is commonly spread to humans and other mammals by the blood-sucking "kissing bugs" of the subfamily Triatominae.[4] These insects are known by a number of local names, including: *vinchuca* in Argentina, Bolivia, Chile and Paraguay, *barbeiro* (the barber) in Brazil, *pito* in Colombia, *chinche* in Central America, and *chipo* in Venezuela.[5] The disease may also be spread through blood transfusion, organ transplantation, eating food contaminated with the parasites, and by vertical transmission (from a mother to her fetus).[1] Diagnosis of early disease is by finding the parasite in the blood using a microscope.[3] Chronic disease is diagnosed by finding antibodies for *T. cruzi* in the blood.[3]

Prevention mostly involves eliminating kissing bugs and avoiding their bites.[1] Other preventative efforts include screening blood used for transfusions.[1] A vaccine has not been developed as of 2013.[1] Early infections are treatable with the medication benznidazole or nifurtimox.[1] Medication nearly always results in a cure if given early, but becomes less effective the longer a person has had Chagas disease.[1] When used in chronic disease, medication may delay or prevent the development of end-stage symptoms.[1] Benznidazole and nifurtimox cause temporary side effects in up to 40% of people[1] including skin disorders, brain toxicity, and digestive system irritation.[2][6][7]

It is estimated that 7 to 8 million people, mostly in Mexico, Central America and South America, have Chagas disease as of 2013.[1] In 2006, Chagas was estimated to result in 12,500 deaths per year.[2] Most people with the disease are poor,[2] and most people with the disease do not realize they are infected.[8]

[edit on Wikidata]

Large-scale population movements have increased the areas where Chagas disease is found and these include many European countries and the United States.[1] These areas have also seen an increase in the years up to 2014.[9] The disease was first described in 1909 by Carlos Chagas after whom it is named.[1] It affects more than 150 other animals.[2]

**Contents**

## Signs and symptoms [edit]

The human disease occurs in two stages: an acute stage, which occurs shortly after an initial infection, and a chronic stage that develops over many years.

The acute phase lasts for the first few weeks or months of infection. It usually occurs unnoticed because it is symptom-free or exhibits only mild symptoms that are not unique to Chagas disease. These can include fever, fatigue, body aches, muscle pain, headache, rash, loss of appetite, diarrhea, nausea, and vomiting. The signs on physical examination can include mild enlargement of the liver or spleen, swollen glands, and local swelling (a chagoma) where the parasite entered the body.[10]

The most recognized marker of acute Chagas disease is called Romaña's sign, which includes swelling of the eyelids on the side of the face near the bite wound or where the bug feces were deposited or accidentally rubbed into the eye. Rarely, young children, or adults may die from the acute disease due to severe inflammation/infection of the heart muscle (myocarditis) or brain (meningoencephalitis).[10] The acute phase also can be severe in people with weakened immune systems.[4]

If symptoms develop during the acute phase, they usually resolve spontaneously within three to eight weeks in approximately 90% of individuals.[2][6] Although the symptoms resolve, even with treatment the infection persists and enters a chronic phase. Of individuals with chronic Chagas disease, 60–80% will never develop symptoms (called *indeterminate* chronic Chagas disease), while the remaining 20–40% will develop life-threatening heart and/or digestive disorders during their lifetime (called *determinate* chronic Chagas disease). In 10% of individuals, the disease progresses directly from the acute form to a symptomatic clinical form of chronic Chagas disease.[2][6]

An acute Chagas disease infection with swelling of the right eye (Romaña's sign).

Large scale anatomy of a heart that has been damaged by chronic Chagas disease – see also: Chagas heart, radiology

The symptomatic (determinate) chronic stage affects the nervous system, digestive system and heart. About two-thirds of people with chronic symptoms have cardiac damage, including dilated cardiomyopathy, which causes heart rhythm abnormalities and may result in sudden death. About one-third of patients go on to develop digestive system damage, resulting in dilation of the digestive tract (megacolon and megaesophagus), accompanied by severe weight loss. Swallowing difficulties (secondary achalasia) may be the first symptom of digestive disturbances and may lead to malnutrition.[11]

20% to 50% of individuals with intestinal involvement also exhibit cardiac involvement.[11] Up to 10% of chronically infected individuals develop neuritis that results in altered tendon reflexes and sensory impairment. Isolated cases exhibit central nervous system involvement, including dementia, confusion, chronic encephalopathy and sensory and motor deficits.[12]

The clinical manifestations of Chagas disease are due to cell death in the target tissues that occurs during the infective cycle, by sequentially inducing an inflammatory response, cellular lesions, and fibrosis. For example, intracellular amastigotes destroy the intramural neurons of the autonomic nervous system in the intestine and heart, leading to megaintestine and heart aneurysms, respectively. If left untreated, Chagas disease can be fatal, in most cases due to heart muscle damage.[11]

## Transmission [edit]

*Rhodnius prolixus* is the principal vector in Colombia, Venezuela, Guatemala, Honduras, and some parts of Nicaragua and El Salvador.

In Chagas-endemic areas, the main mode of transmission is through an insect vector called a triatomine bug.[4] A triatomine becomes infected with *T. cruzi* by feeding on the blood of an infected person or animal. During the day, triatomines hide in crevices in the walls and roofs.[4]

The bugs emerge at night, when the inhabitants are sleeping. Because they tend to feed on people's faces, triatomine bugs are also known as "kissing bugs". After they bite and ingest blood, they defecate on the person. Triatomines pass *T. cruzi* parasites (called trypomastigotes) in feces left near the site of the bite wound.[4]

Scratching the site of the bite causes the trypomastigotes to enter the host through the wound, or through intact mucous membranes, such as the conjunctiva. Once inside the host, the trypomastigotes invade cells, where they differentiate into intracellular amastigotes. The amastigotes multiply by binary fission and differentiate into trypomastigotes, which are then released into the bloodstream. This cycle is repeated in each newly infected cell. Replication resumes only when the parasites enter another cell or are ingested by another vector.[4] (See also: Life cycle and transmission of *T. cruzi*)

Dense vegetation (such as that of tropical rainforests) and urban habitats are not ideal for the establishment of the human transmission cycle. However, in regions where the sylvatic habitat and its fauna are thinned by economic exploitation and human habitation, such as in newly deforested areas, piassava palm culture areas, and some parts of the Amazon region, a human transmission cycle may develop as the insects search for new food sources.[13]

*T. cruzi* can also be transmitted through blood transfusions. With the exception of blood derivatives (such as fractionated antibodies), all blood components are infective. The parasite remains viable at 4 °C for at least 18 days or up to 250 days when kept at room temperature. It is unclear whether *T. cruzi* can be transmitted through frozen-thawed blood components.[14]

Other modes of transmission include organ transplantation, through breast milk,[15] and by accidental laboratory exposure. Chagas disease can also be spread congenitally (from a pregnant woman to her baby) through the placenta, and accounts for approximately 13% of stillborn deaths in parts of Brazil.[16]

Oral transmission is an unusual route of infection, but has been described. In 1991, farm workers in the state of Paraíba, Brazil, were infected by eating contaminated food; transmission has also occurred via contaminated açaí palm fruit juice and garapa.[17][18][19][20][21] A 2007 outbreak in 103 Venezuelan school children was attributed to contaminated guava juice.[22]

Chagas disease is a growing problem in Europe, because the majority of cases with chronic infection are asymptomatic and because of migration from Latin America.[23]

## Diagnosis [edit]

The presence of *T. cruzi* is diagnostic of Chagas disease. It can be detected by microscopic examination of fresh anticoagulated blood, or its buffy coat, for motile parasites; or by preparation of thin and thick blood smears stained with Giemsa, for direct visualization of parasites. Microscopically, *T. cruzi* can be confused with *Trypanosoma rangeli*, which is not known to be pathogenic in humans. Isolation of *T. cruzi* can occur by inoculation into mice, by culture in specialized media (for example, NNN, LIT); and by xenodiagnosis,[24] where uninfected Reduviidae bugs are fed on the patient's blood, and their gut contents examined for parasites.[11]

Various immunoassays for *T. cruzi* are available and can be used to distinguish among strains (zymodemes of *T.cruzi* with divergent pathogenicities). These tests include: detecting complement fixation, indirect hemagglutination, indirect fluorescence assays, radioimmunoassays, and ELISA. Alternatively, diagnosis and strain identification can be made using polymerase chain reaction (PCR).[11]

## Prevention [edit]

There is currently no vaccine against Chagas disease.[25] Prevention is generally focused on decreasing the numbers of the insect that spreads it (*Triatoma*) and decreasing their contact with humans. This is done by using sprays and paints containing insecticides (synthetic pyrethroids), and improving housing and sanitary conditions in rural areas.[26] For urban dwellers, spending vacations and camping out in the wilderness or sleeping at hostels or mud houses in endemic areas can be dangerous; a mosquito net is recommended. Some measures of vector control include:

- A yeast trap can be used for monitoring infestations of certain species of triatomine bugs (*Triatoma sordida*, *Triatoma brasiliensis*, *Triatoma pseudomaculata*, and *Panstrongylus megistus*).[27]
- Promising results were gained with the treatment of vector habitats with the fungus *Beauveria bassiana*.[28]
- Targeting the symbionts of Triatominae through paratransgenesis can be done.[29]

A number of potential vaccines are currently being tested. Vaccination with *Trypanosoma rangeli* has produced positive results in animal models.[30] More recently, the potential of DNA vaccines for

Awareness and prevention

immunotherapy of acute and chronic Chagas disease is being tested by several research groups.[31]

campaign poster in Cayenne, French Guiana, 2008

Blood transfusion was formerly the second-most common mode of transmission for Chagas disease, but the development and implementation of blood bank screening tests has dramatically reduced this risk in the 21st century. Blood donations in all endemic Latin American countries undergo Chagas screening, and testing is expanding in countries, such as France, Spain and the United States, that have significant or growing populations of immigrants from endemic areas.[32][33] In Spain, donors are evaluated with a questionnaire to identify individuals at risk of Chagas exposure for screening tests.[33]

The US FDA has approved two Chagas tests, including one approved in April 2010, and has published guidelines that recommend testing of all donated blood and tissue products.[33][34] While these tests are not required in US, an estimated 75–90% of the blood supply is currently tested for Chagas, including all units collected by the American Red Cross, which accounts for 40% of the U.S. blood supply.[34][35] The Chagas Biovigilance Network reports current incidents of Chagas-positive blood products in the United States, as reported by labs using the screening test approved by the FDA in 2007.[36]

## Management [edit]

There are two approaches to treating Chagas disease: antiparasitic treatment, to kill the parasite; and symptomatic treatment, to manage the symptoms and signs of the infection. Management uniquely involves addressing selective incremental failure of the parasympathetic nervous system. Autonomic disease imparted by Chagas may eventually result in megaesophagus, megacolon and accelerated dilated cardiomyopathy. The mechanisms that explain why Chagas targets the parasympathetic autonomic nervous system and spares the sympathetic autonomic nervous system remain poorly understood.

### Medication [edit]

Antiparasitic treatment is most effective early in the course of infection, but is not limited to cases in the acute phase. Drugs of choice include azole or nitro derivatives, such as benznidazole[37] or nifurtimox. Both agents are limited in their capacity to completely eliminate *T. cruzi* from the body (parasitologic cure), especially in chronically infected patients, and resistance to these drugs has been reported.[38]

Studies suggest antiparasitic treatment leads to parasitological cure in more than 90% of infants but only about 60–85% of adults treated in the first year of acute phase Chagas disease. Children aged six to 12 years with chronic disease have a cure rate of about 60% with benznidazole. While the rate of cure declines the longer an adult has been infected with Chagas, treatment with benznidazole has been shown to slow the onset of heart disease in adults with chronic Chagas infections.[2][11]

Treatment of chronic infection in women prior to or during pregnancy does not appear to reduce the probability the disease will be passed on to the infant. Likewise, it is unclear whether prophylactic treatment of chronic infection is beneficial in persons who will undergo immunosuppression (for example, organ transplant recipients) or in persons who are already immunosuppressed (for example, those with HIV infection).[11]

### Complications [edit]

In the chronic stage, treatment involves managing the clinical manifestations of the disease. For example, pacemakers and medications for irregular heartbeats, such as the anti-arrhythmia drug amiodarone, may be life saving for some patients with chronic cardiac disease,[39] while surgery may be required for megaintestine. The disease cannot be cured in this phase, however. Chronic heart disease caused by Chagas disease is now a common reason for heart transplantation surgery. Until recently, however, Chagas disease was considered a contraindication for the procedure, since the heart damage could recur as the parasite was expected to seize the opportunity provided by the immunosuppression that follows surgery.[40]

# Epidemiology [edit]

Chagas disease affects 8 to 10 million people living in endemic Latin American countries, with an additional 300,000–400,000 living in nonendemic countries, including Spain and the United States. An estimated 41,200 new cases occur annually in endemic countries, and 14,400 infants are born with congenital Chagas disease annually.[2][11] in 2010 it resulted in approximately 10,300 deaths up from 9,300 in 1990.[41]

Chagas disease in Latin America (endemic zones).

The disease is present in 18 countries on the American continents, ranging from the southern United States to northern Argentina.[4] Chagas exists in two different ecological zones. In the Southern Cone region, the main vector lives in and around human homes. In Central America and Mexico, the main vector species lives both inside dwellings and in uninhabited areas. In both zones, Chagas occurs almost exclusively in rural areas, where triatomines breed and feed on the more than 150 species from 24 families of domestic and wild mammals, as well as humans, that are the natural reservoirs of *T. cruzi*.[42]

Although Triatominae bugs feed on them, birds appear to be immune to infection and therefore are not considered to be a *T. cruzi* reservoir. Even when colonies of insects are eradicated from a house and surrounding domestic animal shelters, they can re-emerge from plants or animals that are part of the ancient, sylvatic (referring to wild animals) infection cycle. This is especially likely in zones with mixed open savannah, with clumps of trees interspersed by human habitation.[43]

The primary wildlife reservoirs for *Trypanosoma cruzi* in the United States include opossums, raccoons, armadillos, squirrels, woodrats, and mice.[44] Opossums are particularly important as reservoirs, because the parasite can complete its life cycle in the anal glands of this animal without having to re-enter the insect vector.[44] Recorded prevalence of the disease in opossums in the U.S. ranges from 8.3%[44] to 37.5%.[45]

Studies on raccoons in the Southeast have yielded infection rates ranging from 47%[46] to as low as 15.5%.[44] Armadillo prevalence studies have been described in Louisiana, and range from a low of 1.1%[45] to 28.8%.[47] Additionally, small rodents, including squirrels, mice, and rats, are important in the sylvatic transmission cycle because of their importance as bloodmeal sources for the insect vectors. A Texas study revealed 17.3% percent *T. cruzi* prevalence in 75 specimens representing four separate small rodent species.[48]

Chronic Chagas disease remains a major health problem in many Latin American countries, despite the effectiveness of hygienic and preventive measures, such as eliminating the transmitting insects. However, several landmarks have been achieved in the fight against it in Latin America, including a reduction by 72% of the incidence of human infection in children and young adults in the countries of the Southern Cone Initiative, and at least three countries (Uruguay, in 1997, and Chile, in 1999, and Brazil in 2006) have been certified free of vectorial and transfusional transmission.[11][49][50] In Argentina, vectorial transmission has been interrupted in 13 of the 19 endemic provinces,[49] and major progress toward this goal has also been made in both Paraguay and Bolivia.

Screening of donated blood, blood components, and solid organ donors, as well as donors of cells, tissues,

and cell and tissue products for *T. cruzi* is mandated in all Chagas-endemic countries and has been implemented.[51] Approximately 300,000 infected people live in the United States, which is likely the result of immigration from Latin American countries,[52] and there have been 23 cases acquired from kissing bugs in the United States reported between 1955 and 2014.[53] With increased population movements, the possibility of transmission by blood transfusion became more substantial in the United States. Transfusion blood and tissue products are now actively screened in the U.S., thus addressing and minimizing this risk.[54]

## History [edit]

*Further information: Carlos Chagas § Discovery of Chagas disease*

Carlos Chagas, in his laboratory at the Instituto Oswaldo Cruz.

The disease was named after the Brazilian physician and epidemiologist Carlos Chagas, who first described it in 1909.[55][56][57][58] The disease was not seen as a major public health problem in humans until the 1960s (the outbreak of Chagas disease in Brazil in the 1920s went widely ignored[59]). Dr Chagas discovered that the intestines of Triatomidae (now Reduviidae: Triatominae) harbored a flagellate protozoan, a new species of the *Trypanosoma* genus, and was able to demonstrate experimentally that it could be transmitted to marmoset monkeys that were bitten by the infected bug. Later studies showed squirrel monkeys were also vulnerable to infection.[60]

Chagas named the pathogenic parasite as *Trypanosoma cruzi*[55] and later that year as *Schizotrypanum cruzi*,[57] both honoring Oswaldo Cruz, the noted Brazilian physician and epidemiologist who successfully fought epidemics of yellow fever, smallpox, and bubonic plague in Rio de Janeiro and other cities in the beginning of the 20th century. Chagas was also the first to unknowingly discover and illustrate the parasitic fungal genus *Pneumocystis*, later infamously linked to PCP (*Pneumocystis* pneumonia in AIDS victims).[56] Confusion between the two pathogens' life-cycles led him to briefly recognize his genus *Schizotrypanum*, but following the description of *Pneumocystis* by others as an independent genus, Chagas returned to the use of the name *Trypanosoma cruzi*.

In Argentina, the disease is known as *mal de Chagas-Mazza*, in honor of Salvador Mazza, the Argentine physician who in 1926 began investigating the disease and over the years became the principal researcher of this disease in the country.[61] Mazza produced the first scientific confirmation of the existence of *Trypanosoma cruzi* in Argentina in 1927, eventually leading to support from local and European medical schools and Argentine government policy makers.[62]

It has been hypothesized that Charles Darwin might have suffered from Chagas disease as a result of a bite of the so-called great black bug of the Pampas (*vinchuca*) (see Charles Darwin's illness). The episode was reported by Darwin in his diaries of the Voyage of the Beagle as occurring in March 1835 to the east of the Andes near Mendoza. Darwin was young and generally in good health, though six months previously he had been ill for a month near Valparaiso, but in 1837, almost a year after he returned to England, he began to suffer intermittently from a strange group of symptoms, becoming incapacitated for much of the rest of his life. Attempts to test Darwin's remains at Westminster Abbey by using modern PCR techniques were met with a refusal by the Abbey's curator.[63]

## Research [edit]

Several experimental treatments have shown promise in animal models. These include inhibitors of oxidosqualene cyclase and squalene synthase,[64][65] cysteine protease inhibitors,[64][66] dermaseptins collected from frogs in the genus *Phyllomedusa* (*P. oreades* and *P. distincta*),[67] the sesquiterpene lactone [68]

dehydroleucodine (DhL), which affects the growth of cultured epimastigote-phase *Trypanosoma cruzi*, inhibitors of purine uptake,[64] and inhibitors of enzymes involved in trypanothione metabolism.[69] Hopefully, new drug targets may be revealed following the sequencing of the *T. cruzi* genome.[70]

Chagas disease has a serious economic impact on the United States and the world. The cost of treatment in the United States alone, where the disease is not indigenous, is estimated to be $900 million annually, which includes hospitalization and medical devices such as pacemakers. The global cost is estimated at $7 billion.[71]

Megazol in a study seems more active against Chagas than benznidazole but has not been studied in humans.[72] A Chagas vaccine (TcVac3) has been found to be effective in mice with plans for studies in dogs. It is hoped that it will be commercially available by 2018.[73]

# Common cold

From Wikipedia, the free encyclopedia

*For other uses, see Cold (disambiguation).*

**Common cold**, also known simply as a **cold**, is a viral infectious disease of the upper respiratory tract that primarily affects the nose.[2] The throat, sinuses, and voice box may also be affected.[3] Signs and symptoms may begin less than two days following exposure.[3] They include coughing, sore throat, runny nose, sneezing, headache, and fever.[4][5] People usually recover in seven to ten days.[4] Some symptoms may last up to three weeks.[6] In those with other health problems, pneumonia may occasionally develop.[4]

Well over 200 virus strains are implicated in the cause of the common cold, the rhinoviruses are the most common.[7] They spread through the air during close contact with infected people and indirectly through contact with objects in the environment followed by transfer to the mouth or nose.[4] Risk factors include going to daycare, not sleeping well, and psychological stress.[3] Symptoms are mostly due to the body's immune response to the infection rather than to tissue destruction by the viruses themselves.[8] People with influenza often show similar symptoms as people with a cold, though symptoms are usually more severe in the former.[3]

There is no vaccine for the common cold. The primary methods of prevention are hand washing; not touching the eyes, nose or mouth with unwashed hands; and staying away from other sick people.[4] Some evidence supports the use of face masks.[9] No cure for the common cold exists, but the symptoms can be treated.[4] Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen may help with pain.[10] Antibiotics should not be used.[11] Evidence does not support a benefit from cough medicines.[3]

The common cold is the most frequent infectious disease in humans.[12] The average adult gets two to four colds a year, while the average child may get six to eight.[13] They occur more commonly during the winter.[4] These infections have been with humanity since ancient times.[14]

# Signs and symptoms

The typical symptoms of a cold include a cough, a runny nose, nasal congestion and a sore throat, sometimes accompanied by muscle ache, fatigue, headache, and loss of appetite.[15] A sore throat is present in about 40% of the cases and a cough in about 50%,[2] while muscle ache occurs in about half.[5] In adults, a fever is generally not present but it is common in infants and young children.[5] The cough is usually mild compared to that accompanying influenza.[5] While a cough and a fever indicate a higher likelihood of influenza in adults, a great deal of similarity exists between these two conditions.[16] A number of the viruses that cause the common cold may also result in asymptomatic infections.[17][18]

The color of the sputum or nasal secretion may vary from clear to yellow to green and does not indicate the class of agent causing the infection.[19]

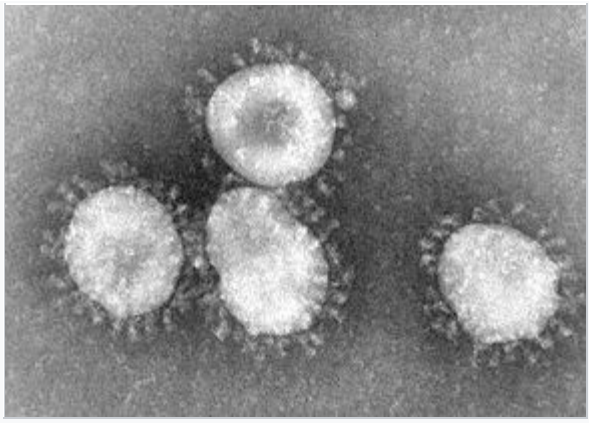
## Progression

A cold usually begins with fatigue, a feeling of being chilled, sneezing, and a headache, followed in a couple of days by a runny nose and cough.[15] Symptoms may begin within sixteen hours of exposure[20] and typically peak two to four days after onset.[5][21] They usually resolve in seven to ten days, but some can last for up to three weeks.[6] The average duration of cough is eighteen days[22] and in some cases people develop a post-viral cough which can linger after the infection is gone.[23] In children, the cough lasts for more than ten days in 35%–40% of the cases and continues for more than 25 days in 10%.[24]

# Cause

## Viruses

The common cold is a viral infection of the upper respiratory tract. The most commonly implicated virus is a rhinovirus (30%–80%), a type of picornavirus with 99 known



Coronaviruses are a group of viruses known for causing the common cold. They have a halo or crown-like (corona) appearance when viewed under an electron microscope.

serotypes.[25][26] Other commonly implicated viruses include human coronavirus (≈15%),[27][28] influenza viruses (10%–15%),[29] adenoviruses (5%),[29] human respiratory syncytial virus, enteroviruses other than rhinoviruses, human parainfluenza viruses, and metapneumovirus.[30] Frequently more than one virus is present.[31] In total over 200 different viral types are associated with colds.[5]

## Transmission

The common cold virus is typically transmitted via airborne droplets (aerosols), direct contact with infected nasal secretions, or fomites (contaminated objects).[2][32] Which of these routes is of primary importance has not been determined; however, hand-to-hand and hand-to-surface-to-hand contact seems of more importance than transmission via aerosols.[33] The viruses may survive for prolonged periods in the environment (over 18 hours for rhinoviruses) and can be picked up by people's hands and subsequently carried to their eyes or nose where infection occurs.[32] Transmission is common in daycare and at school due to the proximity of many children with little immunity and frequently poor hygiene.[34] These infections are then brought home to other members of the family.[34] There is no evidence that recirculated air during commercial flight is a method of transmission.[32] People sitting in close proximity appear to be at greater risk of infection.[33]

Rhinovirus-caused colds are most infectious during the first three days of symptoms; they are much less infectious afterwards.[35]

## Weather

The traditional theory is that a cold can be "caught" by prolonged exposure to cold weather such as rain or winter conditions, which is how the disease got its name.[36] Some of the viruses that cause the common colds are seasonal, occurring more frequently during cold or wet weather.[37] The reason for the seasonality has not been conclusively determined.[38] Possible explanations may include cold temperature-induced changes in the respiratory system,[39] decreased immune response,[40] and low humidity causing an increase in viral transmission rates, perhaps due to dry air allowing small viral droplets to disperse farther and stay in the air longer.[41]

The apparent seasonality may also be due to social factors, such as people spending more time indoors, near infected people,[39] and specifically children at school.[34][38] There is some controversy over the role of low body temperature as a risk factor for the common cold; the majority of the evidence suggests that it may result in greater susceptibility to infection.[40]

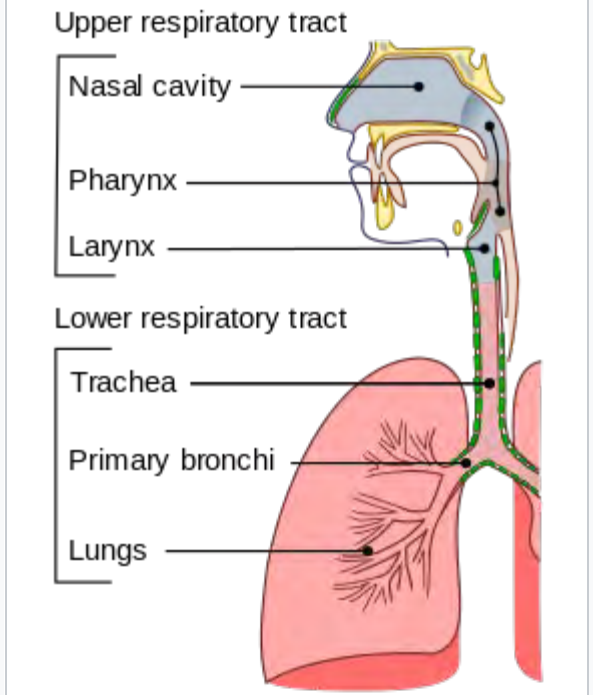
## Other

Herd immunity, generated from previous exposure to cold viruses, plays an important role in limiting viral spread, as seen with younger populations that have greater rates of respiratory infections.[42] Poor immune function is a risk factor for disease.[42][43] Insufficient sleep and malnutrition have been associated with a greater risk of developing infection following rhinovirus exposure; this is believed to be due to their effects on immune function.[44][45] Breast feeding decreases the risk of acute otitis media and lower respiratory tract infections among other diseases,[46] and it is recommended that breast feeding be continued when an infant has a cold.[47] In the developed world breast feeding may not be protective against the common cold

in and of itself.[48]

## Pathophysiology

The symptoms of the common cold are believed to be primarily related to the immune response to the virus.[8] The mechanism of this immune response is virus specific. For example, the rhinovirus is typically acquired by direct contact; it binds to human ICAM-1 receptors through unknown mechanisms to trigger the release of inflammatory mediators.[8] These inflammatory mediators then produce the symptoms.[8] It does not generally cause damage to the nasal epithelium.[5] The respiratory syncytial virus (RSV), on the other hand, is contracted by direct contact and airborne droplets. It then replicates in the nose and throat before frequently spreading to the lower respiratory tract.[49] RSV does cause epithelium damage.[49] Human parainfluenza virus typically results in inflammation of the nose, throat, and bronchi.[50] In young children when it affects the trachea it may produce the symptoms of croup due to the small size of their airways.[50]



The common cold is a disease of the upper respiratory tract.

## Diagnosis

The distinction between viral upper respiratory tract infections is loosely based on the location of symptoms with the common cold affecting primarily the nose, pharyngitis the throat, and bronchitis the lungs.[2] However, there can be significant overlap and multiple areas can be affected.[2] The common cold is frequently defined as nasal inflammation with varying amount of throat inflammation.[51] Self-diagnosis is frequent.[5] Isolation of the viral agent involved is rarely performed,[51] and it is generally not possible to identify the virus type through symptoms.[5]

## Prevention

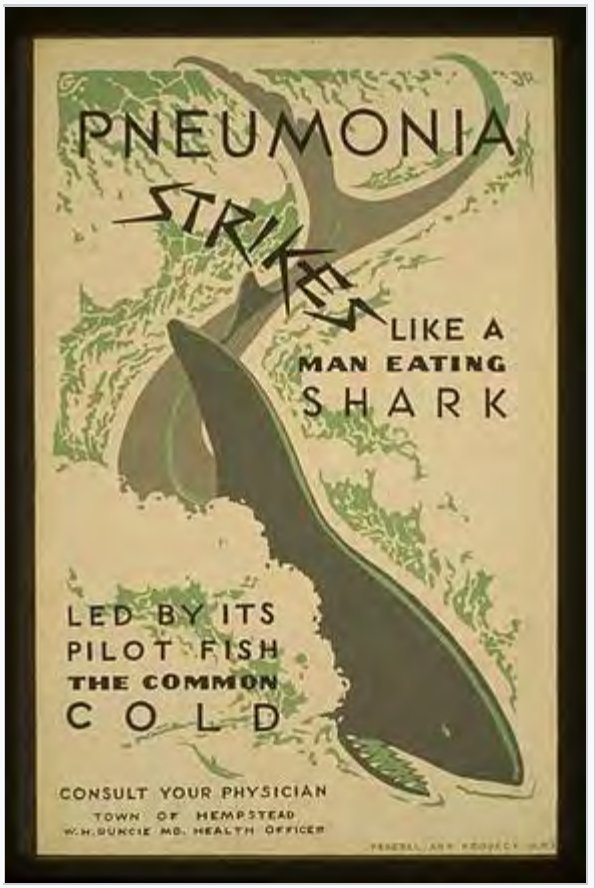
The only useful ways to reduce the spread of cold viruses are physical measures[9] such as hand washing and face masks; in the healthcare environment, gowns and disposable gloves are also used.[9] Isolation or quarantine is not used as the disease is so widespread and symptoms are non-specific. Vaccination has proved difficult as there are many viruses involved and they mutate rapidly.[9] Creation of a broadly effective vaccine is, thus, highly improbable.[52]

Regular hand washing appears to be effective in reducing the transmission of cold viruses, especially among children.[53] Whether the addition of antivirals or antibacterials to normal hand washing provides greater benefit is unknown.[53] Wearing face masks when around people who are infected may be beneficial; however, there is insufficient evidence for maintaining a greater social distance.[53]

Zinc supplements may help to reduce the prevalence of colds.[54] Routine vitamin C supplements do not reduce the risk or severity of the common cold, though they may reduce its duration.[55] Gargling with water was found useful in one small trial.[56]

# Management

No medications or herbal remedies have been conclusively demonstrated to shorten the duration of infection.[57] Treatment thus comprises symptomatic relief.[13] Getting plenty of rest, drinking fluids to maintain hydration, and gargling with warm salt water are reasonable conservative measures.[30] Much of the benefit from treatment is, however, attributed to the placebo effect.[58]



Poster from 1937 encouraging citizens to "consult your physician" for treatment of the common cold

## Symptomatic

Treatments that help with symptoms include simple pain medication and medications for fevers such as ibuprofen[59][*needs update*] and acetaminophen/paracetamol.[60] There is not good evidence for cough medicines.[61][*needs update*][62] Cough medicine are not recommended for use in children due to a lack of evidence supporting effectiveness and the potential for harm.[63][64] In 2009, Canada restricted the use of over-the-counter cough and cold medication in children six years and under due to concerns regarding risks and unproven benefits.[63] The misuse of dextromethorphan (an over-the-counter cough medicine) has led to its ban in a number of countries.[65]

In adults short term use of nasal decongestants may have a small benefit.[66] Antihistamines may improve symptoms in the first day or two; however, there is no longer-term benefit and they have adverse effects such as drowsiness.[67] Other decongestants such as pseudoephedrine appear effective in adults.[68][69] Ipratropium nasal spray may reduce the symptoms of a runny nose but has little effect on stuffiness.[70][*needs update*] The safety and effectiveness of nasal decongestant use in children is unclear.[69]

Due to lack of studies, it is not known whether increased fluid intake improves symptoms or shortens respiratory illness,[71] and there is a similar lack of data for the use of heated humidified air.[72] One study has found chest vapor rub to provide some relief of nocturnal cough, congestion, and sleep difficulty.[73]

## Antibiotics and antivirals

Antibiotics have no effect against viral infections or against the viruses that cause the common cold.[74] Due to their side effects, antibiotics cause overall harm but are still frequently prescribed.[74][75] Some of the reasons that antibiotics are so commonly prescribed include people's expectations for them, physicians' desire to help, and the difficulty in excluding complications that may be amenable to antibiotics.[76] There are no effective antiviral drugs for the common cold even though some preliminary research has shown benefits.[13][77]

## Alternative medicine

While there are many alternative treatments used for the common cold, there is insufficient scientific evidence to support the use of most.[13] As of 2014 there is insufficient evidence to recommend for or against honey.[78] As of 2015 there is tentative evidence to support nasal irrigation.[79] Zinc has been used

to treat symptoms, with studies suggesting that zinc, if taken within 24 hours of the onset of symptoms, reduces the duration and severity of the common cold in otherwise healthy people.[54] Due to wide differences between the studies, further research may be needed to determine how and when zinc may be effective.[80] Whereas zinc lozenges may produce side effects, there is only a weak rationale for physicians to recommend zinc for the treatment of the common cold.[81] Some zinc remedies directly applied to the inside of the nose have led to the loss of the sense of smell.[82]

Vitamin C's effect on the common cold, while extensively researched, is disappointing, except in limited circumstances: specifically, individuals exercising vigorously in cold environments.[55][83] There is no firm evidence that Echinacea products provide any meaningful benefit in treating or preventing colds.[84] It is unknown if garlic is effective.[85] A single trial of vitamin D did not find benefit.[86]

## Prognosis

The common cold is generally mild and self-limiting with most symptoms generally improving in a week.[2] Half of cases go away in 10 days and 90% in 15 days.[87] Severe complications, if they occur, are usually in the very old, the very young, or those who are immunosuppressed.[12] Secondary bacterial infections may occur resulting in sinusitis, pharyngitis, or an ear infection.[88] It is estimated that sinusitis occurs in 8% and ear infection in 30% of cases.[89]

## Epidemiology

The common cold is the most common human disease[12] and affects people all over the globe.[34] Adults typically have two to five infections annually,[2][5] and children may have six to ten colds a year (and up to twelve colds a year for school children).[13] Rates of symptomatic infections increase in the elderly due to declining immunity.[42]

Native Americans and Inuit are more likely to be infected with colds and develop complications such as otitis media than Caucasians.[29] This may be explained by issues such as poverty and overcrowding rather than by ethnicity.[29]

## History

While the cause of the common cold has only been identified since the 1950s, the disease has been with humanity since ancient times.[14] Its symptoms and treatment are described in the Egyptian Ebers papyrus, the oldest existing medical text, written before the 16th century BCE.[91] The name "cold" came into use in the 16th century, due to the similarity between its symptoms and those of exposure to cold weather.[92]

In the United Kingdom, the Common Cold Unit was set up by the Medical Research Council in 1946 and it was where the rhinovirus was discovered in 1956.[93] In the 1970s, the CCU demonstrated that treatment with interferon during the incubation phase of rhinovirus infection protects somewhat against the disease,[94] but no practical treatment could be developed. The unit was closed in 1989, two years after it completed research of zinc gluconate lozenges in the prophylaxis and treatment of rhinovirus colds, the only [95]

A British poster from World War II describing the cost of the common cold[90]

successful treatment in the history of the unit.

## Society and culture

The economic impact of the common cold is not well understood in much of the world.[89] In the United States, the common cold leads to 75–100 million physician visits annually at a conservative cost estimate of $7.7 billion per year. Americans spend $2.9 billion on over-the-counter drugs and another $400 million on prescription medicines for symptom relief.[96] More than one-third of people who saw a doctor received an antibiotic prescription, which has implications for antibiotic resistance.[96] An estimated 22–189 million school days are missed annually due to a cold. As a result, parents missed 126 million workdays to stay home to care for their children. When added to the 150 million workdays missed by employees suffering from a cold, the total economic impact of cold-related work loss exceeds $20 billion per year.[30][96] This accounts for 40% of time lost from work in the United States.[97]

## Research directions

Antivirals have been tested for effectiveness in the common cold; as of 2009, none had been both found effective and licensed for use.[77] There are ongoing trials of the anti-viral drug pleconaril which shows promise against picornaviruses as well as trials of BTA-798.[98] The oral form of pleconaril had safety issues and an aerosol form is being studied.[98] DRACO, a broad-spectrum antiviral therapy, has shown preliminary effectiveness in treating rhinovirus, as well as other infectious viruses.[99]

The genomes for all known human rhinovirus strains have been sequenced.[100]

# Cysticercosis

From Wikipedia, the free encyclopedia

*This article is about the infection. For the organism, see Taenia solium.*

**Cysticercosis** is a tissue infection caused by the young form of the pork tapeworm.[1][2] People may have few or no symptoms for years.[3][4] In some cases, particularly in Asia, solid lumps of between one and two centimetres may develop under the skin.[2] After months or years these lumps can become painful and swollen and then resolve.[3][4] A specific form called neurocysticercosis, which affects the brain, can cause neurological symptoms. In developing countries this is one of the most common causes of seizures.[4]

Cysticercosis is usually acquired by eating food or drinking water that has tapeworm eggs in it. Among foods, uncooked vegetables are the major source.[2] The tapeworm eggs are present in the feces of a person infected with the adult worms, a condition known as taeniasis.[4][5] Taeniasis, in the strict sense, is a different disease and is due to eating cysts in poorly cooked pork.[2] People who live with someone with the tapeworm have a greater risk of getting cysticercosis.[5] The diagnosis can be made by aspiration of a cyst.[4] Taking pictures of the brain with computer tomography (CT) or magnetic resonance imaging (MRI) are most useful for the diagnosis of disease in the brain. An increased number of a type of white blood cell, called eosinophils, in the cerebral spinal fluid and blood is also an indicator.[4]

Infection can be effectively prevented by personal hygiene and sanitation: this includes cooking pork well, proper toilets and sanitary practices, and improved access to clean water. Treating those with taeniasis is important to prevent spread.[2] Treating the disease when it does not involve the nervous system may not be required.[4] Treatment of those with neurocysticercosis may be with the medications praziquantel or albendazole. These may be required for long periods of time.[2] Steroids, for anti-inflammation during treatment, and anti-seizure medications may also be required. Surgery is sometimes done to remove the cysts.[2]

The pork tapeworm is particularly common in Asia, Sub-Saharan Africa, and Latin America.[4] In some areas it is believed that up to 25% of people are affected.[4] In the developed world it is very uncommon.[6] Worldwide as of 2010 it caused about 1,200 deaths, up from 700 in 1990.[7] Cysticercosis also affects pigs and cows but rarely causes symptoms as most do not live long enough.[2] The disease has occurred in humans throughout history.[6] It is one of the neglected tropical diseases.[8]

## Signs and symptoms [edit]

### Muscles [edit]

Cysticerci can develop in any voluntary muscles in humans. Invasion of muscle by cysticerci can cause myositis, with fever, eosinophilia, and muscular pseudohypertrophy, which initiates with muscle swelling and later progress to atrophy and fibrosis. In most cases, it is asymptomatic since the cysticerci die and become calcified.[9]

### Nervous system [edit]

The term neurocysticercosis is generally accepted to refer to cysts in the parenchyma of the brain. It presents with seizures and, less commonly, headaches.[10] Cysticerca in brain parenchyma are usually 5–20 mm in diameter. In subarachnoid space and fissures, lesions may be as large as 6 cm in diameter and lobulated. They may be numerous and life-threatening.[11]

Cysts located within the ventricles of the brain can block the outflow of cerebrospinal fluid and present with symptoms of increased intracranial pressure.[12]

Racemose neurocysticercosis refers to cysts in the subarachnoid space. These can occasionally grow into large lobulated masses causing pressure on surrounding structures.[13]

Neurocysticercosis involving the spinal cord, most commonly presenting as back pain and radiculopathy.[14]

### Eyes [edit]

In some cases, cysticerci may be found in the globe, extraocular muscles, and under the conjunctiva (*subconjunctiva*). Depending on the location, they may cause visual difficulties that fluctuate with eye position, retinal edema, hemorrhage, a decreased vision or even a visual loss.[9]

### Skin [edit]

Subcutaneous cysts are in the form of firm, mobile nodules, occurring mainly on the trunk and extremities.[15] Subcutaneous nodules are sometimes painful.

## Cause [edit]

The cause of human cysticercosis is the egg form of *Taenia solium* (often abbreviated as *T. solium* and also called pork tapeworm), which is transmitted through the oral-fecal route. Eggs are accidentally ingested from contaminated water or vegetables. The eggs enter the intestine where they develop into larvae. The larvae enter bloodstream and invade host tissues, where they further develop into larvae called cysticerci. The cysticercus larva completes development in about 2 months. It is semitransparent, opalescent white, and elongate oval in shape and may reach a length of 0.6 to 1.8 cm.[9]

## Diagnosis [edit]

The traditional method of demonstrating either tapeworm eggs or proglottids in stool samples diagnoses only taeniasis, carriage of the tapeworm stage of the life cycle.[5] Only a small minority of patients with cysticercosis will harbor a tapeworm, rendering stool studies ineffective for diagnosis.[16] Ophthalmic cysticercosis can be diagnosed by visualizing parasite in eye by fundoscopy.

Life cycle of *Taenia solium*

In cases of human cysticercosis, diagnosis is a sensitive problem and requires biopsy of the infected tissue or sophisticated instruments.[17] *Taenia solium* eggs and proglottids found in feces, ELISA, or polyacrylamide gel electrophoresis diagnose only taeniasis and not cysticercosis. Radiological tests, such as X-ray, CT scans which demonstrate "ring-enhancing brain lesions", and MRIs, can also be used to detect diseases. X-rays are used to identify calcified larvae in the subcutaneous and muscle tissues, and CT scans and MRIs are used to find lesions in the brain.[18][19]

### Serological [edit]

Antibodies to cysticerci can be demonstrated in serum by EITB (Enzyme Linked Immunotransfer Blot) assay and in CSF by ELISA. An immunoblot assay using lentil-lectin (agglutinin from Lens culinaris) is highly sensitive and specific. However, Individuals with intracranial lesions and calcifications may be seronegative. In the CDC's immunoblot assay, cysticercosis-specific antibodies can react with structural glycoprotein antigens from the larval cysts of *Taenia solium*.[5] However, this is mainly a research tool not widely available in clinical practice and nearly unobtainable in resource limited settings.

### Neurocysticercosis [edit]

The diagnosis of neurocysticercosis is mainly clinical, based on a compatible presentation of symptoms and findings of imaging studies.

### Imaging [edit]

Neuroimaging with CT or MRI is the most useful method of diagnosis. CT scan shows both calcified and uncalcified cysts, as well as distinguishing active and inactive cysts. Cystic lesions can show ring enhancement and focal enhancing lesions. Some cystic lesions, especially the ones in ventricles and subarachnoid space may not be visible on CT scan, since the cyst fluid is isodense with cerebrospinal fluid (CSF). Thus diagnosis of extraparenchymal cysts usually relies on signs like hydrocephalus or enhanced basilar meninges. In such cases CT scan with intraventricular contrast or MRI can be used. MRI is more sensitive in detection of intraventricular cysts.[20][21]

### CSF [edit]

CSF findings include pleocytosis, elevated protein levels and depressed glucose levels; but these may not be always present.

## Prevention [edit]

Cysticercosis is considered as "tools-ready disease" according to WHO.[22] International Task Force for Disease Eradication in 1992 reported that cysticercosis is potentially eradicable.[23] It is feasible because there are no animal reservoirs besides humans and pigs. The only source of *Taenia solium* infection for pigs is from humans, a definite host. Theoretically, breaking the life cycle seems easy by doing intervention strategies from various stages in the life cycle.[24]

For example,

1. Massive chemotherapy of infected individuals, improving sanitation, and educating people are all major ways to discontinue the cycle, in which eggs from human feces are transmitted to other humans and/or pigs.
2. Cooking of pork or freezing it and inspecting meat are effective means to cease the life cycle
3. The management of pigs by treating them or vaccinating them is another possibility to intervene
4. The separation of pigs from human faeces by confining them in enclosed piggeries. In Western European countries post World War 2 the pig industry developed rapidly and most pigs were housed.[*citation needed*] This was the main reason for pig cysticercosis largely being eliminated from the region. This of course is not a quick answer to the problem in developing countries.

## Pigs [edit]

The intervention strategies to eradicate cysticercosis includes surveillance of pigs in foci of transmission and massive chemotherapy treatment of humans.[23] In reality, control of *T. solium* by a single intervention, for instance, by treating only human population will not work because the existing infected pigs can still carry on the cycle. The proposed strategy for eradication is to do multilateral intervention by treating both human and porcine populations.[25] It is feasible because treatment pigs with oxfendazole have been shown to be effective and once treated, they are protected from further infections for at least 3 months.[26]

## Limitations [edit]

Even with the concurrent treatment of humans and pigs, complete elimination is hard to achieve. In one study conducted in 12 villages in Peru, both humans and porcine were treated with praziquantel and oxfendazole, with the coverage of more than 75% in humans and 90% in pigs[27] The result shows a decreased in prevalence and incidence in the intervention area; however the effect did not completely eliminate *T. solium*. The possible reason includes the incomplete coverage and re-infection.[28] Even though *T. solium* could be eliminated through mass treatment of human and porcine population, it is not sustainable.[25] Moreover, both tapeworm carriers of humans and pigs tend to spread the disease from endemic to non-endemic areas resulting in periodic outbreaks of cysticercosis or outbreaks in new areas.[29][30]

## Vaccines [edit]

Given the fact that pigs are part of a life cycle, vaccination of pigs is another feasible intervention to eliminate cysticercosis. Research studies have been focusing on vaccine against cestode parasites, since many immune cell types are found to be capable of destroying cysticercus.[31] Many vaccine candidates are extracted from antigens of different cestodes such as *Taenia solium*, *T. crassiceps*, *T. saginata*, *T. ovis* and target oncospheres and/or cysticerci. In 1983, Molinari et al. reported the first vaccine candidate against porcine cysticercosis using antigen from cysticercus cellulosae drawn out from naturally infected.[32] Recently, vaccines extracted from genetically engineered 45W-4B antigens have been successfully tested to pigs in an experimental condition.[33] This type of vaccine can protect against cysticercosis in both Chinese and Mexican type of *T. solium*. However, it has not been tested in endemic field conditions, which is important because the realistic condition in the field differ greatly from experimental condition, and this can result in a great difference in the chances of infection and immune reaction.[31]

Even though vaccines have been successfully generated, the feasibility of its production and usage in rural free ranging pigs still remains a challenge. If a vaccine is to be injected, the burden of work and the cost of vaccine administration to pigs will remain high and unrealistic.[31] The incentives of using vaccines by pig owners will decrease if the vaccine administration to pigs takes time by injecting every single pig in their livestock. A hypothetical oral vaccine is proposed to be more effective in this case as it can be easily delivered to the pigs by food.[31]

## S3PVAC vaccine [edit]

The vaccine constituted by 3 peptide synthetically produced (S3Pvac) has proven its efficacy in natural conditions of transmission.[34] The S3PVAC vaccine so far, can be considered as the best vaccine candidate to be used in endemic areas such as Mexico (20). S3Pvac consists of three protective peptides: KETc12, KETc1 and GK1, whose sequences belong to native antigens that are present in the different developmental stages of *T. solium* and other cestode parasites.[31][35]

Non-infected pigs from rural villages in Mexico were vaccinated with S3Pvac and the vaccine reduced 98% the number of cysticerci and 50% the number of prevalence.[34][36] The diagnostic method involves necropsy and tongue inspection of pigs. The natural challenge conditions used in the study proved the efficacy of the S3Pvac vaccine in transmission control of *T. solium* in Mexico.[31] The S3Pvac vaccine is owned by the National Autonomous University of Mexico and the method of high scale production of the vaccine has already been developed.[31] The validation of the vaccine in agreement with the Secretary of Animal Health in Mexico is currently in the process of completion.[37] It is also hoped that the vaccine will be well-accepted by pig owners because they also lose their income if pigs are infected cysticercosis.[37] Vaccination of pigs against cysticercosis, if succeeded, can potentially have a great impact on transmission control since there is no chance of re-infection once pigs receive vaccination.

## Other [edit]

Cysticercosis can also be prevented by routine inspection of meat and condemnation of measly meat by the local government.[38] However, in areas where food is scarce, cyst-infected meat might be considered as wasted since pork can provide high quality protein.[39] At times, infected pigs are consumed within the locality or sold at low prices to traffickers who take the uninspected pigs at urban areas for sale.[40]

Due to these limitations, cysticercosis has not been eliminated in any endemic areas.

# Management [edit]

## Neurocysticercosis [edit]

Asymptomatic cysts, such as those discovered incidentally on neuroimaging done for another reason, may never lead to symptomatic disease and in many cases do not require therapy. Calcified cysts have already died and involuted. Further antiparasitic therapy will be of no benefit.

Neurocysticercosis may present as hydrocephalus and acute onset seizures, thus the immediate therapy is emergent reduction of intracranial pressure and anticonvulsant medications. Once the seizures have been brought under control, antihelminthic treatments may be undertaken. The decision to treat with antiparasitic therapy is complex and based on the stage and number of cysts present, their location, and the persons specific symptoms.[41]

Adult *Taenia solium* are easily treated with niclosamide, and is most commonly used in taeniasis. However cysticercosis is a complex disease and requires careful medication. Praziquantel (PZQ) is the drug of choice. In neurocysticercosis praziquantel is widely used.[42] Albendazole appears to be more effective and a safe drug for neurocysticercosis.[43][44] In complicated situation a combination of praziquantel, albendazole and steroid (such as corticosteroids to reduces the inflammation) is recommended.[45] In the brain the cysts can be usually found on the surface. Most cases of brain cysts are found by accident, during diagnosis for other ailments. Surgical removals are the only option of complete removal even if treated successfully with medications.[18]

Antiparasitic treatment should be given in combination with corticosteroids and anticonvulsants to reduce inflammation surrounding the cysts and lower the risk of seizures. When corticosteroids are given in combination with praziquantel, cimetidine is also given, as corticosteroids decrease action of praziquantel by enhancing its first pass metabolism. Albendazole is generally preferable over praziquantel due to its lower cost and fewer drug interactions.[43]

Surgical intervention is much more likely to be needed in cases of intraventricular, racemose, or spinal neurocysticercosis. Treatments includes direct excision of ventricular cysts, shunting procedures, and removal of cysts via endoscopy.

## Eyes [edit]

In eye disease, surgical removal is necessary for cysts within the eye itself as treating intraocular lesions with anthelmintics will elicit an inflammatory reaction causing irreversible damage to structural components. Cysts outside the globe can be treated with anthelmintics and steroids. Treatment recommendations for subcutaneous cysticercosis includes surgery, praziquantel and albendazole.[15]

## Skin [edit]

In general, subcutaneous disease does not need specific therapy. Painful or bothersome cysts can be surgically removed.

# Epidemiology [edit]

## Regions [edit]

*Taenia solium* is found worldwide, but is more common where pork is part of the diet. Cysticercosis is most prevalent where humans live in close contact with pigs. Therefore, high prevalences are reported in Mexico, Latin America, West Africa, Russia, India, Pakistan, North-East China, and Southeast Asia.[46] In Europe it is most widespread among Slavic people.[18][47]

The frequency has decreased in developed countries owing to stricter meat inspection, better hygiene and better sanitation of facilities.

## Infection estimates [edit]

In Latin America, an estimated 75 million persons live in endemic areas and 400,000 people have symptomatic disease.[48] Some studies suggest that the prevalence of cysticercosis in Mexico is between 3.1 and 3.9 percent. Other studies have found the seroprevalence in areas of Guatemala, Bolivia, and Peru as high as 20 percent in humans, and 37 percent in pigs.[49] In Ethiopia, Kenya and the Democratic Republic of Congo around 10% of the population is infected, in Madagascar 16%. The distribution of cysticercosis coincides with the distribution of *T. solium*.[50] Cysticercosis is the most common cause of symptomatic epilepsy worldwide.[51]

Prevalence rates in the United States have shown immigrants from Mexico, Central and South America, and Southeast Asia account for most of the domestic cases of cysticercosis.[52]

In 1990 and 1991, four unrelated members of an Orthodox Jewish community in New York City developed recurrent seizures and brain lesions, which were found to have been caused by *T. solium*. All of the families had housekeepers from Latin American countries and were suspected to be source of the infections.[53][54]

## Deaths [edit]

Worldwide as of 2010 it caused about 1,200 deaths, up from 700 in 1990.[7]

In US during 1990–2002, 221 cysticercosis deaths were identified. Mortality rates were highest for Latinos and men. The mean age at death was 40.5 years (range 2–88). Most patients, 84.6%, were foreign born, and 62% had emigrated from Mexico. The 33 US-born persons who died of cysticercosis represented 15% of all cysticercosis-related deaths. The cysticercosis mortality rate was highest in California, which accounted for 60% of all cysticercosis deaths.[55]

## History [edit]

Scolex (head) of *Taenia solium*

The earliest reference to tapeworms were found in the works of ancient Egyptians that date back to almost 2000 BC.[56] The description of measled pork in the *History of Animals* written by Aristotle (384–322 BC) showed that the infection of pork with tapeworm was known to ancient Greeks at that time.[56] It was also known to Jewish[57] and later to early Muslim physicians and has been proposed as one of the reasons for pork being forbidden by Jewish and Islamic dietary laws.[58] Recent examination of evolutionary histories of hosts and parasites and DNA evidence show that over 10,000 years ago, ancestors of modern humans in Africa became exposed to tapeworm when they scavenged for food or preyed on antelopes and bovids, and later passed the infection on to domestic animals such as pigs.[59]

Cysticercosis was described by Johannes Udalric Rumler in 1555; however, the connection between tapeworms and cysticercosis had not been recognized at that time.[60] Around 1850, Friedrich Küchenmeister fed pork containing cysticerci of *T. solium* to humans awaiting execution in a prison, and after they had been executed, he recovered the developing and adult tapeworms in their intestines.[56][60] By the middle of the 19th century, it was established that cysticercosis was caused by the ingestion of the eggs of *T. solium*.[61]

## Society and culture [edit]

- The first patient on the television show *House* (in the pilot episode) had cysticercosis.
- In the crossover of the series *Grey's Anatomy* (season 5, episode 15) and *Private Practice* (season 2), Archer Montgomery, brother of *Addison Forbes Montgomery*, suffered from neurocysticercosis. He was cured via the surgical removal of the cysts by his former brother-in-law Derek Shepherd.

# Dracunculiasis

From Wikipedia, the free encyclopedia
(Redirected from Dracunculiasis)

**Dracunculiasis**, also called **Guinea-worm disease** (**GWD**), is an infection by the Guinea worm. A person becomes infected when they drink water that contains water fleas infected with guinea worm larvae.[1] Initially there are no symptoms.[2] About one year later, the person develops a painful burning feeling as the female worm forms a blister in the skin, usually on the lower limb.[1] The worm then comes out of the skin over the course of a few weeks.[3] During this time, it may be difficult to walk or work.[2] It is very uncommon for the disease to cause death.[1]

In humans, the only known cause is *Dracunculus medinensis*.[2] The worm is about one to two millimeters wide, and an adult female is 60 to 100 centimeters long (males are much shorter at 12–29 mm or 0.47–1.14 in).[1][2] Outside of humans, the young form can survive up to three weeks,[4] during which they must be eaten by water fleas to continue to develop.[1] The larva inside water fleas may survive up to four months.[4] Thus, in order for the disease to remain in an area, it must occur each year in humans.[5] A diagnosis of the disease can usually be made based on the signs and symptoms of the disease.[6]

Prevention is by early diagnosis of the disease followed by keeping the person from putting the wound in drinking water to decrease spread of the parasite. Other efforts include improving access to clean water and otherwise filtering water if it is not clean.[1] Filtering through a cloth is often enough.[3] Contaminated drinking water may be treated with a chemical called temefos to kill the larva. There is no medication or vaccine against the disease.[1] The worm may be slowly removed over a few weeks by rolling it over a stick. The ulcers formed by the emerging worm may get infected by bacteria. Pain may continue for months after the worm has been removed.[2]

In 2015 there were 22 reported cases of the disease[7] and in the first half of 2016 there were 7 confirmed cases.[8] This is down from an estimated 3.5 million cases in 1986.[2] It only exists in 4 countries in Africa, down from 20 countries in the 1980s.[1][7] It will likely be the first parasitic disease to be globally eradicated.[9] Guinea worm disease has been known since ancient times.[2] It is mentioned in the Egyptian medical Ebers Papyrus, dating from 1550 BC.[10] The name dracunculiasis is derived from the Latin "affliction with little dragons",[11] while the name "guinea worm" appeared after Europeans saw the disease on the Guinea coast of West Africa in the 17th century.[10] Other *Dracunculus* species are known to infect various mammals, but do not appear to infect humans.[12][13] Dracunculiasis is classified as a neglected tropical disease.[14] Because dogs may also become infected,[15] the eradication program is monitoring and treating dogs as well.[16]

[edit on Wikidata]

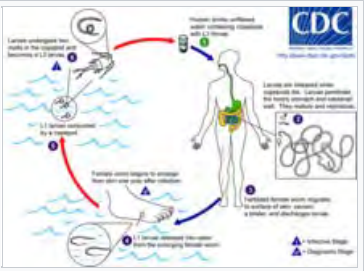
## Signs and symptoms [edit]

Dracunculiasis is diagnosed by seeing the worms emerging from the lesions on the legs of infected individuals and by microscopic examinations of the larvae.[17]

As the worm moves downwards, usually to the lower leg, through the subcutaneous tissues, it leads to intense pain localized to its path of travel. The painful, burning sensation experienced by infected people has led to the disease being called "the fiery serpent". Other symptoms include fever, nausea, and vomiting.[18] Female worms cause allergic reactions during blister formation as they migrate to the skin, causing an intense burning pain. Such allergic reactions produce rashes, nausea, diarrhea, dizziness, and localized edema. When the blister bursts, allergic reactions subside, but skin ulcers form, through which the worm can protrude. Only when the worm is removed is healing complete. Death of adult worms in joints can lead to arthritis and paralysis in the spinal cord.[19]

## Cause [edit]

Dracunculiasis is caused by drinking water contaminated by water fleas that host the *D. medinensis* larvae.[18] Dracunculiasis has a history of being very common in some of the world's poorest areas, particularly those with limited or no access to clean water.[20] In these areas, stagnant water sources may still host copepods, which can carry the larvae of the guinea worm.



Life cycle of *Dracunculus medinensis*

Humans and dogs are the only known animals that guinea worms infect.[2][15] Other species in the Dracunculus genus affect other mammals.

After ingestion, the copepods die and are digested, thus releasing the stage 3 larvae, which then penetrate the host's stomach or intestinal wall, and then enter into the abdominal cavity and retroperitoneal space. After maturation, which takes approximately three months, mating takes place; the male worm dies after mating and is absorbed by the host's body.

Approximately one year after mating, the fertilized females migrate in the subcutaneous tissues adjacent to long bones or joints of the extremities.[10] They then move towards the surface, resulting in blisters on the skin, generally on the distal lower extremity (foot). Within 72 hours, the blister ruptures, exposing one end of the emergent worm. The blister causes a very painful burning sensation as the worm emerges, and the sufferer will often immerse the affected limb in water to relieve the burning sensation. When a blister or open sore is submerged in water, the adult female releases hundreds of thousands of stage 1 guinea worm larvae, thereby contaminating the water.

During the next few days, the female worm can release more larvae whenever it comes in contact with water, as it extends its posterior end through the hole in the host's skin. These larvae are eaten by copepods, and after two weeks (and two molts), the stage 3 larvae become infectious and, if not filtered from drinking water, will cause the cycle to repeat. Infected copepods can live in the water for up to 4 months.

The male guinea worm is typically much smaller (12–29 mm or 0.47–1.14 in) than the female, which, as an adult, can grow to 60–100 cm (2–3 ft) long and be as thick as a spaghetti noodle.[10][20]

Infection does not create immunity, so people can repeatedly experience Dracunculiasis throughout their lives.[20]

In drier areas just south of the Sahara desert, cases of the disease often emerge during the rainy season, which for many agricultural communities is also the planting or harvesting season. Elsewhere, the emerging worms are more prevalent during the dry season, when ponds and lakes are smaller and copepods are thus more concentrated in them. Guinea worm disease outbreaks can cause serious disruption to local food supplies and school attendance.[20]

The infection can be acquired by eating a fish paratenic host, but this is rare. No reservoir hosts are known; that is, each generation of worms must pass through a human – or possibly a dog.[19][21]

## Prevention [edit]

Guinea worm disease can be transmitted only by drinking contaminated water, and can be completely prevented through two relatively simple measures:[18]

1. Prevent people from drinking contaminated water containing the Cyclops copepod (water flea), which can be seen in clear water as swimming white specks.
   - Drink water drawn only from sources free from contamination.
   - Filter all drinking water, using a fine-mesh cloth filter like nylon, to remove the guinea worm-containing crustaceans. Regular cotton cloth folded over a few times is an effective filter.
   - Filter the water through ceramic or sand filters.
   - Boil the water.
   - Develop new sources of drinking water without the parasites, or repair dysfunctional water sources.
   - Treat water sources with larvicides to kill the water fleas.[22]
2. Prevent people with emerging Guinea worms from entering water sources used for drinking.

Community-level case detection and containment is key. For this, staff must go door to door looking for cases, and the population must be willing to help and not hide their cases.
- Immerse emerging worms in buckets of water to reduce the number of larvae in those worms, and then discard that water on dry ground.
- Discourage all members of the community from setting foot in the drinking water source.
- Guard local water sources to prevent people with emerging worms from entering.

## Treatment [edit]

There is no vaccine or medicine to treat or prevent Guinea worm disease.[18] Once a Guinea worm begins emerging, the first step is to do a controlled submersion of the affected area in a bucket of water. This causes the worm to discharge many of its larvae, making it less infectious. The water is then discarded on the ground far away from any water source. Submersion results in subjective relief of the burning sensation and makes subsequent extraction of the worm easier. To extract the worm, a person must wrap the live worm around a piece of gauze or a stick. The process can be long, taking anywhere from hours to a week. Gently massaging the area around the blister can help loosen the worm.[9] This is nearly the same treatment that is noted in the famous ancient Egyptian medical text, the Ebers papyrus from 1550 BC.[10] Some people have said that extracting a Guinea worm feels like the afflicted area is on fire.[23][24] However, if the infection is identified before an ulcer forms, the worm can also be surgically removed by a trained doctor in a medical facility.[20]

Although Guinea worm disease is usually not fatal, the wound where the worm emerges could develop a secondary bacterial infection such as tetanus, which may be life-threatening—a concern in endemic areas where there is typically limited or no access to health care.[25] Analgesics can be used to help reduce swelling and pain and antibiotic ointments can help prevent secondary infections at the wound site.[20] At least in the Northern region of Ghana, the Guinea worm team found that antibiotic ointment on the wound site caused the wound to heal too well and too quickly making it more difficult to extract the worm and more likely that pulling would break the worm. The local team preferred to use something called "Tamale oil" (after the regional capital) which lubricated the worm and aided its extraction.

It is of great importance not to break the worm when pulling it out. Broken worms have a tendency to putrefy or petrify. Putrefaction leads to the skin sloughing off around the worm. Petrification is a problem if the worm is in a joint or wrapped around a vein or other important area.

Use of metronidazole or thiabendazole may make extraction easier, but also may lead to migration to other parts of the body.[26]

## Epidemiology [edit]

In 1986, there were an estimated 3.5 million cases of Guinea worm in 20 endemic nations in Asia and Africa.[9] Ghana alone reported 180,000 cases in 1989. The number of cases has since been reduced by more than 99.999% to 22 in 2015[27] — in the four remaining endemic nations of Africa: South Sudan, Chad, Mali and Ethiopia. This is the lowest number of cases since the eradication campaign began. As of 2010, however, the WHO predicted it will be "a few years yet" before eradication is achieved, on the basis that it took 6–12 years for the countries that have so far eliminated Guinea worm transmission to do so after reporting a similar number of cases to that reported in southern Sudan (now South Sudan) in 2009.[28]

The World Health Organization is the international body that certifies whether a disease has been eliminated from a country or eradicated from the world.[29] Former U.S. President Jimmy Carter's not-for-profit organization, the Carter Center, also reports the status of the Guinea worm eradication program by country.[30]

### Certified free [edit]

Endemic countries must report to the International Commission for the Certification of Dracunculiasis Eradication and document the absence of indigenous cases of Guinea worm disease for at least three consecutive years to be certified as Guinea worm-free by the World Health Organization.[31]

The results of this certification scheme have been remarkable: by 2007, Benin, Burkina Faso, Chad, Côte d'Ivoire, Kenya, Mauritania, Togo, and Uganda had stopped transmission, and Cameroon, Central African Republic, India, Pakistan, Senegal, Yemen were WHO certified.[32] Nigeria was certified as having ended transmission in 2013, followed by Ghana in 2015.[33]

### Endemic [edit]

With the current eradication campaign the areas that dracunculiasis are found are shrinking. In the early 1980s, the disease was endemic in Pakistan, Yemen and 17 countries in Africa with a total of 3.5 million cases per year. In 1985, 3.5 million cases were still reported annually, but by 2008, the number had dropped to 5,000.[34] This number further dropped to 1058 in 2011. At the end of 2013, South Sudan, Mali, Ethiopia and Chad still had endemic transmissions. For many years the major focus was South Sudan (independent after 2011, formerly the southern region of Sudan), which reported 76% of all cases in 2013. Now all 4 countries with endemic cases look close to eliminating the disease.[27]

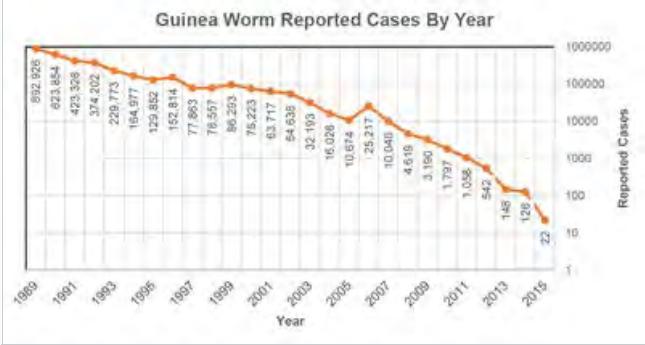
## Eradication program [edit]

In 1984, the WHO asked the United States Centers for Disease Control and Prevention (CDC) to spearhead the effort to eradicate dracunculiasis, an effort that was further supported by the Carter Center, former U.S. President Jimmy Carter's not-for-profit organization.[34] In 1986, Carter and the Carter Center began leading the global campaign, in conjunction with CDC, UNICEF, and WHO.[37] At that time the disease was endemic in Pakistan, Yemen and 17 countries in Africa, which reported a total of 3.5 million cases per year.



Logarithmic scale of reported human cases of guinea worm by year, 1989–2015 (2015 data is provisional). Data from Guinea Worm Eradication Program.[36]

Since humans are the principal host for Guinea worm, and there is no evidence that *D. medinensis* has ever been reintroduced to humans in any formerly endemic country as the result of non-human infections, the disease can be controlled by identifying all cases and modifying human behavior to prevent it from recurring.[9][38] Once all human cases are eliminated, the disease cycle will be broken, resulting in its eradication.[9]

The eradication of Guinea worm disease has faced several challenges:

- Inadequate security in some endemic countries
- Lack of political will from the leaders of some of the countries in which the disease is endemic
- The need for change in behavior in the absence of a magic bullet treatment like a vaccine or medication
- Inadequate funding at certain times[11]

Carter made a personal visit to a Guinea-worm endemic village in 1988. He said, "Encountering those victims first-hand, particularly the teenagers and small children, propelled me and Rosalynn [his wife] to step up the Carter Center's efforts to eradicate Guinea worm disease."[39]

In 1991, the World Health Assembly (WHA) agreed that Guinea worm disease should be eradicated.[25] At this time there were 400,000 cases reported each year. The Carter Center has continued to lead the eradication efforts, primarily through its Guinea Worm Eradication Program.[40]

In the 1980s, Carter persuaded President Zia al-Haq of Pakistan to accept the proposal of the eradication program, and by 1993, Pakistan was free of the disease. Key to the effort was, according to Carter, the work of "village volunteers" who educated people about the need to filter drinking water.[34] Other countries followed, and by 2004, the worm was eradicated in Asia.

In December 2008, The Carter Center announced new financial support totaling $55 million from the Bill & Melinda Gates Foundation and the United Kingdom Department for International Development.[41] The funds will help address the higher cost of identifying and reporting the last cases of Guinea worm disease. Since the worm has a one-year incubation period, there is a very high cost of maintaining a broad and sensitive monitoring system and providing a rapid response when necessary.[41]

One of the most significant challenges facing Guinea worm eradication has been the civil war in southern Sudan, which was largely inaccessible to health workers due to violence.[11][42] To address some of the humanitarian needs in southern Sudan, in 1995, the longest ceasefire in the history of the war, and the longest humanitarian cease-fire in history,[43] was achieved through negotiations by Jimmy Carter.[11][42] Commonly called the "Guinea worm cease-fire," both warring parties agreed to halt hostilities for nearly six months to allow public health officials to begin Guinea worm eradication programming, among other interventions.[42][44]

Public health officials cite the formal end of the war in 2005 as a turning point in Guinea worm eradication because it has allowed health care workers greater access to southern Sudan's endemic areas.[45] In 2006, there was an increase from 5,569 cases in 2005 to 15,539 cases, as a result of better reporting from areas that were no longer war-torn. The Southern Sudan Guinea Worm Eradication Program (SSGWEP) has deployed over 28,000 village volunteers, supervisors and other health staff to work on the program full-time. The SSGWEP was able to slash the number of cases reported in 2006 by 63% to 5,815 cases in

2007. Since 2011, at the time that South Sudan became independent, its northern neighbor Sudan had reported no endemic cases of dracunculiasis .[46]

Sporadic insecurity or widespread civil conflict could at any time ignite, thwarting eradication efforts.[46] The remaining endemic communities in South Sudan are remote, poor and devoid of infrastructure, presenting significant hurdles for effective delivery of interventions against disease. Moreover, residents in these communities are nomadic, moving seasonally with cattle in pursuit of water and pasture, making it very difficult to know where and when transmission occurred. The peak transmission season coincides with the rainy season, hampering travel by public health workers.[47]

One remaining area in West Africa outside of Ghana remains challenging to ending Guinea worm: northern Mali, where Tuareg rebels have made some affected areas unsafe for health workers. Four of Mali's regions—(Kayes, Koulikoro, Ségou, and Sikasso)—have eliminated dracunculiasis, while the disease is still endemic in the country's other four regions (Gao, Kidal, Mopti, and Timbuktu). Late detection of two outbreaks, due to inadequate surveillance resulted in a meager 36% containment rate in Mali in 2007.[46] The years 2008 and 2009 were more successful, however, with containment rates of 85% and 73% respectively.[48] The civil war prevented accurate information from being gathered in northern Mali in 2012.

From June 2006 to March 2008, there had been no cases reported in Ethiopia.[49]

Before 2010, Chad had not reported any indigenous cases of guinea worm in over 10 years.[50]

In Ghana, after a decade of frustration and stagnation, in 2006 a decisive turnaround was achieved. Multiple changes can be attributed to the improved containment and lower incidence of dracunculiasis: better supervision and accountability, active oversight of infected people daily by paid staff, and an intensified public awareness campaign. After Jimmy Carter's visit to Ghana in August 2006, the government of Ghana declared Guinea worm disease to be a public health emergency. The overall rate of contained cases has increased in Ghana from 60% in 2005, to 75% in 2006, 84% in 2007, 85% in 2008, 93% in 2009, and 100% in 2010.[46][48][50]

On 30 January 2012 the WHO meeting at the Royal College of Physicians in London launched the most ambitious and largest coalition health project ever, known as *London Declaration on Neglected Tropical Diseases* which aims to end/control dracunculiasis by 2020, among other neglected tropical disease.[51] This project is supported of all major pharmaceutical companies, the Bill & Melinda Gates Foundation, the governments of the United States, United Kingdom DFID and United Arab Emirates and the World Bank.[52]

In 2015 22 cases of dracunculiasis were reported: 9 in Chad, 3 in Ethiopia, 5 in Mali and 5 in South Sudan. This is an 83% reduction from 2014. The proportion of people contained (i.e. treated and isolated from drinking water sources early enough to remove the risk they can contaminate the water source) is 36%, compared to 73% in 2014. That means 14 cases have not been contained in 2015, compared to 34 cases in 2014. 9 of these 14 cases not contained were in Chad.[53]

A significant change from 2014 is the increased effort being used to identify and treat infected dogs—mainly in Chad where the vast majority of cases of dogs hosting the worm have been found, but also significantly in Ethiopia. In 2015, 483 infected dogs were identified and treated in Chad — more than 20 times the number reported in humans worldwide. This is more than 4 times larger than the number treated in 2014 (114 dogs). A major factor in this increase is probably the financial reward started in January for reporting an infected dog. 68% of dogs treated were also contained, compared to 40% in 2014. Dogs are believed to be the major source of the parasite infecting humans in Chad. 15 dogs outside Chad have also been identified and treated, as well 5 cats and 1 baboon. The August Carter Center report predicts that Chad may be the last country that eliminates dracunculiasis, and reports on further ongoing research into the relationship between the parasite and dogs there, and some different treatments for dogs. It also predicts that the large increase in monitoring, treating and containing dogs this year will not affect the number of human cases for many months due to the 1 year incubation period of the disease.[35][53][54]

In August 2015, when discussing his diagnosis of melanoma metastasized to his brain, Jimmy Carter stated that he hopes the last Guinea worm dies before he does.[55]

In 2016 11 cases have been reported up to 31 July - 5 in Chad, 4 in South Sudan and 2 in Ethiopia - compared to 8 cases last year in the same period - 6 in Chad, 1 in South Sudan and 1 in Ethiopia. Insecurity around Juba in South Sudan has caused the evacuation of all expatriate Guinea Worm Eradication Program (GWEP) staff. Members of the local staff have been given the option of continuing to work if possible. It is unclear what impact this is having. Mali has not reported any new cases in 7 months. The efforts against infected dogs continue to increase in Chad, with 498 dogs being identified and treated up to 31 May, compared to 196 cases in the same period the previous year. The level of containment of infected dogs before they become a risk of spreading the parasite has improved to 81% compared to 67% last year.[56]

## Society and culture [edit]

The pain caused by the worm's emergence—which typically occurs during planting and harvesting seasons—prevents many people from working or attending school for as long as three months. In heavily burdened agricultural villages fewer people are able to tend their fields or livestock, resulting in food shortages and lower earnings.[9][45] A study in southeastern Nigeria, for example, found that rice farmers in a small area lost US$20 million in just one year due to outbreaks of Guinea worm disease.[9]

## History [edit]

Dracunculiasis has been a recognized disease for thousands of years:

- Guinea worm has been found in calcified Egyptian mummies.[9]
- An Old Testament description of "fiery serpents" may have been referring to Guinea worm: "And the Lord sent fiery serpents among the people, and they bit the people; and much people of Israel died." (Numbers 21:4–9).[10]
- The 2nd century BC, Greek writer Agatharchides, described this affliction as being endemic amongst certain nomads in what is now Sudan and along the Red Sea.[10]
- The unusually high incidence of dracunculiasis in the city of Medina led to it being included in part of the disease's scientific name "medinensis." A similar high incidence along the Guinea coast of West Africa gave the disease its more commonly used name.[10] Guinea worm is no longer endemic in either location.

The Russian scientist Alexei Pavlovich Fedchenko (1844–1873) during the 1860s while living in Samarkand was provided with a number of specimens of the worm by a local doctor which he kept in water. While examining the worms Fedchenko noted the presence of water fleas with embryos of the guinea worm within them.

In modern times, the first to describe dracunculiasis and its pathogenesis was the Bulgarian physician Hristo Stambolski, during his exile in Yemen (1877–1878).[57] His theory was that the cause was infected water which people were drinking.

### Etymology [edit]

Dracunculiasis once plagued a wide band of tropical countries in Africa and Asia. Its Latin name, *Dracunculus medinensis* ("little dragon from Medina"), derives from its one-time high incidence in the city of Medina, and its common name, Guinea worm, is due to a similar past high incidence along the Guinea coast of West Africa; both of these locations are now free of Guinea worm.[58] In the 18th century, Swedish naturalist Carl Linnaeus identified *D. medinensis* in merchants who traded along the Gulf of Guinea (West African Coast), hence the name Guinea worm.

## Other animals [edit]

A very similar or possibly the same worm has been found in dogs.[15] It is unclear if dog and human infections are related.[59] It is possible that dogs may be able to spread the disease to people, that a third organism may be able to spread it to both dogs and people, or that this may be a different type of *Dracunculus*.[59]

# Ebola virus disease

From Wikipedia, the free encyclopedia

*"Ebola" redirects here. For other uses, see Ebola (disambiguation).*

**Ebola virus disease** (**EVD**), also known as **Ebola hemorrhagic fever** (**EHF**) or simply **Ebola**, is a viral hemorrhagic fever of humans and other primates caused by ebolaviruses. Signs and symptoms typically start between two days and three weeks after contracting the virus with a fever, sore throat, muscular pain, and headaches. Then, vomiting, diarrhea and rash usually follow, along with decreased function of the liver and kidneys. At this time some people begin to bleed both internally and externally.[1] The disease has a high risk of death, killing between 25 and 90 percent of those infected, with an average of about 50 percent.[1] This is often due to low blood pressure from fluid loss, and typically follows six to sixteen days after symptoms appear.[2]

The virus spreads by direct contact with body fluids, such as blood, of an infected human or other animals.[1] This may also occur through contact with an item recently contaminated with bodily fluids.[1] Spread of the disease through the air between primates, including humans, has not been documented in either laboratory or natural conditions.[3] Semen or breast milk of a person after recovery from EVD may carry the virus for several weeks to months.[1][4][5] Fruit bats are believed to be the normal carrier in nature, able to spread the virus without being affected by it. Other diseases such as malaria, cholera, typhoid fever, meningitis and other viral hemorrhagic fevers may resemble EVD. Blood samples are tested for viral RNA, viral antibodies or for the virus itself to confirm the diagnosis.[1]

Control of outbreaks requires coordinated medical services, alongside a certain level of community engagement. The medical services include rapid detection of cases of disease, contact tracing of those who have come into contact with infected individuals, quick access to laboratory services, proper healthcare for those who are infected, and proper disposal of the dead through cremation or burial.[1][6] Samples of body fluids and tissues from people with the disease should be handled with special caution. Prevention includes limiting the spread of disease from infected animals to humans. This may be done by handling potentially infected bushmeat only while wearing protective clothing and by thoroughly cooking it before eating it. It also includes wearing

Ebola virus disease

Two nurses standing near Mayinga N'Seka, a nurse with Ebola virus disease in the 1976 outbreak in Zaire. N'Seka died a few days later.

proper protective clothing and washing hands when around a person with the disease. No specific treatment or vaccine for the virus is available, although a number of potential treatments are being studied. Supportive efforts, however, improve outcomes. This includes either oral rehydration therapy (drinking slightly sweetened and salty water) or giving intravenous fluids as well as treating symptoms.[1]

[edit on Wikidata]

The disease was first identified in 1976 in two simultaneous outbreaks, one in Nzara, and the other in Yambuku, a village near the Ebola River from which the disease takes its name.[7] EVD outbreaks occur intermittently in tropical regions of sub-Saharan Africa.[1] Between 1976 and 2013, the World Health Organization reports a total of 24 outbreaks involving 1,716 cases.[1][8] The largest outbreak to date was the epidemic in West Africa, which occurred from December 2013 to January 2016 with 28,616 cases and 11,310 deaths.[9][10][11] It was declared no longer an emergency on 29 March 2016.[12]

**Contents**

# Signs and symptoms

## Onset

Signs and symptoms of Ebola[13]

The length of time between exposure to the virus and the development of symptoms (incubation period) is between 2 and 21 days,[1][13] and usually between 4 and 10 days.[14] However, recent estimates based on mathematical models predict that around 5% of cases may take greater than 21 days to develop.[15]

Symptoms usually begin with a sudden influenza-like stage characterized by feeling tired, fever, weakness, decreased appetite, muscular pain, joint pain, headache, and sore throat.[1][14][16][17] The fever is usually higher than 38.3 °C (101 °F).[18] This is often followed by vomiting, diarrhea and abdominal pain.[17] Next, shortness of breath and chest pain may occur, along with swelling, headaches and confusion.[17] In about half of the cases, the skin may develop a maculopapular rash, a flat red area covered with small bumps, 5 to 7 days after symptoms begin.[14][18]

## Bleeding

In some cases, internal and external bleeding may occur.[1] This typically begins five to seven days after the first symptoms.[19] All infected people show some decreased blood clotting.[18] Bleeding from mucous membranes or from sites of needle punctures has been reported in 40–50 percent of cases.[20] This may cause vomiting blood, coughing up of blood, or blood in stool.[21] Bleeding into the skin may create petechiae, purpura, ecchymoses or hematomas (especially around needle injection sites).[22] Bleeding into the whites of the eyes may also occur. Heavy bleeding is uncommon; if it occurs, it is usually located within the gastrointestinal tract.[18][23]

## Recovery and death

Recovery may begin between 7 and 14 days after first symptoms.[17] Death, if it occurs, follows typically 6 to 16 days from first symptoms and is often due to low blood pressure from fluid loss.[2] In general, bleeding often indicates a worse outcome, and blood loss may result in death.[16] People are often in a coma near the end of life.[17]

Those who survive often have ongoing muscular and joint pain, liver inflammation, decreased hearing, and may have continued feelings of tiredness, continued weakness, decreased appetite, and difficulty returning to pre-illness weight.[17][24] Problems with vision may develop.[25]

Additionally, they develop antibodies against Ebola that last at least 10 years, but it is unclear if they are immune to repeated infections.[26]

# Cause

EVD in humans is caused by four of five viruses of the genus *Ebolavirus*. The four are Bundibugyo virus (BDBV), Sudan virus (SUDV), Taï Forest virus (TAFV) and one simply called Ebola virus (EBOV, formerly Zaire Ebola virus).[27] EBOV, species *Zaire ebolavirus*, is the most dangerous of the known EVD-causing viruses, and is responsible for the largest number of outbreaks.[28] The fifth virus, Reston virus (RESTV), is not thought to cause disease in humans, but has caused disease in other primates.[29][30] All five viruses

are closely related to marburgviruses.[27]

## Virology

*Main articles:* Ebolavirus *(taxonomic group)* and *Ebola virus (specific virus)*

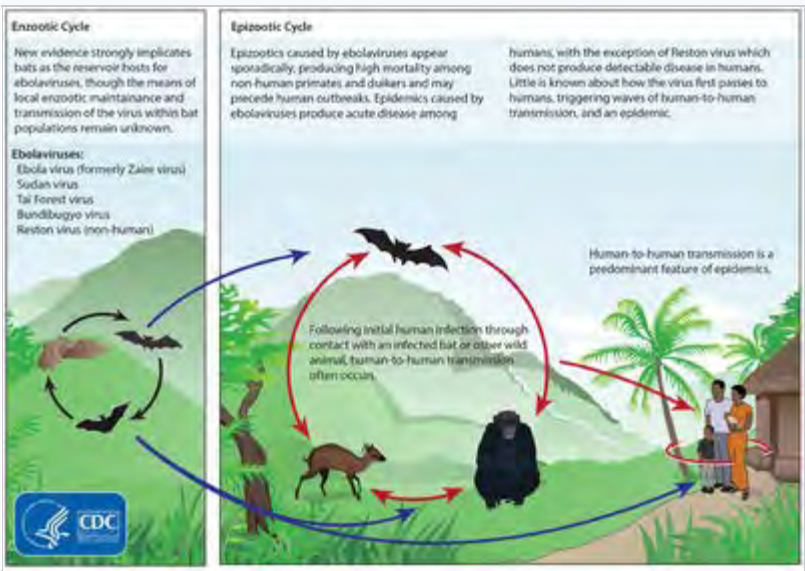
Ebolaviruses contain single-stranded, non-infectious RNA genomes.[31] *Ebolavirus* genomes contain seven genes including 3'-UTR-*NP-VP35-VP40-GP-VP30-VP24-L*-5'-UTR.[22][32] The genomes of the five different ebolaviruses (BDBV, EBOV, RESTV, SUDV and TAFV) differ in sequence and the number and location of gene overlaps. As with all filoviruses, ebolavirus virions are filamentous particles that may appear in the shape of a shepherd's crook, of a "U" or of a "6," and they may be coiled, toroid or branched.[32][33] In general, ebolavirions are 80 nanometers (nm) in width and may be as long as 14,000 nm.[34]

Electron micrograph of an Ebola virus virion

Their life cycle is thought to begin with a virion attaching to specific cell-surface receptors such as C-type lectins, DC-SIGN, or integrins, which is followed by fusion of the viral envelope with cellular membranes.[35] The virions taken up by the cell then travel to acidic endosomes and lysosomes where the viral envelope glycoprotein GP is cleaved.[35] This processing appears to allow the virus to bind to cellular proteins enabling it to fuse with internal cellular membranes and release the viral nucleocapsid.[35] The *Ebolavirus* structural glycoprotein (known as GP1,2) is responsible for the virus' ability to bind to and infect targeted cells.[36] The viral RNA polymerase, encoded by the *L* gene, partially uncoats the nucleocapsid and transcribes the genes into positive-strand mRNAs, which are then translated into structural and nonstructural proteins. The most abundant protein produced is the nucleoprotein, whose concentration in the host cell determines when L switches from gene transcription to genome replication. Replication of the viral genome results in full-length, positive-strand antigenomes that are, in turn, transcribed into genome copies of negative-strand virus progeny.[37] Newly synthesized structural proteins and genomes self-assemble and accumulate near the inside of the cell membrane. Virions bud off from the cell, gaining their envelopes from the cellular membrane from which they bud. The mature progeny particles then infect other cells to repeat the cycle. The genetics of the Ebola virus are difficult to study because of EBOV's virulent characteristics.[38]

## Transmission

It is believed that between people, Ebola disease spreads only by direct contact with the blood or other body fluids of a person who has developed symptoms of the disease.[39][40][41] Body fluids that may contain Ebola viruses include saliva, mucus, vomit, feces, sweat, tears, breast milk, urine and semen.[4][26] The WHO states that only people who are very sick are able to spread Ebola disease in saliva, and whole virus has not been reported to be transmitted through sweat. Most people spread the virus through blood, feces and vomit.[42] Entry points for the virus include the nose, mouth, eyes, open wounds, cuts and abrasions.[26] Ebola may be spread through large droplets; however, this is believed to occur only when a person is very sick.[43] This contamination can happen if a person is splashed with droplets.[43] Contact with surfaces or objects contaminated by the virus,



Life cycles of the *Ebolavirus*

particularly needles and syringes, may also transmit the infection.[44][45] The virus is able to survive on objects for a few hours in a dried state, and can survive for a few days within body fluids outside of a person.[26][46]

The Ebola virus may be able to persist for more than 3 months in the semen after recovery, which could lead to infections via sexual intercourse.[4][47][48] Virus persistence in semen for over a year has been recorded in a national screening programme.[49] Ebola may also occur in the breast milk of women after recovery, and it is not known when it is safe to breastfeed again.[5] The virus was also found in the eye of one patient in 2014, two months after it was cleared from his blood.[50] Otherwise, people who have recovered are not infectious.[44]

The potential for widespread infections in countries with medical systems capable of observing correct medical isolation procedures is considered low.[51] Usually when someone has symptoms of the disease, they are unable to travel without assistance.[52]

Dead bodies remain infectious; thus, people handling human remains in practices such as traditional burial rituals or more modern processes such as embalming are at risk.[51] 69% of the cases of Ebola infections in Guinea during the 2014 outbreak are believed to have been contracted via unprotected (or unsuitably protected) contact with infected corpses during certain Guinean burial rituals.[53][54]

Health-care workers treating people with Ebola are at greatest risk of infection.[44] The risk increases when they do not have appropriate protective clothing such as masks, gowns, gloves and eye protection; do not wear it properly; or handle contaminated clothing incorrectly.[44] This risk is particularly common in parts of Africa where the disease mostly occurs and health systems function poorly.[55] There has been transmission in hospitals in some African countries that reuse hypodermic needles.[56][57] Some health-care centers caring for people with the disease do not have running water.[58] In the United States the spread to two medical workers treating infected patients prompted criticism of inadequate training and procedures.[59]

Human-to-human transmission of EBOV through the air has not been reported to occur during EVD outbreaks,[3] and airborne transmission has only been demonstrated in very strict laboratory conditions, and then only from pigs to primates, but not from primates to primates.[39][45] Spread of EBOV by water, or food other than bushmeat, has not been observed.[44][45] No spread by mosquitos or other insects has been reported.[44] Other possible methods of transmission are being studied.[46]

The apparent lack of airborne transmission among humans is believed to be due to low levels of the virus in the lungs and other parts of the respiratory system of primates, insufficient to cause new infections.[60] A number of studies examining airborne transmission broadly concluded that transmission from pigs to primates could happen without direct contact because, unlike humans and primates, pigs with EVD get very high ebolavirus concentrations in their lungs, and not their bloodstream.[61] Therefore, pigs with EVD can spread the disease through droplets in the air or on the ground when they sneeze or cough.[62] By contrast, humans and other primates accumulate the virus throughout their body and specifically in their blood, but not very much in their lungs.[62] It is believed that this is the reason researchers have observed pig to primate transmission without physical contact, but no evidence has been found of primates being infected without actual contact, even in experiments where infected and uninfected primates shared the same air.[61][62]

## Initial case

Although it is not entirely clear how Ebola initially spreads from animals to humans, the spread is believed to involve direct contact with an infected wild animal or fruit bat.[44] Besides bats, other wild animals sometimes infected with EBOV include several monkey species, chimpanzees, gorillas, baboons and duikers.[66]

Animals may become infected when they eat fruit partially eaten by bats [67]

Bushmeat being prepared for cooking in Ghana. In Africa, wild animals including fruit bats are hunted for food and are referred to as bushmeat.[63][64] In equatorial Africa, human consumption of bushmeat has been linked to animal-to-human transmission of diseases, including Ebola.[65]

carrying the virus. Fruit production, animal behavior and other factors may trigger outbreaks among animal populations.[67]

Evidence indicates that both domestic dogs and pigs can also be infected with EBOV.[68] Dogs do not appear to develop symptoms when they carry the virus, and pigs appear to be able to transmit the virus to at least some primates.[68] Although some dogs in an area in which a human outbreak occurred had antibodies to EBOV, it is unclear whether they played a role in spreading the disease to people.[68]

### Reservoir

The natural reservoir for Ebola has yet to be confirmed; however, bats are considered to be the most likely candidate species.[45] Three types of fruit bats (*Hypsignathus monstrosus*, *Epomops franqueti* and *Myonycteris torquata*) were found to possibly carry the virus without getting sick.[69] As of 2013, whether other animals are involved in its spread is not known.[68] Plants, arthropods and birds have also been considered possible viral reservoirs.[1]

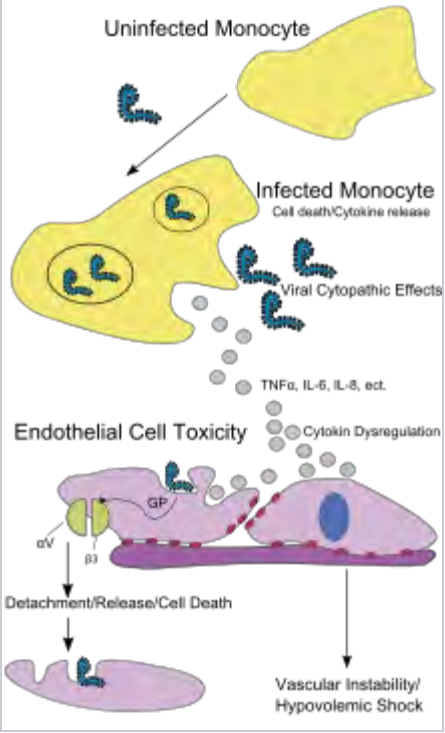
Bats were known to roost in the cotton factory in which the first cases of the 1976 and 1979 outbreaks were observed, and they have also been implicated in Marburg virus infections in 1975 and 1980.[70] Of 24 plant and 19 vertebrate species experimentally inoculated with EBOV, only bats became infected.[71] The bats displayed no clinical signs of disease, which is considered evidence that these bats are a reservoir species of EBOV. In a 2002–2003 survey of 1,030 animals including 679 bats from Gabon and the Republic of the Congo, 13 fruit bats were found to contain EBOV RNA.[72] Antibodies against Zaire and Reston viruses have been found in fruit bats in Bangladesh, suggesting that these bats are also potential hosts of the virus and that the filoviruses are present in Asia.[73]

Between 1976 and 1998, in 30,000 mammals, birds, reptiles, amphibians and arthropods sampled from regions of EBOV outbreaks, no Ebola virus was detected apart from some genetic traces found in six rodents (belonging to the species *Mus setulosus* and *Praomys*) and one shrew (*Sylvisorex ollula*) collected from the Central African Republic.[70][74] However, further research efforts have not confirmed rodents as a reservoir.[75] Traces of EBOV were detected in the carcasses of gorillas and chimpanzees during outbreaks in 2001 and 2003, which later became the source of human infections. However, the high rates of death in these species resulting from EBOV infection make it unlikely that these species represent a natural reservoir for the virus.[70]

## Pathophysiology

Similar to other filoviruses, EBOV replicates very efficiently in many cells, producing large amounts of virus in monocytes, macrophages, dendritic cells and other cells including liver cells, fibroblasts, and adrenal gland cells.[76] Viral replication triggers the release of high levels of inflammatory chemical signals and leads to a septic state.[24]

EBOV is thought to infect humans through contact with mucous membranes or through skin breaks.[39] Once infected, endothelial cells (cells lining the inside of blood vessels), liver cells, and several types of immune cells such as macrophages, monocytes, and dendritic cells are



Pathogenesis schematic

the main targets of infection.[39] Following infection with the virus, the immune cells carry the virus to nearby lymph nodes where further reproduction of the virus takes place.[39] From there, the virus can enter the bloodstream and lymphatic system and spread throughout the body.[39] Macrophages are the first cells infected with the virus, and this infection results in programmed cell death.[34] Other types of white blood cells, such as lymphocytes, also undergo programmed cell death leading to an abnormally low concentration of lymphocytes in the blood.[39] This contributes to the weakened immune response seen in those infected with EBOV.[39]

Endothelial cells may be infected within 3 days after exposure to the virus.[34] The breakdown of endothelial cells leading to blood vessel injury can be attributed to EBOV glycoproteins. This damage occurs due to the synthesis of Ebola virus glycoprotein (GP), which reduces the availability of specific integrins responsible for cell adhesion to the intercellular structure and causes liver damage, leading to improper clotting. The widespread bleeding that occurs in affected people causes swelling and shock due to loss of blood volume.[77] The dysfunction in bleeding and clotting commonly seen in EVD has been attributed to increased activation of the extrinsic pathway of the coagulation cascade due to excessive tissue factor production by macrophages and monocytes.[14]

After infection, a secreted glycoprotein, small soluble glycoprotein (sGP or GP) is synthesized. EBOV replication overwhelms protein synthesis of infected cells and the host immune defenses. The GP forms a trimeric complex, which tethers the virus to the endothelial cells. The sGP forms a dimeric protein that interferes with the signaling of neutrophils, another type of white blood cell, which enables the virus to evade the immune system by inhibiting early steps of neutrophil activation. The presence of viral particles and the cell damage resulting from viruses budding out of the cell causes the release of chemical signals (such as TNF-α, IL-6 and IL-8), which are molecular signals for fever and inflammation.[*citation needed*]

## Immune system evasion

Filoviral infection also interferes with proper functioning of the innate immune system.[35][37] EBOV proteins blunt the human immune system's response to viral infections by interfering with the cells' ability to produce and respond to interferon proteins such as interferon-alpha, interferon-beta, and interferon gamma.[36][78]

The VP24 and VP35 structural proteins of EBOV play a key role in this interference. When a cell is infected with EBOV, receptors located in the cell's cytosol (such as RIG-I and MDA5) or outside of the cytosol (such as Toll-like receptor 3 (TLR3), TLR7, TLR8 and TLR9), recognize infectious molecules associated with the virus.[36] On TLR activation, proteins including interferon regulatory factor 3 and interferon regulatory factor 7 trigger a signaling cascade that leads to the expression of type 1 interferons.[36] The type 1 interferons are then released and bind to the IFNAR1 and IFNAR2 receptors expressed on the surface of a neighboring cell.[36] Once interferon has bound to its receptors on the neighboring cell, the signaling proteins STAT1 and STAT2 are activated and move to the cell's nucleus.[36] This triggers the expression of interferon-stimulated genes, which code for proteins with antiviral properties.[36] EBOV's V24 protein blocks the production of these antiviral proteins by preventing the STAT1 signaling protein in the neighboring cell from entering the nucleus.[36] The VP35 protein directly inhibits the production of interferon-beta.[78] By

inhibiting these immune responses, EBOV may quickly spread throughout the body.[34]

# Diagnosis

When EVD is suspected in a person, his or her travel and work history, along with an exposure to wildlife, are important factors to consider with respect to further diagnostic efforts.

## Laboratory testing

Possible non-specific laboratory indicators of EVD include a low platelet count; an initially decreased white blood cell count followed by an increased white blood cell count; elevated levels of the liver enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST); and abnormalities in blood clotting often consistent with disseminated intravascular coagulation (DIC) such as a prolonged prothrombin time, partial thromboplastin time, and bleeding time.[79] Filovirions, such as EBOV, may be identified by their unique filamentous shapes in cell cultures examined with electron microscopy, but this method cannot distinguish the various filoviruses.[80]

The specific diagnosis of EVD is confirmed by isolating the virus, detecting its RNA or proteins, or detecting antibodies against the virus in a person's blood. Isolating the virus by cell culture, detecting the viral RNA by polymerase chain reaction (PCR)[14] and detecting proteins by enzyme-linked immunosorbent assay (ELISA) are methods best used in the early stages of the disease and also for detecting the virus in human remains. Detecting antibodies against the virus is most reliable in the later stages of the disease and in those who recover.[81] IgM antibodies are detectable two days after symptom onset and IgG antibodies can be detected 6 to 18 days after symptom onset.[14] During an outbreak, isolation of the virus via cell culture methods is often not feasible. In field or mobile hospitals, the most common and sensitive diagnostic methods are real-time PCR and ELISA.[82] In 2014, with new mobile testing facilities deployed in parts of Liberia, test results were obtained 3–5 hours after sample submission.[83] In 2015 a rapid antigen test which gives results in 15 minutes was approved for use by WHO. It is able to confirm Ebola in 92% of those affected and rule it out in 85% of those not affected.[84]

## Differential diagnosis

Early symptoms of EVD may be similar to those of other diseases common in Africa, including malaria and dengue fever.[16] The symptoms are also similar to those of other viral hemorrhagic fevers such as Marburg virus disease.[85]

The complete differential diagnosis is extensive and requires consideration of many other infectious diseases such as typhoid fever, shigellosis, rickettsial diseases, cholera, sepsis, borreliosis, EHEC enteritis, leptospirosis, scrub typhus, plague, Q fever, candidiasis, histoplasmosis, trypanosomiasis, visceral leishmaniasis, measles, and viral hepatitis among others.[86]

Non-infectious diseases that may result in symptoms similar to those of EVD include acute promyelocytic leukemia, hemolytic uremic syndrome, snake envenomation, clotting factor deficiencies/platelet disorders, thrombotic thrombocytopenic purpura, hereditary hemorrhagic telangiectasia, Kawasaki disease, and warfarin poisoning.[82][87][88][89]

# Prevention

## Infection control

People who care for those infected with Ebola should wear protective clothing including masks, gloves, gowns and [90]

VHF isolation precautions poster

goggles. The US Centers for Disease Control (CDC) recommend that the protective gear leaves no skin exposed.[91] These measures are also recommended for those who may handle objects contaminated by an infected person's body fluids.[92] In 2014, the CDC began recommending that medical personnel receive training on the proper suit-up and removal of personal protective equipment (PPE); in addition, a designated person, appropriately trained in biosafety, should be watching each step of these procedures to ensure they are done correctly.[91] In Sierra Leone, the typical training period for the use of such safety equipment lasts approximately 12 days.[93]

The infected person should be in barrier-isolation from other people.[90] All equipment, medical waste, patient waste and surfaces that may have come into contact with body fluids need to be disinfected.[92] During the 2014 outbreak, kits were put together to help families treat Ebola disease in their homes, which include protective clothing as well as chlorine powder and other cleaning supplies.[94] Education of those who provide care in these techniques, and the provision of such barrier-separation supplies has been a priority of Doctors Without Borders.[95]

British woman wearing protective gear

Ebolaviruses can be eliminated with heat (heating for 30 to 60 minutes at 60 °C or boiling for 5 minutes). To disinfect surfaces, some lipid solvents such as some alcohol-based products, detergents, sodium hypochlorite (bleach) or calcium hypochlorite (bleaching powder), and other suitable disinfectants may be used at appropriate concentrations.[66][96] Education of the general public about the risk factors for Ebola infection and of the protective measures individuals may take to prevent infection is recommended by the World Health Organization.[1] These measures include avoiding direct contact with infected people and regular hand washing using soap and water.[97]

Bushmeat, an important source of protein in the diet of some Africans, should be handled and prepared with appropriate protective clothing and thoroughly cooked before consumption.[1] Some research suggests that an outbreak of Ebola disease in the wild animals used for consumption may result in a corresponding human outbreak. Since 2003, such animal outbreaks have been monitored to predict and prevent Ebola outbreaks in humans.[98]

If a person with Ebola disease dies, direct contact with the body should be avoided.[90] Certain burial rituals, which may have included making various direct contacts with a dead body, require reformulation such that they consistently maintain a proper protective barrier between the dead body and the living.[99][100][101] Social anthropologists may help find alternatives to traditional rules for burials.[102]

Transportation crews are instructed to follow a certain isolation procedure, should anyone exhibit symptoms resembling EVD.[103] As of August 2014, the WHO does not consider travel bans to be useful in decreasing spread of the disease.[52] In October 2014, the CDC defined four risk levels used to determine the level of 21-day monitoring for symptoms and restrictions on public activities.[104] In the United States, the CDC recommends that restrictions on public activity, including travel restrictions, are not required for the

following defined risk levels:[104]

- having been in a country with widespread Ebola disease transmission and having no known exposure (low risk); or having been in that country more than 21 days ago (no risk)
- encounter with a person showing symptoms; but not within 3 feet of the person with Ebola without wearing PPE; and no direct contact of body fluids
- having had brief skin contact with a person showing symptoms of Ebola disease when the person was believed to be not very contagious (low risk)
- in countries without widespread Ebola disease transmission: direct contact with a person showing symptoms of the disease while wearing PPE (low risk)
- contact with a person with Ebola disease before the person was showing symptoms (no risk).

The CDC recommends monitoring for the symptoms of Ebola disease for those both at "low risk" and at higher risk.[104]

In laboratories where diagnostic testing is carried out, biosafety level 4-equivalent containment is required.[105] Laboratory researchers must be properly trained in BSL-4 practices and wear proper PPE.[105]

## Isolation

Isolation refers to separating those who are sick from those who are not. Quarantine refers to separating those who may have been exposed to a disease until they either show signs of the disease or are no longer at risk.[106] Quarantine, also known as enforced isolation, is usually effective in decreasing spread.[107][108] Governments often quarantine areas where the disease is occurring or individuals who may transmit the disease outside of an initial area.[109] In the United States, the law allows quarantine of those infected with ebolaviruses.[110]

## Contact tracing

Contact tracing is considered important to contain an outbreak. It involves finding everyone who had close contact with infected individuals and watching for signs of illness for 21 days. If any of these contacts comes down with the disease, they should be isolated, tested and treated. Then the process is repeated by tracing the contacts' contacts.[111][112]

# Management

No specific treatment is currently approved.[113] The Food and Drug Administration (FDA) advises people to be careful of advertisements making unverified or fraudulent claims of benefits supposedly gained from various anti-Ebola products.[114][115]

## Standard support

Treatment is primarily supportive in nature.[116] Early supportive care with rehydration and symptomatic treatment improves survival.[1] Rehydration may be via the oral or by intravenous route.[116] These measures may include management of pain, nausea, fever and anxiety.[116] The World Health Organization recommends avoiding the use of aspirin or ibuprofen for pain due to the bleeding risk associated with use of these medications.[117]

Blood products such as packed red blood cells, platelets or fresh frozen plasma may also be used.[116] Other regulators of coagulation have also been tried including heparin in an effort to prevent disseminated intravascular coagulation and clotting factors to decrease bleeding.[116] Antimalarial medications and antibiotics are often used before the diagnosis is confirmed,[116] though there is no evidence to suggest such treatment helps. A number of experimental treatments are being studied.

A hospital isolation ward in Gulu, Uganda, during the October 2000 outbreak

If hospital care is not possible, the World Health Organization has guidelines for care at home that have been relatively successful. In such situations, recommendations include using towels soaked in bleach solutions when moving infected people or bodies and applying bleach on stains. It is also recommended that the caregivers wash hands with bleach solutions and cover their mouth and nose with a cloth.[118]

### Intensive care

Intensive care is often used in the developed world.[22] This may include maintaining blood volume and electrolytes (salts) balance as well as treating any bacterial infections that may develop.[22] Dialysis may be needed for kidney failure, and extracorporeal membrane oxygenation may be used for lung dysfunction.[22]

## Prognosis

EVD has a high risk of death in those infected which varies between 25 percent and 90 percent of those infected.[1][119] As of September 2014, the average risk of death among those infected is 50 percent.[1] The highest risk of death was 90 percent in the 2002–2003 Republic of the Congo outbreak.[120]

Death, if it occurs, follows typically six to sixteen days after symptoms appear and is often due to low blood pressure from fluid loss.[2] Early supportive care to prevent dehydration may reduce the risk of death.[121]

If an infected person survives, recovery may be quick and complete. Prolonged cases are often complicated by the occurrence of long-term problems, such as inflammation of the testicles, joint pains, muscular pain, skin peeling, or hair loss.[14] Eye symptoms, such as light sensitivity, excess tearing, and vision loss have been described.[122]

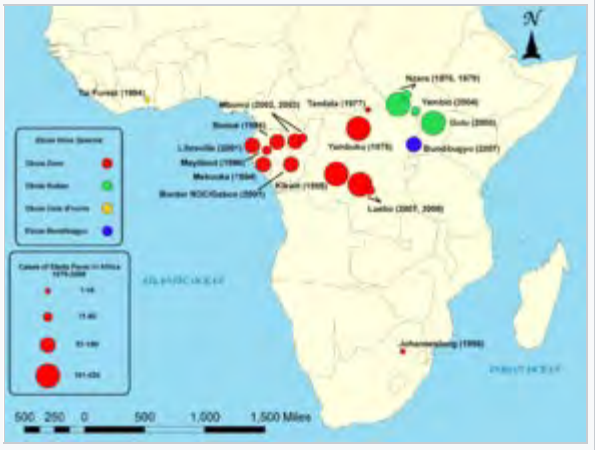
Ebola can stay in some body parts like the eyes,[123] breasts, and testicles after infection.[4][124] Sexual transmission after recovery has been suggested.[125][126] If sexual transmission occurs following recovery it is believed to be a rare event.[127] One case of a condition similar to meningitis has been reported many months after recovery as of Oct. 2015.[128]

A study of 44 survivors of the Ebola virus in Sierra Leone reported musculoskeletal pain in 70%, headache in 48% and eye problems in 14%.[129]

## Epidemiology

*For more about specific outbreaks, see List of Ebola outbreaks.*

The disease typically occurs in outbreaks in tropical regions of Sub-Saharan Africa.[1] From 1976 (when it was first identified) through 2013, the World Health Organization reported 1,716 confirmed cases.[1][8] The largest outbreak to date was the Ebola virus epidemic in West Africa, which had caused a large number of deaths in Guinea, Sierra Leone, and Liberia.[10][11]

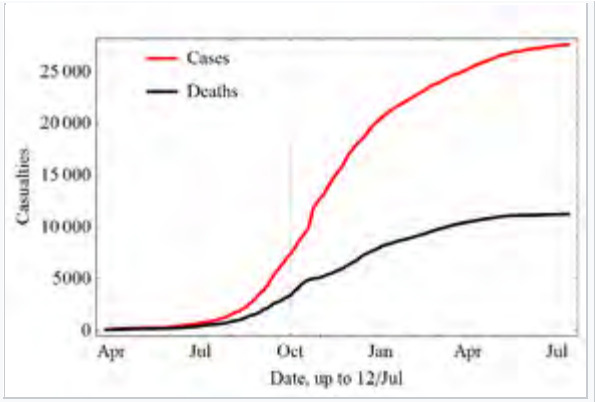


Cases of Ebola fever in Africa from 1979 to 2008

### 2013—2016 West African outbreak

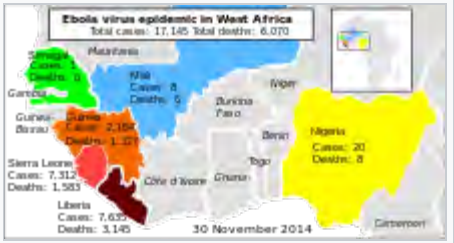
*Main article: West African Ebola virus epidemic*

In March 2014, the World Health Organization (WHO) reported a major Ebola outbreak in Guinea, a western African nation.[130] Researchers traced the outbreak to a one-year-old child who died December 2013.[131][132] The disease then rapidly spread to the neighboring countries of Liberia and Sierra Leone. It is the largest Ebola outbreak ever



Cases and deaths from April 2014 to July 2015 during the 2013–2015 outbreak

documented, and the first recorded in the region.[130] On 8 August 2014, the WHO declared the epidemic to be an international public health emergency. Urging the world to offer aid to the affected regions, the Director-General said, "Countries affected to date simply do not have the capacity to manage an outbreak of this size and complexity on their own. I urge the international community to provide this support on the most urgent basis possible."[133] By mid-August 2014, Doctors Without Borders reported the situation in Liberia's capital Monrovia as "catastrophic" and "deteriorating daily". They reported that fears of Ebola among staff members and patients had shut down much of the city's health system, leaving many people without treatment for other conditions.[134] In a 26 September statement, the WHO said, "The Ebola epidemic ravaging parts of West Africa is the most severe acute public health emergency seen in modern times. Never before in recorded history has a biosafety level four pathogen infected so many people so quickly, over such a broad geographical area, for so long."[135]



2014 Ebola virus epidemic in West Africa

Intense contact tracing and strict isolation techniques largely prevented further spread of the disease in the countries that had imported cases; this disease is still ongoing in Guinea. As of 8 May 2016, 28,616 suspected cases and 11,310 deaths have been reported;[9][136] however, the WHO has said that these numbers may be underestimated.[137] Because they work closely with the body fluids of infected patients, healthcare workers have been especially vulnerable to catching the disease; in August 2014, the WHO reported that ten percent of the dead have been healthcare workers.[138]

Checking for symptoms of Ebola in Sierra Leone, November 2014

In September 2014, it was estimated that the countries' capacity for treating Ebola patients was insufficient by the equivalent of 2,122 beds; by December there were a sufficient number of beds to treat and isolate all reported Ebola cases, although the uneven distribution of cases was resulting in serious shortfalls in some areas.[139] On 28 January 2015, the WHO reported that for the first time since the week ending 29 June 2014, there had been fewer than 100 new confirmed cases reported in a week in the three most-affected countries. The response to the epidemic then moved to a second phase, as the focus shifted from slowing transmission to ending the epidemic.[140] On 8 April 2015, the WHO reported a total of only 30 confirmed cases, the lowest weekly total since the third week of May 2014.[141]

On 29 December 2015, 42 days after the last person tested negative for a second time, Guinea was declared free of Ebola transmission.[142] At that time, a 90-day period of heightened surveillance was announced by that agency. "This is the first time that all three countries – Guinea, Liberia and Sierra Leone – have stopped the original chains of transmission ...", the organization stated in a news release.[143] A new case was detected in Sierra Leone on 14 January 2016.[144] However, the outbreak was declared no longer an emergency on 29 March 2016.[12]

## 2014 Ebola spread outside West Africa

*Main articles: Ebola virus cases in the United States, Ebola virus disease in Spain, and Ebola virus disease in the United Kingdom*

As of 15 October 2014, there have been 17 cases of Ebola treated outside Africa, four of whom have died.[145]

In early October, Teresa Romero, a 44-year-old Spanish nurse, contracted Ebola after caring for a priest who had been repatriated from West Africa. This was the first transmission of the virus to occur outside Africa.[146] On 20 October, it was announced that Teresa Romero had tested negative for the Ebola virus, suggesting that she may have recovered from Ebola infection.[147]

On 19 September, Eric Duncan flew from his native Liberia to Texas; 5 days later he began showing symptoms and visited a hospital but was sent home. His condition worsened and he returned to the hospital on 28 September, where he died on 8 October.[148] Health officials confirmed a diagnosis of Ebola on 30 September—the first case in the United States.[59] On 12 October, the CDC confirmed that a nurse in Texas, Nina Pham, who had treated Duncan was found to be positive for the Ebola virus, the first known case of the disease to be contracted in the United States.[149] On 15 October, a second Texas health-care worker who had treated Duncan was confirmed to have the virus.[150] Both of these people have since recovered.[151]

On 23 October, a doctor in New York City, who returned to the United States from Guinea after working with Doctors Without Borders, tested positive for Ebola. His case is unrelated to the Texas cases.[152] The person has recovered and was discharged from Bellevue Hospital Center on 11 November.[151] On 24 December 2014, a laboratory in Atlanta, Georgia reported that a technician had been exposed to Ebola.[153]

On 29 December 2014, Pauline Cafferkey, a British nurse who had just returned to Glasgow from Sierra Leone was diagnosed with Ebola at Glasgow's Gartnavel General Hospital.[154] After initial treatment in Glasgow, she was transferred by air to RAF Northolt, then to the specialist high-level isolation unit at the Royal Free Hospital in London for longer-term treatment.[155]

## 1995 to 2014

The second major outbreak occurred in Zaire (now the Democratic Republic of the Congo) in 1995, affecting 315 and killing 254.[1]

In 2000, Uganda had an outbreak affecting 425 and killing 224; in this case, the Sudan virus was found to be the Ebola species responsible for the outbreak.[1]

In 2003 there was an outbreak in the Republic of the Congo that affected 143 and killed 128, a death rate of 90 percent, the highest death rate of a genus *Ebolavirus* outbreak to date.[156]

In 2004 a Russian scientist died from Ebola after sticking herself with an infected needle.[157]

Between April and August 2007, a fever epidemic[158] in a four-village region[159] of the Democratic Republic of the Congo was confirmed in September to have cases of Ebola.[160] Many people who attended the recent funeral of a local village chief died.[159] The 2007 outbreak eventually affected 264 individuals and resulted in the deaths of 187.[1]

On 30 November 2007, the Uganda Ministry of Health confirmed an outbreak of Ebola in the Bundibugyo District in Western Uganda. After confirmation of samples tested by the United States National Reference Laboratories and the Centers for Disease Control, the World Health Organization confirmed the presence of a new species of genus *Ebolavirus*, which was tentatively named Bundibugyo.[161] The WHO reported 149 cases of this new strain and 37 of those led to deaths.[1]

The WHO confirmed two small outbreaks in Uganda in 2012. The first outbreak affected 7 people and resulted in the death of 4 and the second affected 24, resulting in the death of 17. The Sudan variant was responsible for both outbreaks.[1]

On 17 August 2012, the Ministry of Health of the Democratic Republic of the Congo reported an outbreak of the Ebola-Bundibugyo variant[162] in the eastern region.[163][164] Other than its discovery in 2007, this was

the only time that this variant has been identified as responsible for an outbreak. The WHO revealed that the virus had sickened 57 people and claimed 29 lives. The probable cause of the outbreak was tainted bush meat hunted by local villagers around the towns of Isiro and Viadana.[1][165]

In 2014, an outbreak of Ebola virus disease occurred in the Democratic Republic of the Congo (DRC). Genome-sequencing has shown that this outbreak was not related to the 2014–15 West Africa Ebola virus outbreak, but was the same EBOV species, the Zaire species.[166] It began in August 2014 and was declared over in November of that year with a total of 66 cases and 49 deaths.[167] This is the 7th outbreak in the DRC, three of which occurred during the period when the country was known as Zaire.[168]

## 1976

### Sudan outbreak

CDC worker incinerates medical waste from Ebola patients in Zaire in 1976.

The first known outbreak of EVD was identified only after the fact, occurring between June and November 1976 in Nzara, South Sudan,[27][169] (then part of Sudan) and was caused by Sudan virus (SUDV). The Sudan outbreak infected 284 people and killed 151. The first identifiable case in Sudan occurred on 27 June in a storekeeper in a cotton factory in Nzara, who was hospitalized on 30 June and died on 6 July.[22][170] Although the WHO medical staff involved in the Sudan outbreak were aware that they were dealing with a heretofore unknown disease, the actual "positive identification" process and the naming of the virus did not occur until some months later in the Democratic Republic of the Congo.[170]

### Zaire outbreak

*See also: Yambuku § Ebola outbreak*

On 26 August 1976, a second outbreak of EVD began in Yambuku, a small rural village in Mongala District in northern Zaire (now known as the Democratic Republic of the Congo).[171][172] This outbreak was caused by EBOV, formerly designated *Zaire ebolavirus*, which is a different member of the genus *Ebolavirus* than in the first Sudan outbreak. The first person infected with the disease was village school headmaster Mabalo Lokela, who began displaying symptoms on 26 August 1976.[173] Lokela had returned from a trip to Northern Zaire near the Central African Republic border, having visited the Ebola River between 12 and 22 August. He was originally believed to have malaria and was given quinine. However, his symptoms continued to worsen, and he was admitted to Yambuku Mission Hospital on 5 September. Lokela died on 8 September 14 days after he began displaying symptoms.[174][175]

Soon after Lokela's death, others who had been in contact with him also died, and people in the village of Yambuku began to panic. This led the country's Minister of Health along with Zaire President Mobutu Sese Seko to declare the entire region, including Yambuku and the country's capital, Kinshasa, a quarantine zone. No one was permitted to enter or leave the area, with roads, waterways, and airfields placed under martial law. Schools, businesses and social organizations were closed.[176] Researchers from the CDC, including Peter Piot, co-discoverer of Ebola, later arrived to assess the effects of the outbreak, observing that "the whole region was in panic."[177][178][179] Piot concluded that the Belgian nuns had inadvertently started the epidemic by giving unnecessary vitamin injections to pregnant women, without sterilizing the syringes and needles. The outbreak lasted 26 days, with the quarantine lasting 2 weeks. Among the reasons that researchers speculated caused the disease to disappear, were the precautions taken by locals, the quarantine of the area, and discontinuing the injections.[176]

During this outbreak, Dr. Ngoy Mushola recorded the first clinical description of EVD in Yambuku, where he

wrote the following in his daily log: "The illness is characterized with a high temperature of about 39 °C (102 °F), hematemesis, diarrhea with blood, retrosternal abdominal pain, prostration with 'heavy' articulations, and rapid evolution death after a mean of 3 days."[180]

The virus responsible for the initial outbreak, first thought to be Marburg virus, was later identified as a new type of virus related to marburgviruses. Virus strain samples isolated from both outbreaks were named as the "Ebola virus" after the Ebola River, located near the originally identified viral outbreak site in Zaire.[22] Reports conflict about who initially coined the name: either Karl Johnson of the American CDC team[181] or Belgian researchers.[182] Subsequently, a number of other cases were reported, almost all centered on the Yambuku mission hospital or having close contact with another case.[173] 318 cases and 280 deaths (an 88 percent fatality rate) occurred in Zaire.[183] Although it was assumed that the two outbreaks were connected, scientists later realized that they were caused by two distinct ebolaviruses, SUDV and EBOV.[172] The Zaire outbreak was contained with the help of the World Health Organization and transport from the Congolese air force, by quarantining villagers, sterilizing medical equipment, and providing protective clothing.

# Society and culture

*See also: Cultural effects of the Ebola crisis*

## Weaponization

*Ebolavirus* is classified as a biosafety level 4 agent, as well as a Category A bioterrorism agent by the Centers for Disease Control and Prevention.[76][184] It has the potential to be weaponized for use in biological warfare,[185][186] and was investigated by Biopreparat for such use, but might be difficult to prepare as a weapon of mass destruction because the virus becomes ineffective quickly in open air.[187] Fake emails pretending to be Ebola information from the WHO or the Mexican Government have in 2014 been misused to spread computer malware.[188] The BBC reported in 2015 that, "North Korean state media has suggested the disease was created by the US military as a biological weapon."[189]

## Literature

Richard Preston's 1995 best-selling book, *The Hot Zone*, dramatized the Ebola outbreak in Reston, Virginia.[190]

William Close's 1995 *Ebola: A Documentary Novel of Its First Explosion* and 2002 *Ebola: Through the Eyes of the People* focused on individuals' reactions to the 1976 Ebola outbreak in Zaire.[191]

Tom Clancy's 1996 novel, *Executive Orders*, involves a Middle Eastern terrorist attack on the United States using an airborne form of a deadly Ebola virus strain named "Ebola Mayinga" (see Mayinga N'Seka).[192][193]

As the Ebola virus epidemic in West Africa developed in 2014, a number of popular self-published and well-reviewed books containing sensational and misleading information about the disease appeared in electronic and printed formats. The authors of some such books admitted that they lacked medical credentials and were not technically qualified to give medical advice. The World Health Organization and the United Nations stated that such misinformation had contributed to the spread of the disease.[194]

# Other animals

## Wild animals

Ebola has a high mortality among primates.[113] Frequent outbreaks of Ebola may have resulted in the deaths of 5,000 gorillas.[195] Outbreaks of Ebola may have been responsible for an 88 percent decline in

tracking indices of observed chimpanzee populations in 420 square kilometer Lossi Sanctuary between 2002 and 2003.[196] Transmission among chimpanzees through meat consumption constitutes a significant risk factor, whereas contact between the animals, such as touching dead bodies and grooming, is not.[197]

Recovered carcasses from gorillas contain multiple Ebola virus strains, which suggest multiple introductions of the virus. Bodies decompose quickly and carcasses are not infectious after 3 to 4 days. Contact between gorilla groups is rare, suggesting transmission among gorilla groups is unlikely, and that outbreaks result from transmission between viral reservoir and animal populations.[196]

### Domestic animals

In 2012 it was demonstrated that the virus can travel without contact from pigs to nonhuman primates, although the same study failed to achieve transmission in that manner between primates.[68][198]

Dogs may become infected with EBOV but not develop symptoms. Dogs in some parts of Africa scavenge for food, and they sometimes eat EBOV-infected animals and also the corpses of humans. A 2005 survey of dogs during an EBOV outbreak found that although they remain asymptomatic, about 32 percent of dogs closest to an outbreak showed a seroprevalence for EBOV versus 9 percent of those farther away.[199] The authors concluded that there were "potential implications for preventing and controlling human outbreaks."

### Reston virus

*For more about the outbreak in Virginia, US, see Reston virus.*

In late 1989, Hazelton Research Products' Reston Quarantine Unit in Reston, Virginia, suffered an outbreak of fatal illness amongst certain lab monkeys. This lab outbreak was initially diagnosed as simian hemorrhagic fever virus (SHFV) and occurred amongst a shipment of crab-eating macaque monkeys imported from the Philippines. Hazelton's veterinary pathologist sent tissue samples from dead animals to the United States Army Medical Research Institute of Infectious Diseases (USAMRIID) at Fort Detrick, Maryland, where an ELISA test indicated the antibodies present in the tissue were a response to Ebola virus and not SHFV.[200] An electron microscopist from USAMRIID discovered filoviruses similar in appearance to Ebola in the tissue samples sent from Hazelton Research Products' Reston Quarantine Unit.[201]

A US Army team headquartered at USAMRIID euthanized the surviving monkeys, and brought all the monkeys to Ft. Detrick for study by the Army's veterinary pathologists and virologists, and eventual disposal under safe conditions.[200] Blood samples were taken from 178 animal handlers during the incident.[202] Of those, six animal handlers eventually seroconverted, including one who had cut himself with a bloody scalpel.[77][203] Despite its status as a Level 4 organism and its apparent pathogenicity in monkeys, when the handlers did not become ill, the CDC concluded that the virus had a very low pathogenicity to humans.[203][204]

The Philippines and the United States had no previous cases of Ebola infection, and upon further isolation, researchers concluded it was another strain of Ebola, or a new filovirus of Asian origin, which they named *Reston ebolavirus* (RESTV) after the location of the incident.[200] Reston virus (RESTV) can be transmitted to pigs.[68] Since the initial outbreak it has since been found in nonhuman primates in Pennsylvania, Texas, and Italy,[205] where the virus had infected pigs.[206] According to the WHO, routine cleaning and disinfection of pig (or monkey) farms with sodium hypochlorite or detergents should be effective in inactivating the *Reston ebolavirus*. Pigs that have been infected with RESTV tend to show symptoms of the disease.

## Research

### Treatments

*Main article: Ebola virus disease treatment research*

As of July 2015, there is no medication which has been proven to be safe and effective in treating Ebola. By the time the Ebola virus epidemic in West Africa began in 2013, there were at least nine different candidate treatments. Several trials were conducted in late 2014 and early 2015, but some were abandoned due to lack of efficacy or lack of people to study.[*citation needed*]

Researchers looking at slides of cultures of cells that make monoclonal antibodies. These are grown in a lab and the researchers are analyzing the products to select the most promising.

## Vaccines

*Main article: Ebola vaccine*

Many Ebola vaccine candidates had been developed in the decade prior to 2014,[207] but as of November 2014, none had been approved for use in humans in the United States.[208][209][210] In December 2016, Ebola virus disease was found to be 70–100% prevented by rVSV-ZEBOV vaccine, making it the first proven vaccine against the disease.[211][212][213]

## Diagnostic tests

One issue which hinders control of Ebola is that diagnostic tests which are currently available require specialized equipment and highly trained personnel. Since there are few suitable testing centers in West Africa, this leads to delay in diagnosis. In December 2014, a conference in Geneva will aim to work out which diagnostic tools could be to identify Ebola reliably and more quickly. The meeting, convened by the WHO and the non-profit Foundation for Innovative New Diagnostics, seeks to identify tests that can be used by untrained staff, do not require electricity or can run on batteries or solar power and use reagents that can withstand temperatures of 40 °C.[214]

On 29 November 2014, a new 15-minute Ebola test was reported that if successful, "not only gives patients a better chance of survival, but it prevents transmission of the virus to other people." The new equipment, about the size of a laptop and solar-powered, allows testing to be done in remote areas. The equipment is currently being tested in Guinea.[215]

On 29 December 2014, the FDA approved LightMix (R) Ebola Zaire rRT-PCR Test on patients with symptoms of Ebola. The report indicates it could help health care authorities around the world.[216]

# Hepatitis A

From Wikipedia, the free encyclopedia

**Hepatitis A** (formerly known as **infectious hepatitis**) is an infectious disease of the liver caused by the hepatitis A virus (HAV).[1] Many cases have few or no symptoms, especially in the young.[2] The time between infection and symptoms, in those who develop them, is between two and six weeks.[3] When symptoms occur, they typically last eight weeks and may include nausea, vomiting, diarrhea, jaundice, fever, and abdominal pain.[2] Around 10–15% of people experience a recurrence of symptoms during the six months after the initial infection.[2] Acute liver failure may rarely occur, with this being more common in the elderly.[2]

It is usually spread by eating food or drinking water contaminated with infected feces.[2] Shellfish which have not been sufficiently cooked are a relatively common source.[4] It may also be spread through close contact with an infectious person.[2] While children often do not have symptoms when infected, they are still able to infect others.[2] After a single infection, a person is immune for the rest of his or her life.[5] Diagnosis requires blood testing, as the symptoms are similar to those of a number of other diseases.[2] It is one of five known hepatitis viruses: A, B, C, D, and E.

The hepatitis A vaccine is effective for prevention.[2][6] Some countries recommend it routinely for children and those at higher risk who have not previously been vaccinated.[2][7] It appears to be effective for life.[2] Other preventive measures include hand washing and properly cooking food.[2] No specific treatment is available, with rest and medications for nausea or diarrhea recommended on an as-needed basis.[2] Infections usually resolve completely and without ongoing liver disease.[2] Treatment of acute liver failure, if it occurs, is with liver transplantation.[2]

Globally, around 1.4 million symptomatic cases occur each year[2] and about 102 million infections (symptomatic and asymptomatic).[8] It is more common in regions of the world with poor sanitation and not enough safe water.[7] In the developing world about 90% of children have been infected by age 10 and thus are immune by adulthood.[7] It often occurs in outbreaks in moderately developed countries where children are not exposed when young and vaccination is not widespread.[7] Acute hepatitis A resulted in 102,000 deaths in 2010.[9] World Hepatitis Day occurs each year on July 28 to bring awareness to viral hepatitis.[7]

## Signs and symptoms [edit]

Early symptoms of hepatitis A infection can be mistaken for influenza, but some sufferers, especially children, exhibit no symptoms at all. Symptoms typically appear 2 to 6 weeks (the incubation period) after the initial infection.[10] 90% of children do not have symptoms. The time between infection and symptoms, in those who develop them, is between two and six weeks with an average of 28 days.[3]

The risk for symptomatic infection is directly related to age, with more than 80% of adults having symptoms compatible with acute viral hepatitis and the majority of children having either asymptomatic or unrecognized infections.[11]

Symptoms usually last less than 2 months, although some people can be ill for as long as 6 months:[12]

- Fatigue
- Fever
- Nausea
- Appetite loss
- Jaundice, a yellowing of the skin or the whites of the eyes owing to hyperbilirubinemia
- Bile is removed from the bloodstream and excreted in the urine, giving it a dark amber colour
- Diarrhea
- Light, or clay-coloured faeces (acholic faeces)
- Abdominal discomfort[13]

## Virology [edit]

### Taxonomy [edit]

*Hepatovirus A* is a species of virus in the order *Picornavirales* in the family *Picornaviridae* and is the type species of the genus *Hepatovirus*. Humans and vertebrates serve as natural hosts.[14][15]

At least 13 additional species of the genus *Hepatovirus* have now been identified.[16] These species infect bats, rodents, hedgehogs and shrews. Phylogenetic analysis suggests a rodent origin for Hepatitis A.

A species of hepatovirus (Phopivirus) has been isolated from a seal.[17] This species shared a common ancestor with hepatitis A virus about 1800

years ago.

Another hepatovirus - Marmota Himalayana hepatovirus - has been isolated from the woodchuck *Marmota himalayana*.[18] This species appears to have had a common ancestor with the primate species ~1000 years ago.

## Genotypes [edit]

One serotype and seven different genetic groups (four humans and three simians) have been described.[19] The human genotypes are numbered I-III. Six subtypes have been described (IA, IB, IIA, IIB, IIIA, IIIB). The simian genotypes have been numbered IV-VI. A single isolate of genotype VII isolated from a human has also been described.[20] Genotype III has been isolated from both humans and owl monkeys. Most human isolates are of genotype I.[21] Of the type I isolates subtype IA accounts for the majority.

The mutation rate in the genome has been estimated to be 1.73–9.76 x $10^{-4}$ nucleotide substitution per site per year.[22][23] The human strains appear to have diverged from the simian about 3600 years ago.[23] The mean age of genotypes III and IIIA strains has been estimated to be 592 and 202 years, respectively.[23]

## Structure [edit]

Hepatovirus A is a picornavirus; it is nonenveloped and contains a single-stranded RNA packaged in a protein shell.[19] There is only one serotype of the virus, but multiple genotypes exist.[24] Codon use within the genome is biased and unusually distinct from its host. It also has a poor internal ribosome entry site.[25] In the region that codes for the HAV capsid, highly conserved clusters of rare codons restrict antigenic variability.[14][26]

| Genus | Structure | Symmetry | Capsid | Genomic arrangement | Genomic segmentation |
|---|---|---|---|---|---|
| Hepatovirus | Icosahedral | Pseudo T=3 | Nonenveloped | Linear | Monopartite |

## Life cycle [edit]

Humans and vertebrates serve as the natural hosts. Transmission routes are fecal-oral and blood.[14]

Following ingestion, HAV enters the bloodstream through the epithelium of the oropharynx or intestine.[27] The blood carries the virus to its target, the liver, where it multiplies within hepatocytes and Kupffer cells (liver macrophages). Viral replication is cytoplasmic. Entry into the host cell is achieved by attachment of the virus to host receptors, which mediates endocytosis. Replication follows the positive-stranded RNA virus replication model. Positive-stranded RNA virus transcription is the method of transcription. Translation takes place by viral initiation. The virus exits the host cell by lysis and viroporins. Virions are secreted into the bile

and released in stool. HAV is excreted in large quantities about 11 days prior to the appearance of symptoms or anti-HAV IgM antibodies in the blood. The incubation period is 15–50 days and mortality is less than 0.5%.

Within the liver hepatocytes, the RNA genome is released from the protein coat and is translated by the cell's own ribosomes. Unlike other picornaviruses, this virus requires an intact eukaryote initiating factor 4G (eIF4G) for the initiation of translation.[28] The requirement for this factor results in an inability to shut down host protein synthesis, unlike other picornaviruses. The virus must then inefficiently compete for the cellular translational machinery which may explain its poor growth in cell culture. Presumably for this reason, the virus has strategically adopted a naturally highly deoptimized codon usage with respect to that of its cellular host. Precisely how this strategy works is not quite clear yet.

No apparent virus-mediated cytotoxicity occurs, presumably because of the virus' own requirement for an intact eIF4G and liver pathology is likely immune-mediated.

| Genus | Host details | Tissue tropism | Entry details | Release details | Replication site | Assembly site | Transmission |
|---|---|---|---|---|---|---|---|
| Hepatovirus | Humans; vertebrates | Liver | Cell receptor endocytosis | Lysis | Cytoplasm | Cytoplasm | Oral-fecal; blood |

## Transmission [edit]

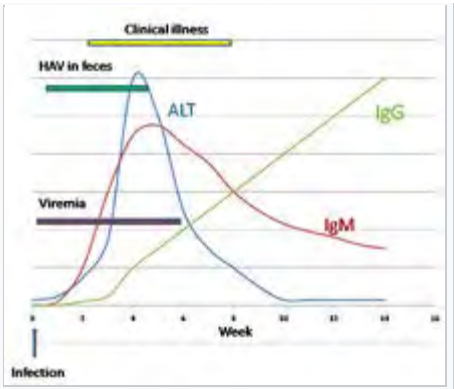
The virus spreads by the fecal–oral route, and infections often occur in conditions of poor sanitation and overcrowding. Hepatitis A can be transmitted by the parenteral route, but very rarely by blood and blood products. Food-borne outbreaks are not uncommon,[29] and ingestion of shellfish cultivated in polluted water is associated with a high risk of infection.[30] About 40% of all acute viral hepatitis is caused by HAV.[27] Infected individuals are infectious prior to onset of symptoms, roughly 10 days following infection. The virus is resistant to detergent, acid (pH 1), solvents (e.g., ether, chloroform), drying, and temperatures up to 60 °C. It can survive for months in fresh and salt water. Common-source (e.g., water, restaurant) outbreaks are typical. Infection is common in children in developing countries, reaching 100% incidence, but following infection, lifelong immunity results. HAV can be inactivated by chlorine treatment (drinking water), formalin (0.35%, 37 °C, 72 hours), peracetic acid (2%, 4 hours), beta-propiolactone (0.25%, 1 hour), and UV radiation (2 μW/cm$^2$/min).

In developing countries, and in regions with poor hygiene standards, the rates of infection with this virus are high[31] and the illness is usually contracted in early childhood. As incomes rise and access to clean water increases, the incidence of HAV decreases.[32] In developed countries, though, the infection is contracted primarily by susceptible young adults, most of whom are infected with the virus during trips to countries with a high incidence of the disease[3] or through contact with infectious persons.

Humans are the only natural reservoir of the virus. There are no known insect or other animal vectors that can transmit the virus. A chronic HAV state has not been reported.[33]

# Diagnosis [edit]

Although HAV is excreted in the feces towards the end of the incubation period, specific diagnosis is made by the detection of HAV-specific IgM antibodies in the blood.[34] IgM antibody is only present in the blood following an acute hepatitis A infection. It is detectable from one to two weeks after the initial infection and persists for up to 14 weeks. The presence of IgG antibodies in the blood means the acute stage of the illness is past and the person is immune to further infection. IgG antibodies to HAV are also found in the blood following vaccination, and tests for immunity to the virus are based on the detection of this antibody.[34]



Serum IgG, IgM and ALT following hepatovirus A infection

During the acute stage of the infection, the liver enzyme alanine transferase (ALT) is present in the blood at levels much higher than is normal. The enzyme comes from the liver cells damaged by the virus.[35]

Hepatovirus A is present in the blood (viremia) and feces of infected people up to two weeks before clinical illness develops.[35]

## Prevention [edit]

*For information about the vaccine, its properties, and its application, see Hepatitis A vaccine.*

Hepatitis A can be prevented by vaccination, good hygiene, and sanitation.[1][36]

The two types of vaccines are one containing inactivated hepatitis A virus, and another containing a live but attenuated virus.[37] Both provide active immunity against a future infection. The vaccine protects against HAV in more than 95% of cases for longer than 25 years.[38] In the US, the vaccine was first used in 1996 for children in high-risk areas, and in 1999 it was spread to areas with elevating levels of infection.[39]

The vaccine is given by injection. An initial dose provides protection starting two to four weeks after vaccination; the second booster dose, given six to 12 months later, provides protection for over 20 years.[39]

### Vaccination programmes [edit]

The vaccine was introduced in 1992 and was initially recommended for persons at high risk. Since then, Bahrain and Israel have embarked on eradication programmes.[40] Australia, China, Belarus, Italy, Spain, and the United States have started similar programmes. The incidence of hepatitis A where widespread vaccination has been practised has decreased dramatically. In China and the United States, the incidence of hepatitis A has decreased by 90% since 1990.[41][42]

In the United States, vaccination of children is recommended at 1 and 2 years of age.[2] It is also recommended in those who have not been previously immunized and who have been exposed or are likely to be exposed due to travel.[2]

## Treatment [edit]

There is no specific treatment for hepatitis A. Recovery from symptoms following infection may be slow and may take several weeks or months. Therapy is aimed at maintaining comfort and adequate nutritional balance, including replacement of fluids that are lost from vomiting and diarrhoea.[13]

## Prognosis [edit]

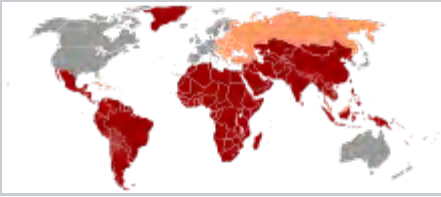
In the United States in 1991, the mortality rate for hepatitis A was four deaths per 1000 cases for the general population, but a higher at 17.5 per 1000 in those aged 50 and over. The risk of death from acute

liver failure following HAV infection increases with age and when the person has underlying chronic liver disease.

Young children who are infected with hepatitis A typically have a milder form of the disease, usually lasting from 1–3 weeks, whereas adults tend to experience a much more severe form of the disease.[29]

# Epidemiology [edit]

Globally, symptomatic HAV infections are believed to occur in around 1.4 million people a year.[2] About 102 million infections (asymptomatic and symptomatic) occurred all together in 2013.[8] In 2010, acute hepatitis A resulted in 102,000 deaths, which is slightly up from 99,000 in 1990.[9] Developed countries have low circulating levels of hepatovirus A while developing countries have higher levels of circulation.[43] Most adolescents and adults in developing countries have already had the disease, thus are immune.[43] Adults in midlevel countries may be at risk of disease with the potential of being exposed.[43]



Hepatitis A distribution 2005

## Countries [edit]

Over 30,000 cases of hepatitis A were reported to the CDC in the US in 1997, but the number has since dropped to less than 2,000 cases reported per year.[44]

The most widespread hepatitis A outbreak in the 2003 United States hepatitis outbreak afflicted at least 640 people (killing four) in northeastern Ohio and southwestern Pennsylvania in late 2003. The outbreak was blamed on tainted green onions at a restaurant in Monaca, Pennsylvania.[45][46] In 1988, more than 300,000 people in Shanghai, China, were infected with HAV after eating clams (*Anadara subcrenata*) from a contaminated river.[27] In June 2013, frozen berries sold by US retailer Costco and purchased by around 240,000 people were the subject of a recall, after at least 158 people were infected with HAV, 69 of whom were hospitalized.[47][48] In April 2016, frozen berries sold by Costco were once again the subject of a recall, after at least 13 people in Canada were infected with HAV, three of whom were hospitalized.[49] In Australia in February 2015, a recall of frozen berries was issued after at least 19 people contracted the illness following their consumption of the product.[50]

[edit on Wikidata]

**Hepatitis B** is an infectious disease caused by the hepatitis B virus (HBV) which affects the liver. It can cause both acute and chronic infections. Many people have no symptoms during the initial infection. Some develop a rapid onset of sickness with vomiting, yellowish skin, tiredness, dark urine and abdominal pain.[1] Often these symptoms last a few weeks and rarely does the initial infection result in death.[1][2] It may take 30 to 180 days for symptoms to begin.[1] In those who get infected around the time of birth 90% develop chronic hepatitis B while less than 10% of those infected after the age of five do.[3] Most of those with chronic disease have no symptoms; however, cirrhosis and liver cancer may eventually develop.[4] These complications result in the death of 15 to 25% of those with chronic disease.[1]

The virus is transmitted by exposure to infectious blood or body fluids. Infection around the time of birth or from contact with other people's blood during childhood is the most frequent method by which hepatitis B is acquired in areas where the disease is common. In areas where the disease is rare, intravenous drug use and sexual intercourse are the most frequent routes of infection.[1] Other risk factors include working in healthcare, blood transfusions, dialysis, living with an infected person, travel in countries where the infection rate is high, and living in an institution.[1][3] Tattooing and acupuncture led to a significant number of cases in the 1980s; however, this has become less common with improved sterility.[5] The hepatitis B viruses cannot be spread by holding hands, sharing eating utensils, kissing, hugging, coughing, sneezing, or breastfeeding.[3] The infection can be diagnosed 30 to 60 days after exposure. Diagnosis is typically by testing the blood for parts of the virus and for antibodies against the virus.[1] It is one of five known hepatitis viruses: A, B, C, D, and E.

The infection has been preventable by vaccination since 1982.[1][6] Vaccination is recommended by the World Health Organization in the first day of life if possible. Two or three more doses are required at a later time for full effect. This vaccine works about 95% of the time.[1] About 180 countries gave the vaccine as part of national programs as of 2006.[7] It is also recommended that all blood be tested for hepatitis B before transfusion and condoms be used to prevent infection. During an initial infection, care is based on the symptoms that a person has. In those who develop chronic disease, antiviral medication such as tenofovir or interferon may be useful; however, these drugs are expensive. Liver transplantation is [1]

sometimes used for cirrhosis.

About a third of the world population has been infected at one point in their lives, including 240 million to 350 million who have chronic infections.[1][8] Another 129 million new infections occurred in 2013.[9] Over 750,000 people die of hepatitis B each year.[1] About 300,000 of these are due to liver cancer.[10] The disease is now only common in East Asia and sub-Saharan Africa where between 5 and 10% of adults are chronically infected. Rates in Europe and North America are less than 1%.[1] It was originally known as "serum hepatitis".[11] Research is looking to create foods that contain HBV vaccine.[12] The disease may affect other great apes as well.[13]

**Contents**

## Signs and symptoms [edit]

Acute infection with hepatitis B virus is associated with acute viral hepatitis, an illness that begins with general ill health, loss of appetite, nausea, vomiting, body aches, mild fever, and dark urine, and then progresses to development of jaundice. It has been noted that itchy skin has been an indication as a possible symptom of all hepatitis virus types. The illness lasts for a few weeks and then gradually improves in most affected people. A few people may have a more severe form of liver disease known as (fulminant hepatic failure) and may die as a result. The infection may be entirely asymptomatic and may go unrecognized.[14]

Chronic infection with hepatitis B virus either may be asymptomatic or may be associated with a chronic inflammation of the liver (chronic hepatitis), leading to cirrhosis over a period of several years. This type of infection dramatically increases the incidence of hepatocellular carcinoma (HCC; liver cancer). Across Europe, hepatitis B and C cause approximately 50% of hepatocellular carcinomas.[15][16] Chronic carriers are encouraged to avoid consuming alcohol as it increases their risk for cirrhosis and liver cancer. Hepatitis B virus has been linked to the development of membranous glomerulonephritis (MGN).[17]

Symptoms outside of the liver are present in 1–10% of HBV-infected people and include serum-sickness–like syndrome, acute necrotizing vasculitis (polyarteritis nodosa), membranous glomerulonephritis, and papular acrodermatitis of childhood (Gianotti–Crosti syndrome).[18][19] The serum-sickness–like syndrome occurs in the setting of acute hepatitis B, often preceding the onset of jaundice.[20] The clinical features are fever, skin rash, and polyarteritis. The symptoms often subside shortly after the onset of jaundice but can persist throughout the duration of acute hepatitis B.[21] About 30–50% of people with acute necrotizing vasculitis (polyarteritis nodosa) are HBV carriers.[22] HBV-associated nephropathy has been described in adults but is more common in children.[23][24] Membranous glomerulonephritis is the most common

form.[20] Other immune-mediated hematological disorders, such as essential mixed cryoglobulinemia and aplastic anemia.[21]

# Cause [edit]

## Transmission [edit]

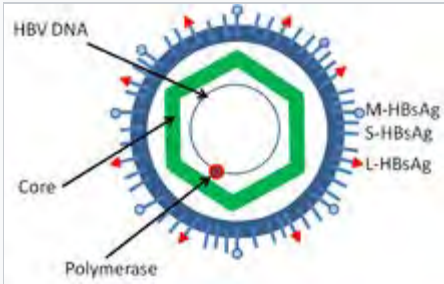
Transmission of hepatitis B virus results from exposure to infectious blood or body fluids containing blood. It is 50 to 100 times more infectious than HIV.[25] Possible forms of transmission include sexual contact,[26] blood transfusions and transfusion with other human blood products,[27] re-use of contaminated needles and syringes,[28] and vertical transmission from mother to child (MTCT) during childbirth. Without intervention, a mother who is positive for HBsAg has a 20% risk of passing the infection to her offspring at the time of birth. This risk is as high as 90% if the mother is also positive for HBeAg. HBV can be transmitted between family members within households, possibly by contact of nonintact skin or mucous membrane with secretions or saliva containing HBV.[29] However, at least 30% of reported hepatitis B among adults cannot be associated with an identifiable risk factor.[30] Breastfeeding after proper immunoprophylaxis does not appear to contribute to mother-to-child-transmission (MTCT) of HBV.[31] The virus may be detected within 30 to 60 days after infection and can persist and develop into chronic hepatitis B. The incubation period of the hepatitis B virus is 75 days on average but can vary from 30 to 180 days.[32]

## Virology [edit]

*Main article: Hepatitis B virus*

## Structure [edit]

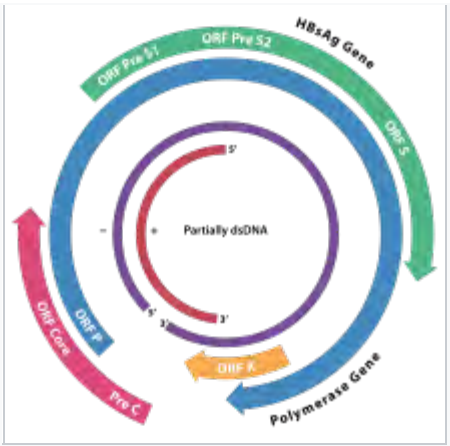
Hepatitis B virus (HBV) is a member of the hepadnavirus family.[33] The virus particle (virion) consists of an outer lipid envelope and an icosahedral nucleocapsid core composed of protein. These virions are 30–42 nm in diameter. The nucleocapsid encloses the viral DNA and a DNA polymerase that has reverse transcriptase activity.[34] The outer envelope contains embedded proteins that are involved in viral binding of, and entry into, susceptible cells. The virus is one of the smallest enveloped animal viruses, and the 42 nm virions, which are capable of infecting liver cells known as hepatocytes, are referred to as "Dane particles".[35] In addition to the Dane particles, filamentous and spherical bodies lacking a core can be found in the serum of infected individuals. These particles are not infectious and are composed of the lipid and protein that forms part of the surface of the virion, which is called the surface antigens (HBsAg), and is produced in excess during the life cycle of the virus.[36]



The structure of hepatitis B virus

## Genome [edit]

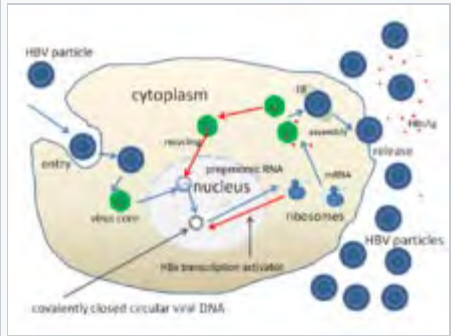
The genome of HBV is made of circular DNA, but it is unusual because the DNA is not fully double-stranded. One end of the full length strand is linked to the viral DNA polymerase. The genome is 3020–3320 nucleotides long (for the full-length strand) and 1700–2800 nucleotides long (for the short length-strand).[37] The negative-sense (non-coding) is complementary to the viral mRNA. The viral DNA is found in the nucleus soon after infection of the cell. The partially double-stranded DNA is rendered fully double-stranded by completion of the (+) sense strand and removal of a protein molecule from the (−) sense strand and



The genome organisation of HBV. The genes overlap.

a short sequence of RNA from the (+) sense strand. Non-coding bases are removed from the ends of the (−) sense strand and the ends are rejoined. There are four known genes encoded by the genome, called C, X, P, and S. The core protein is coded for by gene C (HBcAg), and its start codon is preceded by an upstream in-frame AUG start codon from which the pre-core protein is produced. HBeAg is produced by proteolytic processing of the pre-core protein. In some rare strains of the virus known as Hepatitis B virus precore mutants, no HBeAg is present.[38] The DNA polymerase is encoded by gene P. Gene S is the gene that codes for the surface antigen (HBsAg). The HBsAg gene is one long open reading frame but contains three in frame "start" (ATG) codons that divide the gene into three sections, pre-S1, pre-S2, and S. Because of the multiple start codons, polypeptides of three different sizes called large (the order from surface to the inside: pre-S1, pre-S2, and S ), middle (pre-S2, S), and small (S) [39] are produced.[40] The function of the protein coded for by gene X is not fully understood but it is associated with the development of liver cancer. It stimulates genes that promote cell growth and inactivates growth regulating molecules.[41]

## Pathogenesis [edit]



Hepatitis B virus replication

The life cycle of hepatitis B virus is complex. Hepatitis B is one of a few known pararetroviruses: non-retroviruses that still use reverse transcription in their replication process. The virus gains entry into the cell by binding to NTCP [42] on the surface and being endocytosed. Because the virus multiplies via RNA made by a host enzyme, the viral genomic DNA has to be transferred to the cell nucleus by host proteins called chaperones. The partially double-stranded viral DNA is then made fully double stranded by a viral polymerase and transformed into covalently closed circular DNA (cccDNA). This cccDNA serves as a template for transcription of four viral mRNAs by host RNA polymerase. The largest mRNA, (which is longer than the viral genome), is used to make the new copies of the genome and to make the capsid core protein and the viral DNA polymerase. These four viral transcripts undergo additional processing and go on to form progeny virions that are released from the cell or returned to the nucleus and re-cycled to produce even more copies.[40][43] The long mRNA is then transported back to the cytoplasm where the virion P protein (the DNA polymerase) synthesizes DNA via its reverse transcriptase activity.

## Serotypes and genotypes [edit]

The virus is divided into four major serotypes (adr, adw, ayr, ayw) based on antigenic epitopes presented on its envelope proteins, and into eight major genotypes (A–H). The genotypes have a distinct geographical distribution and are used in tracing the evolution and transmission of the virus. Differences between genotypes affect the disease severity, course and likelihood of complications, and response to treatment and possibly vaccination.[44][45] There are two other genotypes I and J but they are not universally accepted as of 2015[46]

Genotypes differ by at least 8% of their sequence and were first reported in 1988 when six were initially described (A–F).[47] Two further types have since been described (G and H).[48] Most genotypes are now

divided into subgenotypes with distinct properties.[49]

## Mechanisms [edit]

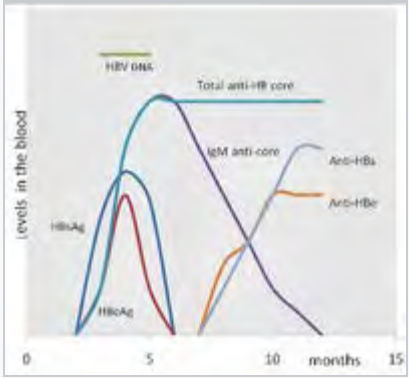
Hepatitis B virus primarily interferes with the functions of the liver by replicating in hepatocytes. A functional receptor is NTCP.[42] There is evidence that the receptor in the closely related duck hepatitis B virus is carboxypeptidase D.[50][51] The virions bind to the host cell via the preS domain of the viral surface antigen and are subsequently internalized by endocytosis. HBV-preS-specific receptors are expressed primarily on hepatocytes; however, viral DNA and proteins have also been detected in extrahepatic sites, suggesting that cellular receptors for HBV may also exist on extrahepatic cells.[52]

During HBV infection, the host immune response causes both hepatocellular damage and viral clearance. Although the innate immune response does not play a significant role in these processes, the adaptive immune response, in particular virus-specific cytotoxic T lymphocytes(CTLs), contributes to most of the liver injury associated with HBV infection. CTLs eliminate HBV infection by killing infected cells and producing antiviral cytokines, which are then used to purge HBV from viable hepatocytes.[53] Although liver damage is initiated and mediated by the CTLs, antigen-nonspecific inflammatory cells can worsen CTL-induced immunopathology, and platelets activated at the site of infection may facilitate the accumulation of CTLs in the liver.[54]

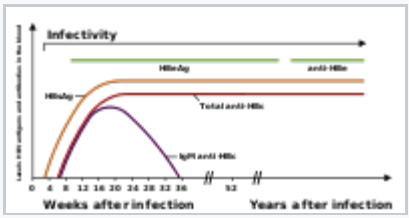
## Diagnosis [edit]

The tests, called assays, for detection of hepatitis B virus infection involve serum or blood tests that detect either viral antigens (proteins produced by the virus) or antibodies produced by the host. Interpretation of these assays is complex.[55]

The hepatitis B surface antigen (HBsAg) is most frequently used to screen for the presence of this infection. It is the first detectable viral antigen to appear during infection. However, early in an infection, this antigen may not be present and it may be undetectable later in the infection as it is being cleared by the host. The infectious virion contains an inner "core particle" enclosing viral genome. The icosahedral core particle is made of 180 or 240 copies of the core protein, alternatively known as hepatitis B core antigen, or HBcAg. During this 'window' in which the host remains infected but is successfully clearing the virus, IgM antibodies specific to the hepatitis B core antigen (*anti-HBc IgM*) may be the only serological evidence of disease. Therefore, most hepatitis B diagnostic panels contain HBsAg and total anti-HBc (both IgM and IgG).[56]



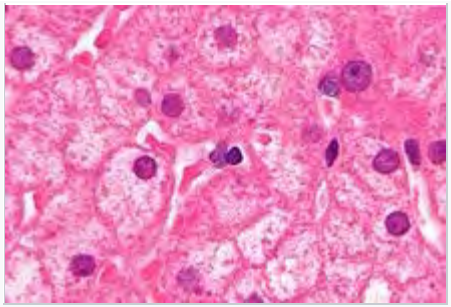
Hepatitis B viral antigens and antibodies detectable in the blood following acute infection



Hepatitis B viral antigens and antibodies detectable in the blood of a chronically infected person

Shortly after the appearance of the HBsAg, another antigen called hepatitis B e antigen (HBeAg) will appear. Traditionally, the presence of HBeAg in a host's serum is associated with much higher rates of viral replication and enhanced infectivity; however, variants of the hepatitis B virus do not produce the 'e' antigen, so this rule does not always hold true.[57] During the natural course of an infection, the HBeAg may be cleared, and antibodies to the 'e' antigen (*anti-HBe*) will arise immediately afterwards. This conversion is usually associated with a dramatic decline in viral replication.

If the host is able to clear the infection, eventually the HBsAg will become undetectable and will be followed by IgG antibodies to the hepatitis B surface antigen and core antigen (*anti-HBs* and *anti HBc IgG*).[33] The time between the removal of the HBsAg and the appearance of anti-HBs



Ground glass hepatocytes as seen in a chronic hepatitis B liver biopsy. H&E stain

is called the window period. A person negative for HBsAg but positive for anti-HBs either has cleared an infection or has been vaccinated previously.

Individuals who remain HBsAg positive for at least six months are considered to be hepatitis B carriers.[58] Carriers of the virus may have chronic hepatitis B, which would be reflected by elevated serum alanine aminotransferase (ALT) levels and inflammation of the liver, if they are in the immune clearance phase of chronic infection. Carriers who have seroconverted to HBeAg negative status, in particular those who acquired the infection as adults, have very little viral multiplication and hence may be at little risk of long-term complications or of transmitting infection to others.[59]

PCR tests have been developed to detect and measure the amount of HBV DNA, called the viral load, in clinical specimens. These tests are used to assess a person's infection status and to monitor treatment.[60] Individuals with high viral loads, characteristically have ground glass hepatocytes on biopsy.

# Prevention [edit]

*Main article: Hepatitis B vaccine*

Vaccines for the prevention of hepatitis B have been routinely recommended for infants since 1991 in the United States.[61] Most vaccines are given in three doses over a course of months. A protective response to the vaccine is defined as an anti-HBs antibody concentration of at least 10 mIU/ml in the recipient's serum. The vaccine is more effective in children and 95 percent of those vaccinated have protective levels of antibody. This drops to around 90% at 40 years of age and to around 75 percent in those over 60 years. The protection afforded by vaccination is long lasting even after antibody levels fall below 10 mIU/ml. Vaccination at birth is recommended for all infants of HBV infected mothers.[62] A combination of hepatitis B immune globulin and an accelerated course of HBV vaccine prevents HBV transmission around the time of birth in 86% to 99% of cases.[63]

All those with a risk of exposure to body fluids such as blood should be vaccinated, if not already.[61] Testing to verify effective immunization is recommended and further doses of vaccine are given to those who are not sufficiently immunized.[61]

In assisted reproductive technology, sperm washing is not necessary for males with hepatitis B to prevent transmission, unless the female partner has not been effectively vaccinated.[64] In females with hepatitis B, the risk of transmission from mother to child with IVF is no different from the risk in spontaneous conception.[64]

Those at high risk of infection should be tested as there is effective treatment for those who have the disease.[65] Groups that screening is recommended for include those who have not been vaccinated and one of the following: people from areas of the world where hepatitis B occurs in more than 2%, those with HIV, intravenous drug users, men who have sex with men, and those who live with someone with hepatitis B.[65]

## Duration of vaccination [edit]

In 10- to 22-year follow-up studies there were no cases of hepatitis B among those with a normal immune system who were vaccinated. Only rare chronic infections have been documented.[66]

# Treatment [edit]

This section needs to be **updated**. Please update this article to reflect recent events or newly available information. *(June 2016)*

Acute hepatitis B infection does not usually require treatment and most adults clear the infection spontaneously.[67][68] Early antiviral treatment may be required in fewer than 1% of people, whose infection takes a very aggressive course (fulminant hepatitis) or who are immunocompromised. On the other hand, treatment of chronic infection may be necessary to reduce the risk of cirrhosis and liver cancer. Chronically infected individuals with persistently elevated serum alanine aminotransferase, a marker of liver damage, and HBV DNA levels are candidates for therapy.[69] Treatment lasts from six months to a year, depending on medication and genotype.[70]

Although none of the available drugs can clear the infection, they can stop the virus from replicating, thus minimizing liver damage. As of 2008, there are seven medications licensed for the treatment of hepatitis B infection in the United States. These include antiviral drugs lamivudine (Epivir), adefovir (Hepsera), tenofovir (Viread), telbivudine (Tyzeka) and entecavir (Baraclude), and the two immune system modulators interferon alpha-2a and PEGylated interferon alpha-2a (Pegasys). The World Health Organization recommended a combination of tenofovir and entecavir as first-line agents.[71] Those with current cirrhosis are in most need of treatment.[71]

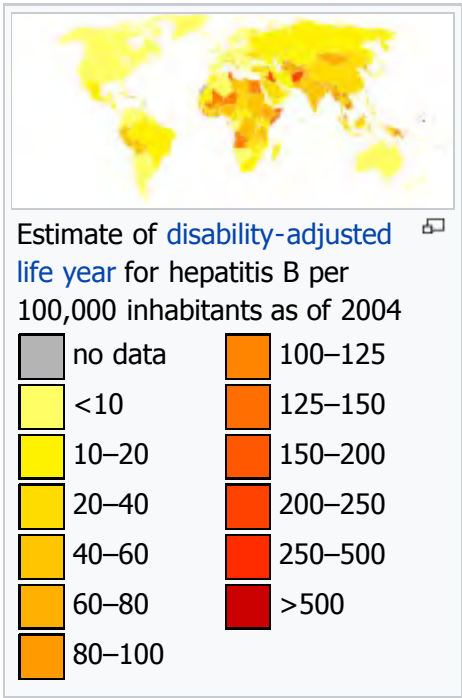
The use of interferon, which requires injections daily or thrice weekly, has been supplanted by long-acting PEGylated interferon, which is injected only once weekly.[72] However, some individuals are much more likely to respond than others, and this might be because of the genotype of the infecting virus or the person's heredity. The treatment reduces viral replication in the liver, thereby reducing the viral load (the amount of virus particles as measured in the blood).[73] Response to treatment differs between the genotypes. Interferon treatment may produce an e antigen seroconversion rate of 37% in genotype A but only a 6% seroconversion in type D. Genotype B has similar seroconversion rates to type A while type C seroconverts only in 15% of cases. Sustained e antigen loss after treatment is ~45% in types A and B but only 25–30% in types C and D.[74]

## Prognosis [edit]

Hepatitis B virus infection may be either acute (self-limiting) or chronic (long-standing). Persons with self-limiting infection clear the infection spontaneously within weeks to months.

Children are less likely than adults to clear the infection. More than 95% of people who become infected as adults or older children will stage a full recovery and develop protective immunity to the virus. However, this drops to 30% for younger children, and only 5% of newborns that acquire the infection from their mother at birth will clear the infection.[75] This population has a 40% lifetime risk of death from cirrhosis or hepatocellular carcinoma.[72] Of those infected between the age of one to six, 70% will clear the infection.[76]

Hepatitis D (HDV) can occur only with a concomitant hepatitis B infection, because HDV uses the HBV surface antigen to form a capsid.[77] Co-infection with hepatitis D increases the risk of liver cirrhosis and liver cancer.[78] Polyarteritis nodosa is more common in people with hepatitis B infection.



### Cirrhosis [edit]

A number of different tests are available to determine the degree of cirrhosis present. Transient elastography (FibroScan) is the test of [71]

choice, but it is expensive. Aspartate aminotransferase to platelet ratio index may be used when cost is an issue.[71]

### Reactivation [edit]

Hepatitis B virus DNA persists in the body after infection, and in some people the disease recurs.[79] Although rare, reactivation is seen most often following alcohol or drug use,[80] or in people with impaired immunity.[81] HBV goes through cycles of replication and non-replication. Approximately 50% of overt carriers experience acute reactivation. Males with baseline ALT of 200 UL/L are three times more likely to develop a reactivation than people with lower levels. Although reactivation can occur spontaneously,[82] people who undergo chemotherapy have a higher risk.[83] Immunosuppressive drugs favor increased HBV replication while inhibiting cytotoxic T cell function in the liver.[84] The risk of reactivation varies depending on the serological profile; those with detectable HBsAg in their blood are at the greatest risk, but those with only antibodies to the core antigen are also at risk. The presence of antibodies to the surface antigen, which are considered to be a marker of immunity, does not preclude reactivation.[83] Treatment with prophylactic antiviral drugs can prevent the serious morbidity associated with HBV disease reactivation.[83]

## Epidemiology [edit]

In 2004, an estimated 350 million individuals were infected worldwide. National and regional prevalences range from over 10% in Asia to under 0.5% in the United States and Northern Europe.

Prevalence of hepatitis B virus as of 2005

Routes of infection include vertical transmission (such as through childbirth), early life horizontal transmission (bites, lesions, and sanitary habits), and adult horizontal transmission (sexual contact, intravenous drug use).[85]

The primary method of transmission reflects the prevalence of chronic HBV infection in a given area. In low prevalence areas such as the continental United States and Western Europe, injection drug abuse and unprotected sex are the primary methods, although other factors may also be important.[86] In moderate prevalence areas, which include Eastern Europe, Russia, and Japan, where 2–7% of the population is chronically infected, the disease is predominantly spread among children. In high-prevalence areas such as China and South East Asia, transmission during childbirth is most common, although in other areas of high endemicity such as Africa, transmission during childhood is a significant factor.[87] The prevalence of chronic HBV infection in areas of high endemicity is at least 8% with 10–15% prevalence in Africa/Far East.[88] As of 2010, China has 120 million infected people, followed by India and Indonesia with 40 million and 12 million, respectively. According to World Health Organization (WHO), an estimated 600,000 people die every year related to the infection.[89]

In the United States about 19,000 new cases occurred in 2011 down nearly 90% from 1990.[61]

## History [edit]

The earliest record of an epidemic caused by hepatitis B virus was made by Lurman in 1885.[90] An outbreak of smallpox occurred in Bremen in 1883 and 1,289 shipyard employees were vaccinated with lymph from other people. After several weeks, and up to eight months later, 191 of the vaccinated workers became ill with jaundice and were diagnosed as suffering from serum hepatitis. Other employees who had been inoculated with different batches of lymph remained healthy. Lurman's paper, now regarded as a classical example of an epidemiological study, proved that contaminated lymph was the source of the outbreak. Later, numerous similar outbreaks were reported following the introduction, in 1909, of hypodermic needles that were used, and, more importantly, reused, for administering Salvarsan for the treatment of syphilis. The virus was not discovered until 1966 when Baruch Blumberg, then working at the

National Institutes of Health (NIH), discovered the Australia antigen (later known to be hepatitis B surface antigen, or HBsAg) in the blood of Australian aboriginal people.[91] Although a virus had been suspected since the research published by Frederick MacCallum in 1947,[92] David Dane and others discovered the virus particle in 1970 by electron microscopy.[93] By the early 1980s the genome of the virus had been sequenced,[94] and the first vaccines were being tested.[95]

## Society and culture [edit]

World Hepatitis Day, observed July 28, aims to raise global awareness of hepatitis B and hepatitis C and encourage prevention, diagnosis, and treatment. It has been led by the World Hepatitis Alliance since 2007 and in May 2010, it got global endorsement from the World Health Organization.[96]

# Hepatitis C

From Wikipedia, the free encyclopedia

**Hepatitis C** is an infectious disease caused by the hepatitis C virus (HCV) that primarily affects the liver.[1] During the initial infection people often have mild or no symptoms. Occasionally a fever, dark urine, abdominal pain, and yellow tinged skin occurs. The virus persists in the liver in about 75% to 85% of those initially infected. Early on chronic infection typically has no symptoms. Over many years however, it often leads to liver disease and occasionally cirrhosis.[2] In some cases, those with cirrhosis will develop complications such as liver failure, liver cancer, or esophageal and gastric varices.[1]

HCV is spread primarily by blood-to-blood contact associated with intravenous drug use, poorly sterilized medical equipment, needlestick injuries in healthcare, and transfusions.[2][3] Using blood screening, the risk from a transfusion is less than one per two million.[2] It may also be spread from an infected mother to her baby during birth.[2] It is not spread by superficial contact.[4] It is one of five known hepatitis viruses: A, B, C, D, and E.[5] Diagnosis is by blood testing to look for either antibodies to the virus or its RNA. Testing is recommended in all people who are at risk.[2]

There is no vaccine against hepatitis C.[2][6] Prevention includes harm reduction efforts among people who use intravenous drugs and testing donated blood.[4] Chronic infection can be cured about 90% of the time with treatments that include the medications sofosbuvir or simeprevir.[2][4] Previous to this a combination of peginterferon and ribavirin was used which had a cure rate around 50% and greater side effects. Getting access to the newer treatments however can be expensive.[4] Those who develop cirrhosis or liver cancer may require a liver transplant. Hepatitis C is the leading reason for liver transplantation, though the virus usually recurs after transplantation.[7]

[edit on Wikidata]

An estimated 130–200 million people worldwide are infected with hepatitis C.[4][8][9] In 2013 about 11 million new cases occurred.[10] It occurs most commonly in Africa and Central and East Asia.[4] About 343,000 deaths due to liver cancer and 358,000 deaths due to cirrhosis occurred in 2013 due to hepatitis C.[11] The existence of hepatitis C – originally identifiable only as a type of non-A non-B hepatitis – was

suggested in the 1970s and proven in 1989.[12] Hepatitis C infects only humans and chimpanzees.[13]

# Signs and symptoms

## Acute infection

Hepatitis C infection causes acute symptoms in 15% of cases.[14] Symptoms are generally mild and vague, including a decreased appetite, fatigue, nausea, muscle or joint pains, and weight loss[15] and rarely does acute liver failure result.[16] Most cases of acute infection are not associated with jaundice.[17] The infection resolves spontaneously in 10–50% of cases, which occurs more frequently in individuals who are young and female.[17]

## Chronic infection

About 80% of those exposed to the virus develop a chronic infection.[18] This is defined as the presence of detectable viral replication for at least six months. Most experience minimal or no symptoms during the initial few decades of the infection.[19] Chronic hepatitis C can be associated with fatigue[20] and mild cognitive problems.[21] Chronic infection after several years may cause cirrhosis or liver cancer.[7] The liver

enzymes are normal in 7–53%.[22] Late relapses after apparent cure have been reported, but these can be difficult to distinguish from reinfection.[22]

Fatty changes to the liver occur in about half of those infected and are usually present before cirrhosis develops.[23][24] Usually (80% of the time) this change affects less than a third of the liver.[23] Worldwide hepatitis C is the cause of 27% of cirrhosis cases and 25% of hepatocellular carcinoma.[25] About 10–30% of those infected develop cirrhosis over 30 years.[7][15] Cirrhosis is more common in those also infected with hepatitis B, schistosoma, or HIV, in alcoholics and in those of male gender.[15] In those with hepatitis C, excess alcohol increases the risk of developing cirrhosis 100-fold.[26] Those who develop cirrhosis have a 20-fold greater risk of hepatocellular carcinoma. This transformation occurs at a rate of 1–3% per year.[7][15] Being infected with hepatitis B in addition to hepatitis C increases this risk further.[27]

Liver cirrhosis may lead to portal hypertension, ascites (accumulation of fluid in the abdomen), easy bruising or bleeding, varices (enlarged veins, especially in the stomach and esophagus), jaundice, and a syndrome of cognitive impairment known as hepatic encephalopathy.[28] Ascites occurs at some stage in more than half of those who have a chronic infection.[29]

## Extrahepatic complications

The most common problem due to hepatitis C but not involving the liver is mixed cryoglobulinemia (usually the type II form) — an inflammation of small and medium-sized blood vessels.[30][31] Hepatitis C is also associated with the autoimmune disorder Sjögren's syndrome, a low platelet count, lichen planus, porphyria cutanea tarda, necrolytic acral erythema, insulin resistance, diabetes mellitus, diabetic nephropathy, autoimmune thyroiditis, and B-cell lymphoproliferative disorders.[32][33] 20–30% of people infected have rheumatoid factor — a type of antibody.[34] Possible associations include Hyde's prurigo nodularis[35] and membranoproliferative glomerulonephritis.[20] Cardiomyopathy with associated abnormal heart rhythms has also been reported.[36] A variety of central nervous system disorders has been reported.[37] Chronic infection seems to be associated with an increased risk of pancreatic cancer.[6][38]

## Occult infection

Persons who have been infected with hepatitis C may appear to clear the virus but remain infected.[39] The virus is not detectable with conventional testing but can be found with ultra-sensitive tests.[40] The original method of detection was by demonstrating the viral genome within liver biopsies, but newer methods include an antibody test for the virus' core protein and the detection of the viral genome after first concentrating the viral particles by ultracentrifugation.[41] A form of infection with persistently moderately elevated serum liver enzymes but without antibodies to hepatitis C has also been reported.[42] This form is known as cryptogenic occult infection.

Several clinical pictures have been associated with this type of infection.[43] It may be found in people with anti-hepatitis-C antibodies but with normal serum levels of liver enzymes; in antibody-negative people with ongoing elevated liver enzymes of unknown cause; in healthy populations without evidence of liver disease; and in groups at risk for HCV infection including those on hemodialysis or family members of people with occult HCV. The clinical relevance of this form of infection is under investigation.[44] The consequences of occult infection appear to be less severe than with chronic infection but can vary from minimal to hepatocellular carcinoma.[41]

The rate of occult infection in those apparently cured is controversial but appears to be low.[22] 40% of those with hepatitis but with both negative hepatitis C serology and the absence of detectable viral genome in the serum have hepatitis C virus in the liver on biopsy.[45] How commonly this occurs in children is unknown.[46]

# Virology

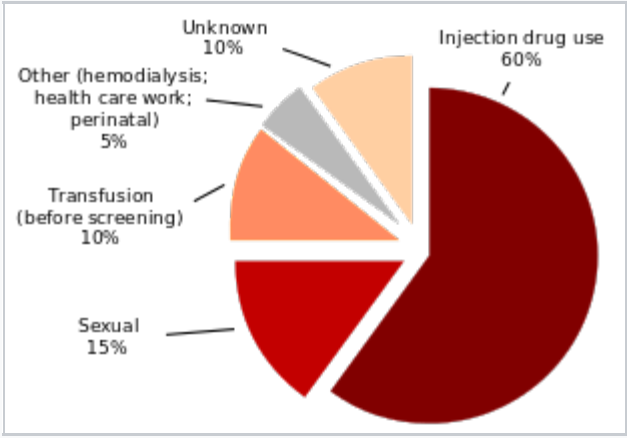
*Main article: Hepatitis C virus*

The hepatitis C virus (HCV) is a small, enveloped, single-stranded, positive-sense RNA virus.[7] It is a member of the *Hepacivirus* genus in the family *Flaviviridae*.[20] There are seven major genotypes of HCV, which are known as genotypes one to seven.[47] The genotypes are divided into several subtypes with the number of subtypes depending on the genotype. In the United States, about 70% of cases are caused by genotype 1, 20% by genotype 2 and about 1% by each of the other genotypes.[15] Genotype 1 is also the most common in South America and Europe.[7]

The half life of the virus particles in the serum is around 3 hours and may be as short as 45 minutes.[48][49] In an infected person, about $10^{12}$ virus particles are produced each day.[48] In addition to replicating in the liver the virus can multiply in lymphocytes.[50]

# Transmission

The primary route of transmission in the developed world is intravenous drug use (IDU), while in the developing world the main methods are blood transfusions and unsafe medical procedures.[3] The cause of transmission remains unknown in 20% of cases;[51] however, many of these are believed to be accounted for by IDU.[17]



Hepatitis C infection in the United States by source

## Drug use

Intravenous drug use (IDU) is a major risk factor for hepatitis C in many parts of the world.[52] Of 77 countries reviewed, 25 (including the United States) were found to have prevalences of hepatitis C in the intravenous drug user population of between 60% and 80%.[18][52] Twelve countries had rates greater than 80%.[18] It is believed that ten million intravenous drug users are infected with hepatitis C; China (1.6 million), the United States (1.5 million), and Russia (1.3 million) have the highest absolute totals.[18] Occurrence of hepatitis C among prison inmates in the United States is 10 to 20 times that of the occurrence observed in the general population; this has been attributed to high-risk behavior in prisons such as IDU and tattooing with nonsterile equipment.[53][54] Shared intranasal drug use may also be a risk factor.[55]

## Healthcare exposure

Blood transfusion, transfusion of blood products, or organ transplants without HCV screening carry significant risks of infection.[15] The United States instituted universal screening in 1992[56] and Canada instituted universal screening in 1990.[57] This decreased the risk from one in 200 units[56] to between one in 10,000 to one in 10,000,000 per unit of blood.[17][51] This low risk remains as there is a period of about 11–70 days between the potential blood donor's acquiring hepatitis C and the blood's testing positive depending on the method.[51] Some countries do not screen for hepatitis C due to the cost.[25]

Those who have experienced a needle stick injury from someone who was HCV positive have about a 1.8% chance of subsequently contracting the disease themselves.[15] The risk is greater if the needle in question is hollow and the puncture wound is deep.[25] There is a risk from mucosal exposures to blood, but this risk is low, and there is no risk if blood exposure occurs on intact skin.[25]

Hospital equipment has also been documented as a method of transmission of hepatitis C, including reuse of needles and syringes; multiple-use medication vials; infusion bags; and improperly sterilized surgical equipment, among others.[25] Limitations in the implementation and enforcement of stringent standard

precautions in public and private medical and dental facilities are known to be the primary cause of the spread of HCV in Egypt, the country with highest rate of infection in the world.[58]

### Sexual intercourse

Whether hepatitis C can be transmitted through sexual activity is controversial.[59] While there is an association between high-risk sexual activity and hepatitis C, and multiple sexual partners are a risk factor for hepatitis C, there is no conclusive evidence that hepatitis C can be transmitted by sexual activity, since people who report transmission with sex as their only risk factor may actually have used drugs but denied it.[15] The majority of evidence supports there being no risk for heterosexual couples with only one sexual partner.[59] Sexual practices that involve higher levels of trauma to the anogenital mucosa, such as anal penetrative sex, or that occur when there is a concurrent sexually transmitted infection, including HIV or genital ulceration, do present a risk.[59] The United States Department of Veterans Affairs recommends condom use to prevent hepatitis C transmission in those with multiple partners, but not those in relationships that involve only a single partner.[60]

### Body modification

Tattooing is associated with two to threefold increased risk of hepatitis C.[61] This can be due to either improperly sterilized equipment or contamination of the dyes being used.[61] Tattoos or piercings performed either before the mid-1980s, "underground," or nonprofessionally are of particular concern, since sterile techniques in such settings may be lacking. The risk also appears to be greater for larger tattoos.[61] It is estimated that nearly half of prison inmates share unsterilized tattooing equipment.[61] It is rare for tattoos in a licensed facility to be directly associated with HCV infection.[62]

### Shared personal items

Personal-care items such as razors, toothbrushes, and manicuring or pedicuring equipment can be contaminated with blood. Sharing such items can potentially lead to exposure to HCV.[63][64] Appropriate caution should be taken regarding any medical condition that results in bleeding, such as cuts and sores.[64] HCV is not spread through casual contact, such as hugging, kissing, or sharing eating or cooking utensils.[64] Neither is it transmitted through food or water.[65]

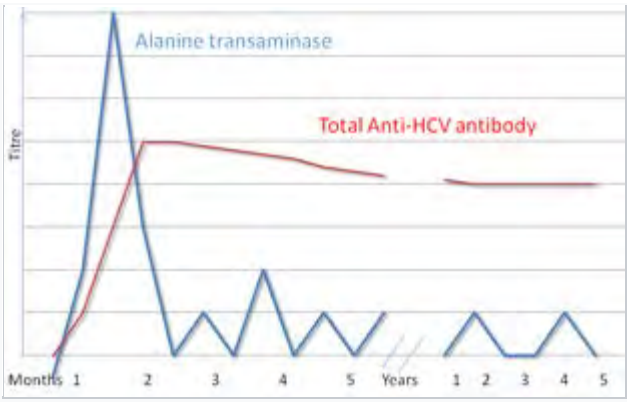
### Mother-to-child transmission

Mother-to-child transmission of hepatitis C occurs in less than 10% of pregnancies.[66] There are no measures that alter this risk.[66] It is not clear when transmission occurs during pregnancy, but it may occur both during gestation and at delivery.[51] A long labor is associated with a greater risk of transmission.[25] There is no evidence that breast-feeding spreads HCV; however, to be cautious, an infected mother is advised to avoid breastfeeding if her nipples are cracked and bleeding,[67] or if her viral loads are high.[51]

## Diagnosis

There are a number of diagnostic tests for hepatitis C, including HCV antibody enzyme immunoassay or ELISA, recombinant immunoblot assay, and quantitative HCV RNA polymerase chain reaction (PCR).[15] HCV RNA can be detected by PCR typically one to two weeks after infection, while antibodies can take substantially longer to form and thus be detected.[28]

Chronic hepatitis C is defined as infection with the



Serologic profile of Hepatitis C infection

hepatitis C virus persisting for more than six months based on the presence of its RNA.[19] Chronic infections are typically asymptomatic during the first few decades,[19] and thus are most commonly discovered following the investigation of elevated liver enzyme levels or during a routine screening of high-risk individuals. Testing is not able to distinguish between acute and chronic infections.[25] Diagnosis in the infant is difficult as maternal antibodies may persist for up to 18 months.[46]

## Serology

Hepatitis C testing typically begins with blood testing to detect the presence of antibodies to the HCV, using an enzyme immunoassay.[15] If this test is positive, a confirmatory test is then performed to verify the immunoassay and to determine the viral load.[15] A recombinant immunoblot assay is used to verify the immunoassay and the viral load is determined by an HCV RNA polymerase chain reaction.[15] If there is no RNA and the immunoblot is positive, it means that the person tested had a previous infection but cleared it either with treatment or spontaneously; if the immunoblot is negative, it means that the immunoassay was wrong.[15] It takes about 6–8 weeks following infection before the immunoassay will test positive.[20] A number of tests are available as point of care testing which means that results are available within 30 minutes.[68]

Liver enzymes are variable during the initial part of the infection[19] and on average begin to rise at seven weeks after infection.[20] The elevation of liver enzymes does not closely follow disease severity.[20]

## Biopsy

Liver biopsies are used to determine the degree of liver damage present; however, there are risks from the procedure.[7] The typical changes seen are lymphocytes within the parenchyma, lymphoid follicles in portal triad, and changes to the bile ducts.[7] There are a number of blood tests available that try to determine the degree of hepatic fibrosis and alleviate the need for biopsy.[7]

## Screening

It is believed that only 5–50% of those infected in the United States and Canada are aware of their status.[61] Testing is recommended for those at high risk, which includes injection drug users, those who have received blood transfusions before 1992,[69] those who have been in jail, those on long term hemodialysis,[70] and those with tattoos.[61] Screening is also recommended in those with elevated liver enzymes, as this is frequently the only sign of chronic hepatitis.[71] Routine screening is not currently recommended in the United States.[15] In 2012, the U.S. Centers for Disease Control and Prevention (CDC) added a recommendation for a single screening test for those born between 1945 and 1965.[72]

# Prevention

*See also: Hepatitis C vaccine*

[73]

As of 2016, no approved vaccine protects against contracting hepatitis C. However, there are a number of vaccines under development and some have shown encouraging results.[73]

A combination of harm reduction strategies, such as the provision of new needles and syringes and treatment of substance use, decreases the risk of hepatitis C in intravenous drug users by about 75%.[74] The screening of blood donors is important at a national level, as is adhering to universal precautions within healthcare facilities.[20] In countries where there is an insufficient supply of sterile syringes, medications should be given orally rather than via injection (when possible).[25]

# Treatment

HCV induces chronic infection in 50–80% of infected persons. Approximately 40–80% of these clear with treatment.[75][76] In rare cases, infection can clear without treatment.[17] Those with chronic hepatitis C are advised to avoid alcohol and medications toxic to the liver,[15] and to be vaccinated for hepatitis A and hepatitis B.[15] Ultrasound surveillance for hepatocellular carcinoma is recommended in those with accompanying cirrhosis.[15]

## Medications

Treatment with antiviral medication is recommended in all people with proven chronic hepatitis C who are not at high risk of dying from other causes.[77] People with the highest complication risk should be treated first, with the risk of complications based on the degree of liver scarring.[77] The initial recommended treatment depends on the type of hepatitis C virus with which a person is infected.[77]

- HCV genotype 1a: 12 weeks of ledipasvir and sofosbuvir OR 12 to 24 weeks of paritaprevir, ombitasvir, dasabuvir, and ribavirin[6][77]
- HCV genotype 1b: 12 weeks of ledipasvir and sofosbuvir OR 12 weeks of paritaprevir, ombitasvir, and dasabuvir[77]
- HCV genotype 2: 12 to 16 weeks of sofosbuvir and ribavirin[77]
- HCV genotype 3: 12 weeks of sofosbuvir, ribavirin, and pegylated interferon[77]
- HCV genotype 4: 12 weeks of ledipasvir and sofosbuvir OR paritaprevir, ritonavir, ombitasvir, and ribavirin, OR 24 weeks of sofosbuvir and ribavirin[77]
- HCV genotype 5 or 6: sofosbuvir and ledipasvir[77]

Sofosbuvir with ribavirin and interferon appears to be around 90% effective in those with genotype 1, 4, 5, or 6 disease.[78] Sofosbuvir with just ribavirin appears to be 70 to 95% effective in type 2 and 3 disease but has a higher rate of adverse effects.[78][79] Treatments that contain ledipasvir and sofosbuvir for genotype 1 has success rates of around 93 to 99% but is very expensive.[80] In genotype 6 infection, pegylated interferon and ribavirin is effective in 60 to 90% of cases.[81] There is some tentative data for simeprevir use in type 6 disease as well.[81]

Prior to 2011, treatments consisted of a combination of pegylated interferon alpha and ribavirin for a period of 24 or 48 weeks, depending on HCV genotype.[15] This produces cure rates of between 70 and 80% for genotype 2 and 3, respectively, and 45 to 70% for genotypes 1 and 4.[79] Adverse effects with these treatments were common, with half of people getting flu like symptoms and a third experiencing emotional problems.[15] Treatment during the first six months is more effective than once hepatitis C has become chronic.[28]

## Surgery

Cirrhosis due to hepatitis C is a common reason for liver transplantation[28] though the virus usually (80–90% of cases) recurs afterwards.[7][82] Infection of the graft leads to 10–30% of people developing cirrhosis within five years.[83] Treatment with pegylated interferon and ribavirin post transplant decreases

the risk of recurrence to 70%.[84]

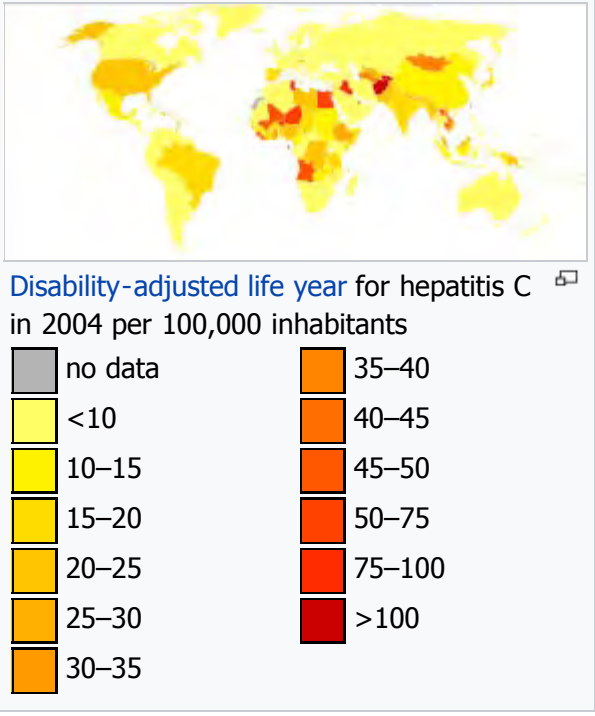
### Alternative medicine

Several alternative therapies are claimed by their proponents to be helpful for hepatitis C including milk thistle, ginseng, and colloidal silver.[85] However, no alternative therapy has been shown to improve outcomes in hepatitis C, and no evidence exists that alternative therapies have any effect on the virus at all.[85][86][87]

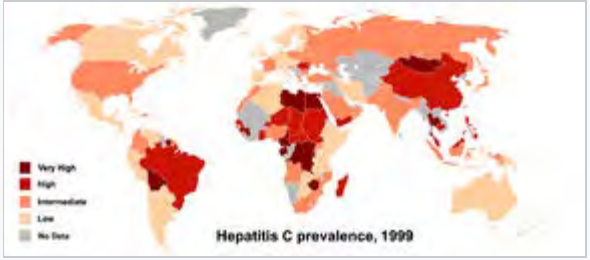
## Prognosis

The responses to treatment is measured by *sustained viral response* (SVR), defined as the absence of detectable RNA of the hepatitis C virus in blood serum for at least 24 weeks after discontinuing the treatment,[88] and rapid virological response (RVR) defined as undetectable levels achieved within four weeks of treatment. Successful treatment decreases the future risk of hepatocellular carcinoma by 75%.[89]

Prior to 2012 sustained response occurs in about 40–50% in people with HCV genotype 1 given 48 weeks of treatment.[7] A sustained response is seen in 70–80% of people with HCV genotypes 2 and 3 with 24 weeks of treatment.[7] A sustained response occurs about 65% in those with genotype 4 after 48 weeks of treatment. The evidence for treatment in genotype 6 disease is sparse and what evidence there is supports 48 weeks of treatment at the same doses used for genotype 1 disease.[90]



## Epidemiology



Prevalence of hepatitis C worldwide in 1999

It is estimated that 150–200 million people, or ~3% of the world's population, are living with chronic hepatitis C.[8][9][91] About 3–4 million people are infected per year, and more than 350,000 people die yearly from hepatitis C-related diseases.[91] During 2010 it is estimated that 16,000 people died from acute infections while 196,000 deaths occurred from liver cancer secondary to the infection.[92] Rates have increased substantially in the 20th century due to a combination of intravenous drug abuse and reused but poorly sterilized medical equipment.[25]

Rates are high (>3.5% population infected) in Central and East Asia, North Africa and the Middle East, they are intermediate (1.5%-3.5%) in South and Southeast Asia, sub-Saharan Africa, Andean, Central and Southern Latin America, Caribbean, Oceania, Australasia and Central, Eastern and Western Europe; and they are low (<1.5%) in Asia-Pacific, Tropical Latin America and North America.[9]

Among those chronically infected, the risk of cirrhosis after 20 years varies between studies but has been estimated at ~10–15% for men and ~1–5% for women. The reason for this difference is not known. Once cirrhosis is established, the rate of developing hepatocellular carcinoma is ~1–4% per year.[93] Rates of new infections have decreased in the Western world since the 1990s due to improved screening of blood

before transfusion.[28]

In the United States, about 2% of people have chronic hepatitis C.[15] In 2014, an estimated 30,500 new acute hepatitis C cases occurred (0.7 per 100,000 population), an increase from 2010–2012.[94] The number of deaths from hepatitis C has increased to 15,800 in 2008[95] having overtaken HIV/AIDS as a cause of death in the USA in 2007.[96] In 2014 it was the single greatest cause of infectious death in the United States.[97] This mortality rate is expected to increase, as those infected by transfusion before HCV testing become apparent.[98] In Europe the percentage of people with chronic infections has been estimated to be between 0.13 and 3.26%.[99]

In England about 160,000 people are chronically infected.[100] Between 2006 and 2011 28,000 about 3%, received treatment.[100]

The total number of people with this infection is higher in some countries in Africa and Asia.[101] Countries with particularly high rates of infection include Egypt (22%), Pakistan (4.8%) and China (3.2%).[91] It is believed that the high prevalence in Egypt is linked to a now-discontinued mass-treatment campaign for schistosomiasis, using improperly sterilized glass syringes.[25]

## History

In the mid-1970s, Harvey J. Alter, Chief of the Infectious Disease Section in the Department of Transfusion Medicine at the National Institutes of Health, and his research team demonstrated how most post-transfusion hepatitis cases were not due to hepatitis A or B viruses. Despite this discovery, international research efforts to identify the virus, initially called *non-A, non-B hepatitis* (NANBH), failed for the next decade. In 1987, Michael Houghton, Qui-Lim Choo, and George Kuo at Chiron Corporation, collaborating with Daniel W. Bradley at the Centers for Disease Control and Prevention, used a novel molecular cloning approach to identify the unknown organism and develop a diagnostic test.[102] In 1988, Alter confirmed the virus by verifying its presence in a panel of NANBH specimens. In April 1989, the discovery of HCV was published in two articles in the journal *Science*.[103][104] The discovery led to significant improvements in diagnosis and improved antiviral treatment.[6][102] In 2000, Drs. Alter and Houghton were honored with the Lasker Award for Clinical Medical Research for "pioneering work leading to the discovery of the virus that causes hepatitis C and the development of screening methods that reduced the risk of blood transfusion-associated hepatitis in the U.S. from 30% in 1970 to virtually zero in 2000."[105]

Chiron filed for several patents on the virus and its diagnosis.[106] A competing patent application by the CDC was dropped in 1990 after Chiron paid $1.9 million to the CDC and $337,500 to Bradley. In 1994, Bradley sued Chiron, seeking to invalidate the patent, have himself included as a coinventor, and receive damages and royalty income. He dropped the suit in 1998 after losing before an appeals court.[107]

## Society and culture

*See also: List of people with hepatitis C*

World Hepatitis Day, held on July 28, is coordinated by the World Hepatitis Alliance.[108] The economic costs of hepatitis C are significant both to the individual and to society. In the United States the average lifetime cost of the disease was estimated at 33,407 USD in 2003[109] with the cost of a liver transplant as of 2011 costing approximately 200,000 USD.[110] In Canada the cost of a course of antiviral treatment is as high as 30,000 CAD in 2003,[111] while the United States costs are between 9,200 and 17,600 in 1998 USD.[109] In many areas of the world, people are unable to afford treatment with antivirals as they either lack insurance coverage or the insurance they have will not pay for antivirals.[112] In the English National Health Service treatment rates for hepatitis C are higher among wealthier groups per 2010–2012 data.[100] Spanish anaesthetist Juan Maeso infected 275 patients between 1988 and 1997 as he used the same

needles to give both himself and the patients opioids.[113] For this he was jailed.[114]

# Research

As of 2011, there are about one hundred medications in development for hepatitis C.[110] These include vaccines to treat hepatitis, immunomodulators, and cyclophilin inhibitors, among others.[115] These potential new treatments have come about due to a better understanding of the hepatitis C virus.[116]

The combination of sofosbuvir and velpatasvir in one trial (reported in 2015) resulted in cure rates of 99%.[117]

## Animal models

One barrier to finding treatments for hepatitis C is the lack of a suitable animal model. Despite moderate success, current research highlights the need for pre-clinical testing in mammalian systems such as mouse, particularly for the development of vaccines in poorer communities. Currently, chimpanzees remain the available living system to study, yet their use has ethical concerns and regulatory restrictions. While scientists have made use of human cell culture systems such as hepatocytes, questions have been raised about their accuracy in reflecting the body's response to infection.[118]

One aspect of hepatitis research is to reproduce infections in mammalian models. A strategy is to introduce liver tissues from humans into mice, a technique known as xenotransplantation. This is done by generating chimeric mice, and exposing the mice HCV infection. This engineering process is known to create humanized mice, and provide opportunities to study hepatitis C within the 3D architectural design of the liver and evaluating antiviral compounds.[118] Alternatively, generating inbred mice with susceptibility to HCV would simplify the process of studying mouse models.

# Special populations

## Children and pregnancy

*Main article: HCV in children and pregnancy*

Compared with adults, infection in children is much less well understood. Worldwide the prevalence of hepatitis C virus infection in pregnant women and children has been estimated to 1–8% and 0.05–5% respectively.[119] The vertical transmission rate has been estimated to be 3–5% and there is a high rate of spontaneous clearance (25–50%) in the children. Higher rates have been reported for both vertical transmission (18%, 6–36% and 41%).[120][121] and prevalence in children (15%).[122]

In developed countries transmission around the time of birth is now the leading cause of HCV infection. In the absence of virus in the mother's blood transmission seems to be rare.[121] Factors associated with an increased rate of infection include membrane rupture of longer than 6 hours before delivery and procedures exposing the infant to maternal blood.[123] Cesarean sections are not recommended. Breastfeeding is considered safe if the nipples are not damaged. Infection around the time of birth in one child does not increase the risk in a subsequent pregnancy. All genotypes appear to have the same risk of transmission.

HCV infection is frequently found in children who have previously been presumed to have non-A, non-B hepatitis and cryptogenic liver disease.[124] The presentation in childhood may be asymptomatic or with elevated liver function tests.[125] While infection is commonly asymptomatic both cirrhosis with liver failure and hepatocellular carcinoma may occur in childhood.

## Immunosuppressed

*See also: Hepatitis C and HIV coinfection*

The rate of hepatitis C in immunosuppressed people is higher than the normal population. This is particularly true in those with human immunodeficiency virus infection, recipients of organ transplants and those with hypogammaglobulinemia.[126] Infection in these people is associated with an unusually rapid progression to cirrhosis.

# HIV/AIDS

From Wikipedia, the free encyclopedia

*This article is about the disease. For the virus, see HIV.*
*"AIDS" redirects here. For other uses, see AIDS (disambiguation).*

**Human immunodeficiency virus infection and acquired immune deficiency syndrome** (**HIV/AIDS**) is a spectrum of conditions caused by infection with the human immunodeficiency virus (HIV).[5][6][7] Following initial infection, a person may not notice any symptoms or may experience a brief period of influenza-like illness.[8] Typically, this is followed by a prolonged period with no symptoms.[9] As the infection progresses, it interferes more with the immune system, increasing the risk of common infections like tuberculosis, as well as other opportunistic infections, and tumors that rarely affect people who have working immune systems.[8] These late symptoms of infection are referred to as AIDS.[9] This stage is often also associated with weight loss.[9]

HIV is spread primarily by unprotected sex (including anal and oral sex), contaminated blood transfusions, hypodermic needles, and from mother to child during pregnancy, delivery, or breastfeeding.[10] Some bodily fluids, such as saliva and tears, do not transmit HIV.[11] Methods of prevention include safe sex, needle exchange programs, treating those who are infected, and male circumcision.[8] Disease in a baby can often be prevented by giving both the mother and child antiretroviral medication.[8] There is no cure or vaccine; however, antiretroviral treatment can slow the course of the disease and may lead to a near-normal life expectancy.[9][12] Treatment is recommended as soon as the diagnosis is made.[13] Without treatment, the average survival time after infection is 11 years.[14]

In 2015 about 36.7 million people were living with HIV and it resulted in 1.1 million deaths.[8] Most of those infected live in sub-Saharan Africa.[8] Between its discovery and 2014 AIDS has caused an estimated 39 million deaths worldwide.[15] HIV/AIDS is considered a pandemic—a disease outbreak which is present over a large area and is actively spreading.[16] HIV is believed to have originated in west-central Africa during the late 19th or early 20th century.[17] AIDS was first recognized by the United States Centers for Disease Control and Prevention (CDC) in 1981 and its

cause—HIV infection—was identified in the early part of the decade.[18]

HIV/AIDS has had a great impact on society, both as an illness and as a source of discrimination.[19] The disease also has large economic impacts.[19] There are many misconceptions about HIV/AIDS such as the belief that it can be transmitted by casual non-sexual contact.[20] The disease has become subject to many controversies involving religion including the Catholic Church's decision not to support condom use as prevention.[21] It has attracted international medical and political attention as well as large-scale funding since it was identified in the 1980s.[22]

Video explanation

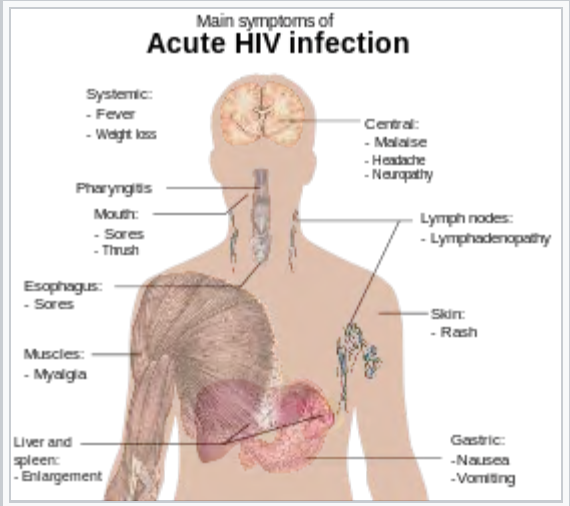
# Signs and symptoms

*Main article: Signs and symptoms of HIV/AIDS*

There are three main stages of HIV infection: acute infection, clinical latency and AIDS.[1]

## Acute infection

The initial period following the contraction of HIV is called acute HIV, primary HIV or acute retroviral syndrome.[2][23] Many individuals develop an influenza-like illness or a mononucleosis-like illness 2–4 weeks post exposure while others have no significant symptoms.[24][25] Symptoms occur in 40–90% of cases and most commonly include fever, large tender lymph nodes, throat inflammation, a rash, headache, and/or sores of the mouth and genitals.[23][25] The rash, which occurs in 20–50% of cases, presents itself on the trunk and is maculopapular, classically.[26] Some people also develop opportunistic infections at this stage.[23] Gastrointestinal symptoms such as nausea, vomiting or diarrhea may occur, as may neurological symptoms of peripheral neuropathy or Guillain–Barré syndrome.[25] The duration of the symptoms varies, but is usually one or two weeks.[25]



Main symptoms of acute HIV infection

Due to their nonspecific character, these symptoms are not often recognized as signs of HIV infection. Even cases that do get seen by a family doctor or a hospital are often misdiagnosed as one of the many common infectious diseases with overlapping symptoms. Thus, it is recommended that HIV be considered in people presenting an unexplained fever who may have risk factors for the infection.[25]

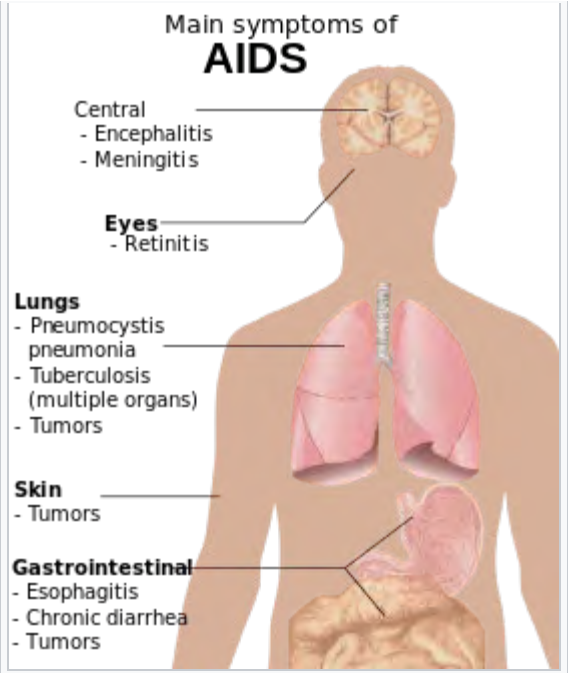
## Clinical latency

The initial symptoms are followed by a stage called clinical latency, asymptomatic HIV, or chronic HIV.[1] Without treatment, this second stage of the natural history of HIV infection can last from about three years[27] to over 20 years[28] (on average, about eight years).[29] While typically there are few or no symptoms at first, near the end of this stage many people experience fever, weight loss, gastrointestinal problems and muscle pains.[1] Between 50 and 70% of people also develop persistent generalized lymphadenopathy, characterized by unexplained, non-painful enlargement of more than one group of lymph nodes (other than in the groin) for over three to six months.[2]

Although most HIV-1 infected individuals have a detectable viral load and in the absence of treatment will eventually progress to AIDS, a small proportion (about 5%) retain high levels of $CD4^+$ T cells (T helper cells) without antiretroviral therapy for more than 5 years.[25][30] These individuals are classified as HIV controllers or long-term nonprogressors (LTNP).[30] Another group consists of those who maintain a low or undetectable viral load without anti-retroviral treatment, known as "elite controllers" or "elite suppressors". They represent approximately 1 in 300 infected persons.[31]

## Acquired immunodeficiency syndrome

Acquired immunodeficiency syndrome (AIDS) is defined in terms of either a $CD4^+$ T cell count below 200 cells per μL or the occurrence of specific diseases in association with an HIV infection.[25] In the absence of specific treatment, around half of people infected with HIV develop AIDS within ten years.[25] The most common initial conditions that alert to the presence of AIDS are pneumocystis pneumonia (40%), cachexia in the form of HIV wasting syndrome (20%), and esophageal candidiasis.[25] Other common signs include recurring respiratory tract infections.[25]



Main symptoms of AIDS.

Opportunistic infections may be caused by bacteria, viruses, fungi, and parasites that are normally controlled by the immune system.[32] Which infections occur depends partly on what organisms are common in the person's environment.[25] These infections may affect nearly every organ system.[33]

People with AIDS have an increased risk of developing various viral-induced cancers, including Kaposi's sarcoma, Burkitt's lymphoma, primary central nervous system lymphoma, and cervical cancer.[26] Kaposi's sarcoma is the most common cancer occurring in 10 to 20% of people with HIV.[34] The second most common cancer is lymphoma, which is the cause of death of nearly 16% of people with AIDS and is the initial sign of AIDS in 3 to 4%.[34] Both these cancers are associated with human herpesvirus 8.[34] Cervical cancer occurs more frequently in those with AIDS because of its association with human papillomavirus (HPV).[34] Conjunctival cancer (of the layer that lines the inner part of eyelids and the white part of the eye) is also more common in those with HIV.[35]

Additionally, people with AIDS frequently have systemic symptoms such as prolonged fevers, sweats (particularly at night), swollen lymph nodes, chills, weakness, and unintended weight loss.[36] Diarrhea is another common symptom, present in about 90% of people with AIDS.[37] They can also be affected by diverse psychiatric and neurological symptoms independent of opportunistic infections and cancers.[38]

# Transmission

HIV is transmitted by three main routes: sexual contact, significant exposure to infected body fluids or tissues, and from mother to child during pregnancy, delivery, or breastfeeding (known as vertical transmission).[10] There is no risk of acquiring HIV if exposed to feces, nasal secretions, saliva, sputum, sweat, tears, urine, or vomit unless these are contaminated with blood.[46] It is possible to be co-infected by more than one strain of HIV—a condition known as HIV superinfection.[47]

**Average per act risk of getting HIV by exposure route to an infected source**

| Exposure route | Chance of infection |
|---|---|
| **Blood transfusion** | 90%[39] |
| **Childbirth (to child)** | 25%[40] |
| **Needle-sharing injection drug use** | 0.67%[39] |
| **Percutaneous needle stick** | 0.30%[41] |
| **Receptive anal intercourse*** | 0.04–3.0%[42] |
| **Insertive anal intercourse*** | 0.03%[43] |
| **Receptive penile-vaginal intercourse*** | 0.05–0.30%[42][44] |
| **Insertive penile-vaginal intercourse*** | 0.01–0.38%[42][44] |
| **Receptive oral intercourse*§** | 0–0.04%[42] |
| **Insertive oral intercourse*§** | 0–0.005%[45] |

## Sexual

The most frequent mode of transmission of HIV is through sexual contact with an infected person.[10] The majority of all transmissions worldwide occur through heterosexual contacts

*** assuming no condom use**
**§ source refers to oral intercourse performed on a man**

(i.e. sexual contacts between people of the opposite sex);[10] however, the pattern of transmission varies significantly among countries. As of 2014, most HIV transmission in the United States occurred among men who had sex with men, with this population accounting for 67% of new cases and 83% of new cases among males over 12 years old.[48] About 15% of gay and bisexual men have HIV while 28 percent of transgender women test positive.[49][48]

With regard to unprotected heterosexual contacts, estimates of the risk of HIV transmission per sexual act appear to be four to ten times higher in low-income countries than in high-income countries.[50] In low-income countries, the risk of female-to-male transmission is estimated as 0.38% per act, and of male-to-female transmission as 0.30% per act; the equivalent estimates for high-income countries are 0.04% per act for female-to-male transmission, and 0.08% per act for male-to-female transmission.[50] The risk of transmission from anal intercourse is especially high, estimated as 1.4–1.7% per act in both heterosexual and homosexual contacts.[50][51] While the risk of transmission from oral sex is relatively low, it is still present.[52] The risk from receiving oral sex has been described as "nearly nil";[53] however, a few cases have been reported.[54] The per-act risk is estimated at 0–0.04% for receptive oral intercourse.[55] In settings involving prostitution in low income countries, risk of female-to-male transmission has been estimated as 2.4% per act and male-to-female transmission as 0.05% per act.[50]

Risk of transmission increases in the presence of many sexually transmitted infections[56] and genital ulcers.[50] Genital ulcers appear to increase the risk approximately fivefold.[50] Other sexually transmitted infections, such as gonorrhea, chlamydia, trichomoniasis, and bacterial vaginosis, are associated with somewhat smaller increases in risk of transmission.[55]

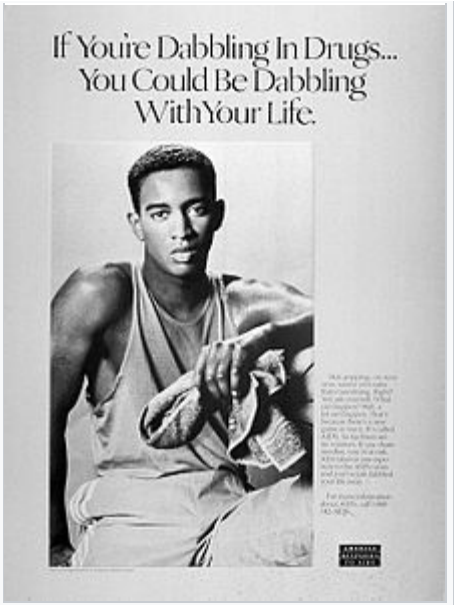
The viral load of an infected person is an important risk factor in both sexual and mother-to-child transmission.[57] During the first 2.5 months of an HIV infection a person's infectiousness is twelve times higher due to this high viral load.[55] If the person is in the late stages of infection, rates of transmission are approximately eightfold greater.[50]

Commercial sex workers (including those in pornography) have an increased rate of HIV.[58][59] Rough sex can be a factor associated with an increased risk of transmission.[60] Sexual assault is also believed to carry an increased risk of HIV transmission as condoms are rarely worn, physical trauma to the vagina or rectum is likely, and there may be a greater risk of concurrent sexually transmitted infections.[61]

## Body fluids

The second most frequent mode of HIV transmission is via blood and blood products.[10] Blood-borne transmission can be through needle-sharing during intravenous drug use, needle stick injury, transfusion of contaminated blood or blood product, or medical injections with unsterilized equipment. The risk from sharing a needle during drug injection is between 0.63 and 2.4% per act, with an average of 0.8%.[62] The risk of acquiring HIV from a needle stick from an HIV-infected person is estimated as 0.3% (about 1 in 333) per act and the risk following mucous membrane exposure to infected blood as 0.09% (about 1 in 1000) per act.[46] In the United States intravenous drug users made up 12% of all new cases of HIV in 2009,[63] and in some areas more than 80% of people who inject drugs are HIV positive.[10]

HIV is transmitted in about 93% of blood transfusions using infected blood.[62] In developed countries the risk of acquiring HIV from a blood transfusion is extremely low (less than one in half a million) where improved donor selection and HIV screening is performed;[10] for



CDC poster from 1989 highlighting the threat of AIDS associated with drug use

example, in the UK the risk is reported at one in five million[64] and in the United States it was one in 1.5 million in 2008.[65] In low income countries, only half of transfusions may be appropriately screened (as of 2008),[66] and it is estimated that up to 15% of HIV infections in these areas come from transfusion of infected blood and blood products, representing between 5% and 10% of global infections.[10][67] Although rare because of screening, it is possible to acquire HIV from organ and tissue transplantation.[68]

Unsafe medical injections play a significant role in HIV spread in sub-Saharan Africa. In 2007, between 12 and 17% of infections in this region were attributed to medical syringe use.[69] The World Health Organization estimates the risk of transmission as a result of a medical injection in Africa at 1.2%.[69] Significant risks are also associated with invasive procedures, assisted delivery, and dental care in this area of the world.[69]

People giving or receiving tattoos, piercings, and scarification are theoretically at risk of infection but no confirmed cases have been documented.[70] It is not possible for mosquitoes or other insects to transmit HIV.[71]

### Mother-to-child

*Main articles: HIV and pregnancy and HIV and breastfeeding*

HIV can be transmitted from mother to child during pregnancy, during delivery, or through breast milk resulting in infection in the baby.[72][73] This is the third most common way in which HIV is transmitted globally.[10] In the absence of treatment, the risk of transmission before or during birth is around 20% and in those who also breastfeed 35%.[72] As of 2008, vertical transmission accounted for about 90% of cases of HIV in children.[72] With appropriate treatment the risk of mother-to-child infection can be reduced to about 1%.[72] Preventive treatment involves the mother taking antiretrovirals during pregnancy and delivery, an elective caesarean section, avoiding breastfeeding, and administering antiretroviral drugs to the newborn.[74] Antiretrovirals when taken by either the mother or the infant decrease the risk of transmission in those who do breastfeed.[75] Many of these measures are however not available in the developing world.[74] If blood contaminates food during pre-chewing it may pose a risk of transmission.[70]

## Virology

*Main article: HIV*

HIV is the cause of the spectrum of disease known as HIV/AIDS. HIV is

a retrovirus that primarily infects components of the human immune system such as CD4+ T cells, macrophages and dendritic cells. It directly and indirectly destroys CD4+ T cells.[76]

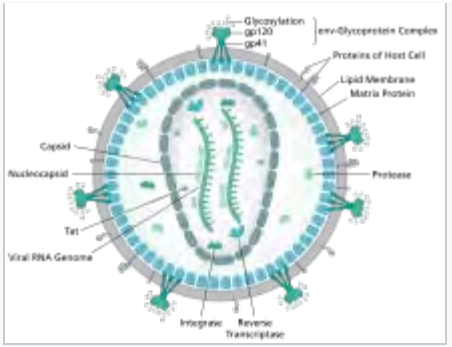


Diagram of a HIV virion structure

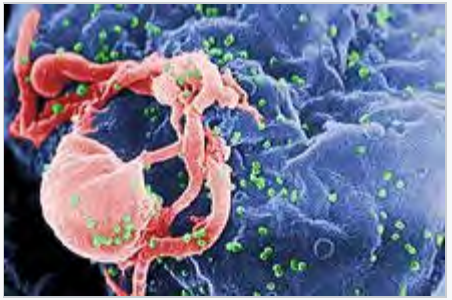
HIV is a member of the genus *Lentivirus*,[77] part of the family *Retroviridae*.[78] Lentiviruses share many morphological and biological characteristics. Many species of mammals are infected by lentiviruses, which are characteristically responsible for long-duration illnesses with a long incubation period.[79] Lentiviruses are transmitted as single-stranded, positive-sense, enveloped RNA viruses. Upon entry into the target cell, the viral RNA genome is converted (reverse transcribed) into double-stranded DNA by a virally encoded reverse transcriptase that is transported along with the viral genome in the virus particle. The resulting viral DNA is then imported into the cell nucleus and integrated into the cellular DNA by a virally encoded integrase and host co-factors.[80] Once integrated, the virus may become latent, allowing the virus and its host cell to avoid detection by the immune system.[81] Alternatively, the virus may be transcribed, producing new RNA genomes and viral proteins that are packaged and released from the cell as new virus particles that begin the replication cycle anew.[82]



Scanning electron micrograph of HIV-1, colored green, budding from a cultured lymphocyte.

HIV is now known to spread between CD4+ T cells by two parallel routes: cell-free spread and cell-to-cell spread, i.e. it employs hybrid spreading mechanisms.[83] In the cell-free spread, virus particles bud from an infected T cell, enter the blood/extracellular fluid and then infect another T cell following a chance encounter.[83] HIV can also disseminate by direct transmission from one cell to another by a process of cell-to-cell spread.[84][85] The hybrid spreading mechanisms of HIV contribute to the virus's ongoing replication against antiretroviral therapies.[83][86]

Two types of HIV have been characterized: HIV-1 and HIV-2. HIV-1 is the virus that was originally discovered (and initially referred to also as LAV or HTLV-III). It is more virulent, more infective,[87] and is the cause of the majority of HIV infections globally. The lower infectivity of HIV-2 as compared with HIV-1 implies that fewer people exposed to HIV-2 will be infected per exposure. Because of its relatively poor capacity for transmission, HIV-2 is largely confined to West Africa.[88]

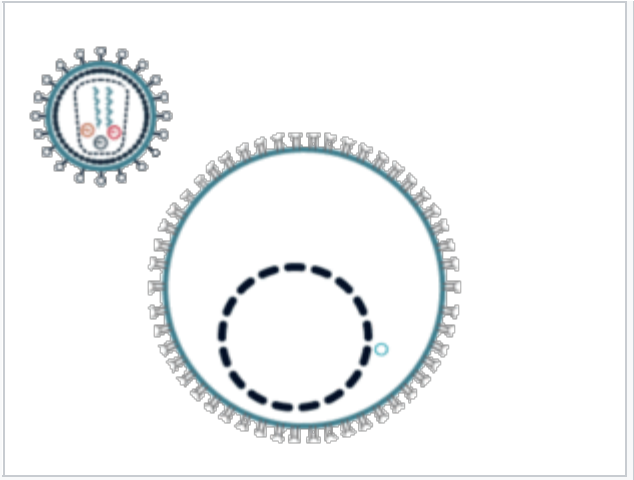
# Pathophysiology

*Main article: Pathophysiology of HIV/AIDS*

After the virus enters the body there is a period of rapid viral replication, leading to an abundance of virus in the peripheral blood. During primary infection, the level of HIV may reach several million virus particles per milliliter of blood.[89] This response is accompanied by a marked drop in the number of circulating CD4+ T cells. The acute viremia is almost invariably associated with activation of CD8+ T cells, which kill HIV-infected cells, and subsequently with antibody production, or seroconversion. The CD8+ T cell response is thought to be important in controlling virus levels, which peak and then decline, as the CD4+ T cell counts recover. A good CD8+ T cell response has been linked to slower disease progression and a better prognosis, though it does not eliminate the virus.[90]

Play media
HIV/AIDS explained in a simple way

Ultimately, HIV causes AIDS by depleting CD4+ T cells. This weakens the immune system and allows opportunistic infections. T cells are essential to the immune response and without them, the body cannot fight infections or kill cancerous cells. The mechanism of CD4+ T cell depletion differs in the acute and chronic phases.[91] During the acute phase, HIV-induced cell lysis and killing of infected cells by cytotoxic T cells accounts for CD4+ T cell depletion, although apoptosis may also be a factor. During the chronic phase, the consequences of generalized immune activation coupled with the gradual loss of the ability of the immune system to generate new T cells appear to account for the slow decline in CD4+ T cell numbers.[92]



HIV replication cycle

Although the symptoms of immune deficiency characteristic of AIDS do not appear for years after a person is infected, the bulk of CD4+ T cell loss occurs during the first weeks of infection, especially in the intestinal mucosa, which harbors the majority of the lymphocytes found in the body.[93] The reason for the preferential loss of mucosal CD4+ T cells is that the majority of mucosal CD4+ T cells express the CCR5 protein which HIV uses as a co-receptor to gain access to the cells, whereas only a small fraction of CD4+ T cells in the bloodstream do so.[94] A specific genetic change that alters the CCR5 protein when present in both chromosomes very effectively prevents HIV-1 infection.[95]

HIV seeks out and destroys CCR5 expressing CD4+ T cells during acute infection.[96] A vigorous immune response eventually controls the infection and initiates the clinically latent phase. CD4+ T cells in mucosal tissues remain particularly affected.[96] Continuous HIV replication causes a state of generalized immune activation persisting throughout the chronic phase.[97] Immune activation, which is reflected by the increased activation state of immune cells and release of pro-inflammatory cytokines, results from the activity of several HIV gene products and the immune response to ongoing HIV replication. It is also linked to the breakdown of the immune surveillance system of the gastrointestinal mucosal barrier caused by the depletion of mucosal CD4+ T cells during the acute phase of disease.[98]

# Diagnosis

*Main article: Diagnosis of HIV/AIDS*

HIV/AIDS is diagnosed via laboratory testing and then staged based on the presence of certain signs or symptoms.[23] HIV screening is recommended by the United States Preventive Services Task Force for all people 15 years to 65 years of age including all pregnant women.[99] Additionally, testing is recommended for those at high risk, which includes anyone diagnosed with a sexually transmitted illness.[26] In many areas of the world, a third of HIV carriers only discover they are infected at an advanced stage of the disease when AIDS or severe immunodeficiency has become apparent.[26]

HIV RNA copies per mL of plasma

## HIV testing

Most people infected with HIV develop specific antibodies (i.e. seroconvert) within three to twelve weeks of the initial infection.[25] Diagnosis of primary HIV before seroconversion is done by measuring HIV-RNA or p24 antigen.[25] Positive results obtained by antibody or PCR testing are confirmed

either by a different antibody or by PCR.[23]

Antibody tests in children younger than 18 months are typically inaccurate due to the continued presence of maternal antibodies.[100] Thus HIV infection can only be diagnosed by PCR testing for HIV RNA or DNA, or via testing for the p24 antigen.[23] Much of the world lacks access to reliable PCR testing and many places simply wait until either symptoms develop or the child is old enough for accurate antibody testing.[100] In sub-Saharan Africa as of 2007–2009 between 30 and 70% of the population were aware of their HIV status.[101] In 2009, between 3.6 and 42% of men and women in Sub-Saharan countries were tested[101] which represented a significant increase compared to previous years.[101]

## Classifications

Two main clinical staging systems are used to classify HIV and HIV-related disease for surveillance purposes: the WHO disease staging system for HIV infection and disease,[23] and the CDC classification system for HIV infection.[102] The CDC's classification system is more frequently adopted in developed countries. Since the WHO's staging system does not require laboratory tests, it is suited to the resource-restricted conditions encountered in developing countries, where it can also be used to help guide clinical management. Despite their differences, the two systems allow comparison for statistical purposes.[2][23][102]

The World Health Organization first proposed a definition for AIDS in 1986.[23] Since then, the WHO classification has been updated and expanded several times, with the most recent version being published in 2007.[23] The WHO system uses the following categories:

- Primary HIV infection: May be either asymptomatic or associated with acute retroviral syndrome.[23]
- Stage I: HIV infection is asymptomatic with a $CD4^+$ T cell count (also known as CD4 count) greater than 500 per microlitre (μl or cubic mm) of blood.[23] May include generalized lymph node enlargement.[23]
- Stage II: Mild symptoms which may include minor mucocutaneous manifestations and recurrent upper respiratory tract infections. A CD4 count of less than 500/μl.[23]
- Stage III: Advanced symptoms which may include unexplained chronic diarrhea for longer than a month, severe bacterial infections including tuberculosis of the lung, and a CD4 count of less than 350/μl.[23]
- Stage IV or AIDS: severe symptoms which include toxoplasmosis of the brain, candidiasis of the esophagus, trachea, bronchi or lungs and Kaposi's sarcoma. A CD4 count of less than 200/μl.[23]

The United States Center for Disease Control and Prevention also created a classification system for HIV, and updated it in 2008 and 2014.[102][103] This system classifies HIV infections based on CD4 count and clinical symptoms, and describes the infection in five groups.[103] In those greater than six years of age it is:[103]

- Stage 0: the time between a negative or indeterminate HIV test followed less than 180 days by a positive test
- Stage 1: CD4 count ≥ 500 cells/μl and no AIDS defining conditions
- Stage 2: CD4 count 200 to 500 cells/μl and no AIDS defining conditions
- Stage 3: CD4 count ≤ 200 cells/μl or AIDS defining conditions
- Unknown: if insufficient information is available to make any of the above classifications

For surveillance purposes, the AIDS diagnosis still stands even if, after treatment, the $CD4^+$ T cell count rises to above 200 per μL of blood or other AIDS-defining illnesses are cured.[2]

# Prevention

*Main article: Prevention of HIV/AIDS*

## Sexual contact

AIDS Clinic, McLeod Ganj, Himachal Pradesh, India, 2010

Consistent condom use reduces the risk of HIV transmission by approximately 80% over the long term.[104] When condoms are used consistently by a couple in which one person is infected, the rate of HIV infection is less than 1% per year.[105] There is some evidence to suggest that female condoms may provide an equivalent level of protection.[106] Application of a vaginal gel containing tenofovir (a reverse transcriptase inhibitor) immediately before sex seems to reduce infection rates by approximately 40% among African women.[107] By contrast, use of the spermicide nonoxynol-9 may increase the risk of transmission due to its tendency to cause vaginal and rectal irritation.[108]

Circumcision in Sub-Saharan Africa "reduces the acquisition of HIV by heterosexual men by between 38% and 66% over 24 months".[109] Due to these studies, both the World Health Organization and UNAIDS recommended male circumcision as a method of preventing female-to-male HIV transmission in 2007 in areas with a high rates of HIV.[110] However, whether it protects against male-to-female transmission is disputed,[111][112] and whether it is of benefit in developed countries and among men who have sex with men is undetermined.[113][114][115] The International Antiviral Society, however, does recommend for all sexually active heterosexual males and that it be discussed as an option with men who have sex with men.[116] Some experts fear that a lower perception of vulnerability among circumcised men may cause more sexual risk-taking behavior, thus negating its preventive effects.[117]

Programs encouraging sexual abstinence do not appear to affect subsequent HIV risk.[118] Evidence of any benefit from peer education is equally poor.[119] Comprehensive sexual education provided at school may decrease high risk behavior.[120] A substantial minority of young people continues to engage in high-risk practices despite knowing about HIV/AIDS, underestimating their own risk of becoming infected with HIV.[121] Voluntary counseling and testing people for HIV does not affect risky behavior in those who test negative but does increase condom use in those who test positive.[122] It is not known whether treating other sexually transmitted infections is effective in preventing HIV.[56]

## Pre-exposure

Antiretroviral treatment among people with HIV whose CD4 count ≤ 550 cells/μL is a very effective way to prevent HIV infection of their partner (a strategy known as treatment as prevention, or TASP).[123] TASP is associated with a 10 to 20 fold reduction in transmission risk.[123][124] Pre-exposure prophylaxis (PrEP) with a daily dose of the medications tenofovir, with or without emtricitabine, is effective in a number of groups including men who have sex with men, couples where one is HIV positive, and young heterosexuals in Africa.[107] It may also be effective in intravenous drug users with a study finding a decrease in risk of 0.7 to 0.4 per 100 person years.[125]

Universal precautions within the health care environment are believed to be effective in decreasing the risk of HIV.[126] Intravenous drug use is an important risk factor and harm reduction strategies such as needle-exchange programs and opioid substitution therapy appear effective in decreasing this risk.[127][128]

## Post-exposure

A course of antiretrovirals administered within 48 to 72 hours after exposure to HIV-positive blood or genital secretions is referred to as post-exposure prophylaxis (PEP).[129] The use of the single agent zidovudine reduces the risk of a HIV infection five-fold following a needle-stick injury.[129] As of 2013, the prevention regimen recommended in the United States consists of three medications—tenofovir,

emtricitabine and raltegravir—as this may reduce the risk further.[130]

PEP treatment is recommended after a sexual assault when the perpetrator is known to be HIV positive, but is controversial when their HIV status is unknown.[131] The duration of treatment is usually four weeks[132] and is frequently associated with adverse effects—where zidovudine is used, about 70% of cases result in adverse effects such as nausea (24%), fatigue (22%), emotional distress (13%) and headaches (9%).[46]

### Mother-to-child

*Main article: HIV and pregnancy*

Programs to prevent the vertical transmission of HIV (from mothers to children) can reduce rates of transmission by 92–99%.[72][127] This primarily involves the use of a combination of antiviral medications during pregnancy and after birth in the infant and potentially includes bottle feeding rather than breastfeeding.[72][133] If replacement feeding is acceptable, feasible, affordable, sustainable, and safe, mothers should avoid breastfeeding their infants; however exclusive breastfeeding is recommended during the first months of life if this is not the case.[134] If exclusive breastfeeding is carried out, the provision of extended antiretroviral prophylaxis to the infant decreases the risk of transmission.[135] In 2015, Cuba became the first country in the world to eradicate mother-to-child transmission of HIV.[136]

### Vaccination

*Main article: HIV vaccine*

Currently, there is no licensed vaccine for HIV or AIDS.[12] The most effective vaccine trial to date, RV 144, was published in 2009 and found a partial reduction in the risk of transmission of roughly 30%, stimulating some hope in the research community of developing a truly effective vaccine.[137] Further trials of the RV 144 vaccine are ongoing.[138][139]

## Treatment

*Main article: Management of HIV/AIDS*

There is currently no cure or effective HIV vaccine. Treatment consists of highly active antiretroviral therapy (HAART) which slows progression of the disease.[140] As of 2010 more than 6.6 million people were taking them in low and middle income countries.[141] Treatment also includes preventive and active treatment of opportunistic infections.

### Antiviral therapy

*Stribild* – a common once-daily

Current HAART options are combinations (or "cocktails") consisting of at least three medications belonging to at least two types, or "classes," of antiretroviral agents.[142] Initially treatment is typically a non-nucleoside reverse transcriptase inhibitor (NNRTI) plus two nucleoside analog reverse transcriptase inhibitors (NRTIs).[143] Typical NRTIs include: zidovudine (AZT) or tenofovir (TDF) and lamivudine (3TC) or emtricitabine (FTC).[143] Combinations of agents which include protease inhibitors (PI) are used if the above regimen loses effectiveness.[142]

The World Health Organization and United States recommends antiretrovirals in people of all ages including pregnant women as soon as the diagnosis is made regardless of CD4 count.[13][116][144] Once treatment is begun it is recommended that it is continued without breaks or "holidays".[26] Many people are diagnosed only after treatment

ART regime consisting of elvitegravir, emtricitabine, tenofovir and the booster cobicistat

ideally should have begun.[26] The desired outcome of treatment is a long term plasma HIV-RNA count below 50 copies/mL.[26] Levels to determine if treatment is effective are initially recommended after four weeks and once levels fall below 50 copies/mL checks every three to six months are typically adequate.[26] Inadequate control is deemed to be greater than 400 copies/mL.[26] Based on these criteria treatment is effective in more than 95% of people during the first year.[26]

Benefits of treatment include a decreased risk of progression to AIDS and a decreased risk of death.[145] In the developing world treatment also improves physical and mental health.[146] With treatment there is a 70% reduced risk of acquiring tuberculosis.[142] Additional benefits include a decreased risk of transmission of the disease to sexual partners and a decrease in mother-to-child transmission.[142] The effectiveness of treatment depends to a large part on compliance.[26] Reasons for non-adherence include poor access to medical care,[147] inadequate social supports, mental illness and drug abuse.[148] The complexity of treatment regimens (due to pill numbers and dosing frequency) and adverse effects may reduce adherence.[149] Even though cost is an important issue with some medications,[150] 47% of those who needed them were taking them in low and middle income countries as of 2010[141] and the rate of adherence is similar in low-income and high-income countries.[151]

Specific adverse events are related to the antiretroviral agent taken.[152] Some relatively common adverse events include: lipodystrophy syndrome, dyslipidemia, and diabetes mellitus, especially with protease inhibitors.[2] Other common symptoms include diarrhea,[152][153] and an increased risk of cardiovascular disease.[154] Newer recommended treatments are associated with fewer adverse effects.[26] Certain medications may be associated with birth defects and therefore may be unsuitable for women hoping to have children.[26]

Treatment recommendations for children are somewhat different from those for adults. The World Health Organization recommends treating all children less than 5 years of age; children above 5 are treated like adults.[155] The United States guidelines recommend treating all children less than 12 months of age and all those with HIV RNA counts greater than 100,000 copies/mL between one year and five years of age.[156]

## Opportunistic infections

Measures to prevent opportunistic infections are effective in many people with HIV/AIDS. In addition to improving current disease, treatment with antiretrovirals reduces the risk of developing additional opportunistic infections.[152] Adults and adolescents who are living with HIV (even on anti-retroviral therapy) with no evidence of active tuberculosis in settings with high tuberculosis burden should receive isoniazid preventive therapy (IPT), the tuberculin skin test can be used to help decide if IPT is needed.[157] Vaccination against hepatitis A and B is advised for all people at risk of HIV before they become infected; however it may also be given after infection.[158] Trimethoprim/sulfamethoxazole prophylaxis between four and six weeks of age and ceasing breastfeeding in infants born to HIV positive mothers is recommended in resource limited settings.[159] It is also recommended to prevent PCP when a person's CD4 count is below 200 cells/uL and in those who have or have previously had PCP.[160] People with substantial immunosuppression are also advised to receive prophylactic therapy for toxoplasmosis and Cryptococcus meningitis.[161] Appropriate preventive measures have reduced the rate of these infections by 50% between 1992 and 1997.[162] Influenza vaccination and pneumococcal polysaccharide vaccine are often recommended in people with HIV/AIDS with some evidence of benefit.[163][164]

## Diet

*Main article: Nutrition and HIV/AIDS*

The World Health Organization (WHO) has issued recommendations regarding nutrient requirements in [165]

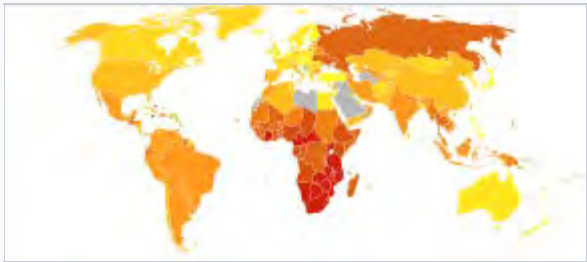
HIV/AIDS. A generally healthy diet is promoted. Some evidence has shown a benefit from micronutrient supplements.[166] Evidence for supplementation with selenium is mixed with some tentative evidence of benefit.[167] There is some evidence that vitamin A supplementation in children reduces mortality and improves growth.[166] In Africa in nutritionally compromised pregnant and lactating women a multivitamin supplementation has improved outcomes for both mothers and children.[166] Dietary intake of micronutrients at RDA levels by HIV-infected adults is recommended by the WHO; higher intake of vitamin A, zinc, and iron can produce adverse effects in HIV positive adults, and is not recommended unless there is documented deficiency.[165][168][169][170]

### Alternative medicine

In the US, approximately 60% of people with HIV use various forms of complementary or alternative medicine,[171] even though the effectiveness of most of these therapies has not been established.[172] There is not enough evidence to support the use of herbal medicines.[173] There is insufficient evidence to recommend or support the use of medical cannabis to try to increase appetite or weight gain.[174]

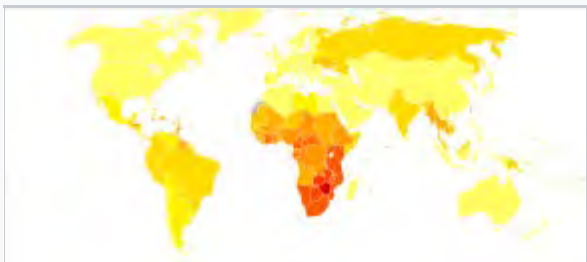
## Prognosis

HIV/AIDS has become a chronic rather than an acutely fatal disease in many areas of the world.[175] Prognosis varies between people, and both the CD4 count and viral load are useful for predicted outcomes.[25] Without treatment, average survival time after infection with HIV is estimated to be 9 to 11 years, depending on the HIV subtype.[14] After the diagnosis of AIDS, if treatment is not available, survival ranges between 6 and 19 months.[176][177] HAART and appropriate prevention of opportunistic infections reduces the death rate by 80%, and raises the life expectancy for a newly diagnosed young adult to 20–50 years.[175][178][179] This is between two thirds[178] and nearly that of the general population.[26][180] If treatment is started late in the infection, prognosis is not as good:[26] for example, if treatment is begun following the diagnosis of AIDS, life expectancy is ~10–40 years.[26][175] Half of infants born with HIV die before two years of age without treatment.[159]



Deaths due to HIV/AIDS per million persons in 2012

| | | |
|---|---|---|
| 0 | 35–61 | 459-1,402 |
| 1–4 | 62–134 | 1,403-5,828 |
| 5–12 | 135–215 | |
| 13–34 | 216–458 | |



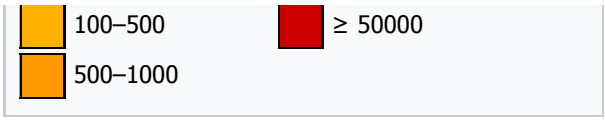
Disability-adjusted life year for HIV and AIDS per 100,000 inhabitants as of 2004.

| | |
|---|---|
| no data | 1000–2500 |
| ≤ 10 | 2500–5000 |
| 10–25 | 5000–7500 |
| 25–50 | 7500-10000 |
| 50–100 | 10000-50000 |

The primary causes of death from HIV/AIDS are opportunistic infections and cancer, both of which are frequently the result of the progressive failure of the immune system.[162][181] Risk of cancer appears to increase once the CD4 count is below 500/μL.[26] The rate of clinical disease progression varies widely between individuals and has been shown to be affected by a number of factors such as a person's susceptibility and immune function;[182] their access to health care, the presence of co-infections;[176][183] and the particular strain (or strains) of the virus involved.[184][185]

Tuberculosis co-infection is one of the leading causes of sickness and death in those with HIV/AIDS being present in a third of all HIV-infected people and causing 25% of HIV-related deaths.[186] HIV is also one of the most important risk factors for tuberculosis.[187] Hepatitis C is another very common co-infection where each disease increases the

progression of the other.[188] The two most common cancers associated with HIV/AIDS are Kaposi's sarcoma and AIDS-related non-Hodgkin's lymphoma.[181]

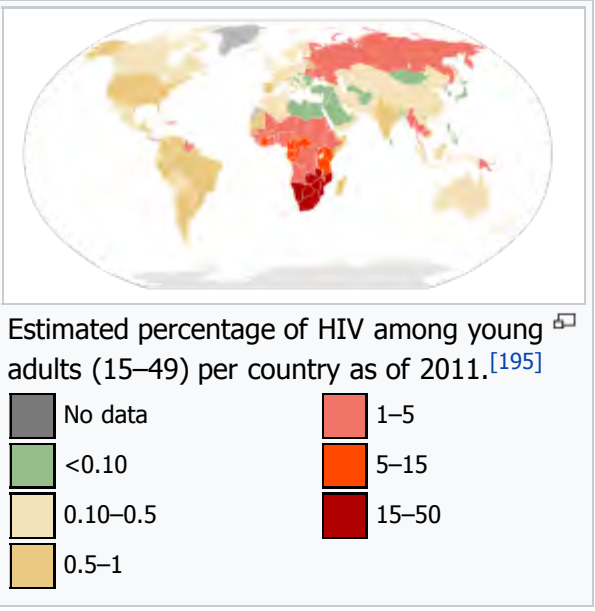


Even with anti-retroviral treatment, over the long term HIV-infected people may experience neurocognitive disorders,[189] osteoporosis,[190] neuropathy,[191] cancers,[192][193] nephropathy,[194] and cardiovascular disease.[153] Some conditions like lipodystrophy may be caused both by HIV and its treatment.[153]

# Epidemiology

*Main article: Epidemiology of HIV/AIDS*

HIV/AIDS is a global pandemic.[196] As of 2014, approximately 37 million people have HIV worldwide with the number of new infections that year being about 2 million.[197] This is down from 3.1 million new infections in 2001.[198] Of these 37 million more than half are women and 2.6 million are less than 15 years old.[197][199] It resulted in about 1.2 million deaths in 2014,[197] down from a peak of 2.2 million in 2005.[141][198]



Estimated percentage of HIV among young adults (15–49) per country as of 2011.[195]

Sub-Saharan Africa is the region most affected. In 2010, an estimated 68% (22.9 million) of all HIV cases and 66% of all deaths (1.2 million) occurred in this region.[200] This means that about 5% of the adult population is infected[201] and it is believed to be the cause of 10% of all deaths in children.[202] Here in contrast to other regions women compose nearly 60% of cases.[200] South Africa has the largest population of people with HIV of any country in the world at 5.9 million.[200] Life expectancy has fallen in the worst-affected countries due to HIV/AIDS; for example, in 2006 it was estimated that it had dropped from 65 to 35 years in Botswana.[16] Mother-to-child transmission, as of 2013, in Botswana and South Africa has decreased to less than 5% with improvement in many other African nations due to improved access to antiretroviral therapy.[203]

South & South East Asia is the second most affected; in 2010 this region contained an estimated 4 million cases or 12% of all people living with HIV resulting in approximately 250,000 deaths.[201] Approximately 2.4 million of these cases are in India.[200]

In 2008 in the United States approximately 1.2 million people were living with HIV, resulting in about 17,500 deaths. The US Centers for Disease Control and Prevention estimated that in 2008 20% of infected Americans were unaware of their infection.[204] As of 2016 about 675,000 people have died HIV/AIDS in the USA since the beginning of the HIV epidemic.[49] In the United Kingdom as of 2009 there were approximately 86,500 cases which resulted in 516 deaths.[205] In Canada as of 2008 there were about 65,000 cases causing 53 deaths.[206] Between the first recognition of AIDS in 1981 and 2009 it has led to nearly 30 million deaths.[207] Prevalence is lowest in Middle East and North Africa at 0.1% or less, East Asia at 0.1% and Western and Central Europe at 0.2%.[201] The worst affected European countries, in 2009 and 2012 estimates, are Russia, Ukraine, Latvia, Moldova, Portugal and Belarus, in decreasing order of prevalence.[208]

# History

*Main article: History of HIV/AIDS*

## Discovery

AIDS was first clinically observed in 1981 in the United States.[34] The initial cases were a cluster of injecting drug users and homosexual men with no known cause of impaired immunity who showed symptoms of *Pneumocystis carinii* pneumonia (PCP), a rare opportunistic infection that was known to occur in people with very compromised immune systems.[209] Soon thereafter, an unexpected number of homosexual men developed a previously rare skin cancer called Kaposi's sarcoma (KS).[210][211] Many more cases of PCP and KS emerged, alerting U.S. Centers for Disease Control and Prevention (CDC) and a CDC task force was formed to monitor the outbreak.[212]

CENTERS FOR DISEASE CONTROL — July 3, 1981 / Vol. 30 / No. 25

MMWR

MORBIDITY AND MORTALITY WEEKLY REPORT

Epidemiologic Notes and Reports

**Kaposi's Sarcoma and *Pneumocystis* Pneumonia Among Homosexual Men — New York City and California**

TABLE 1. Presenting complaints in 20 patients with Kaposi's sarcoma

| Presenting complaint | Number (percentage) of patients |
|---|---|
| Skin lesion(s) only | 10 (50%) |
| Skin lesions plus lymphadenopathy | 4 (20%) |
| Oral mucosal lesion only | 1 (5%) |
| Inguinal adenopathy plus perirectal abscess | 1 (5%) |
| Weight loss and fever | 2 (10%) |
| Weight loss, fever, and pneumonia (one due to *Pneumocystis carinii*) | 2 (10%) |

U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES / PUBLIC HEALTH SERVICE

The *Morbidity and Mortality Weekly Report* reported in 1981 on what was later to be called "AIDS".

In the early days, the CDC did not have an official name for the disease, often referring to it by way of the diseases that were associated with it, for example, lymphadenopathy, the disease after which the discoverers of HIV originally named the virus.[213][214] They also used *Kaposi's sarcoma and opportunistic infections*, the name by which a task force had been set up in 1981.[215] At one point, the CDC coined the phrase "the 4H disease", since the syndrome seemed to affect heroin users, homosexuals, hemophiliacs, and Haitians.[216][217] In the general press, the term "GRID", which stood for gay-related immune deficiency, had been coined.[218] However, after determining that AIDS was not isolated to the gay community,[215] it was realized that the term GRID was misleading and the term AIDS was introduced at a meeting in July 1982.[219] By September 1982 the CDC started referring to the disease as AIDS.[220]

In 1983, two separate research groups led by Robert Gallo and Luc Montagnier declared that a novel retrovirus may have been infecting people with AIDS, and published their findings in the same issue of the journal *Science*.[221][222] Gallo claimed that a virus his group had isolated from a person with AIDS was strikingly similar in shape to other human T-lymphotropic viruses (HTLVs) his group had been the first to isolate. Gallo's group called their newly isolated virus HTLV-III. At the same time, Montagnier's group isolated a virus from a person presenting with swelling of the lymph nodes of the neck and physical weakness, two characteristic symptoms of AIDS. Contradicting the report from Gallo's group, Montagnier and his colleagues showed that core proteins of this virus were immunologically different from those of HTLV-I. Montagnier's group named their isolated virus lymphadenopathy-associated virus (LAV).[212] As these two viruses turned out to be the same, in 1986, LAV and HTLV-III were renamed HIV.[223]

## Origins

Both HIV-1 and HIV-2 are believed to have originated in non-human primates in West-central Africa and were transferred to humans in the early 20th century.[17] HIV-1 appears to have originated in southern Cameroon through the evolution of SIV(cpz), a simian immunodeficiency virus (SIV) that infects wild chimpanzees (HIV-1 descends from the SIVcpz endemic in the chimpanzee subspecies *Pan troglodytes troglodytes*).[224][225] The closest relative of HIV-2 is SIV(smm), a virus of the sooty mangabey (*Cercocebus atys atys*), an Old World monkey living in coastal West Africa (from southern Senegal to western Côte d'Ivoire).[88] New World monkeys such as the owl monkey are resistant to HIV-1 infection, possibly because of a genomic fusion of two viral

Left to right: the African green monkey source of SIV, the sooty mangabey source of HIV-2 and the chimpanzee source of HIV-1

resistance genes.[226] HIV-1 is thought to have jumped the species barrier on at least three separate occasions, giving rise to the three groups of the virus, M, N, and O.[227]

There is evidence that humans who participate in bushmeat activities, either as hunters or as bushmeat vendors, commonly acquire SIV.[228] However, SIV is a weak virus which is typically suppressed by the human immune system within weeks of infection. It is thought that several transmissions of the virus from individual to individual in quick succession are necessary to allow it enough time to mutate into HIV.[229] Furthermore, due to its relatively low person-to-person transmission rate, SIV can only spread throughout the population in the presence of one or more high-risk transmission channels, which are thought to have been absent in Africa before the 20th century.

Specific proposed high-risk transmission channels, allowing the virus to adapt to humans and spread throughout the society, depend on the proposed timing of the animal-to-human crossing. Genetic studies of the virus suggest that the most recent common ancestor of the HIV-1 M group dates back to circa 1910.[230] Proponents of this dating link the HIV epidemic with the emergence of colonialism and growth of large colonial African cities, leading to social changes, including a higher degree of sexual promiscuity, the spread of prostitution, and the accompanying high frequency of genital ulcer diseases (such as syphilis) in nascent colonial cities.[231] While transmission rates of HIV during vaginal intercourse are low under regular circumstances, they are increased many fold if one of the partners suffers from a sexually transmitted infection causing genital ulcers. Early 1900s colonial cities were notable due to their high prevalence of prostitution and genital ulcers, to the degree that, as of 1928, as many as 45% of female residents of eastern Kinshasa were thought to have been prostitutes, and, as of 1933, around 15% of all residents of the same city had syphilis.[231]

An alternative view holds that unsafe medical practices in Africa after World War II, such as unsterile reuse of single use syringes during mass vaccination, antibiotic and anti-malaria treatment campaigns, were the initial vector that allowed the virus to adapt to humans and spread.[229][232][233]

The earliest well-documented case of HIV in a human dates back to 1959 in the Congo.[234] The earliest retrospectively described case of AIDS is believed to have been in Norway beginning in 1966.[235] In July 1960, in the wake its independence, the United Nations recruited Francophone experts and technicians from all over the world to assist in filling administrative gaps left by Belgium, who did not leave behind an African elite to run the country. By 1962, Haitians made up the second largest group of well-educated experts (out of the 48 national groups recruited), that totaled around 4500 in the country.[236][237] Dr. Jacques Pépin, a Quebecer author of *The Origins of AIDS*, stipulates that Haiti was one of HIV's entry points to the United States and that one of them may have carried HIV back across the Atlantic in the 1960s.[237] Although, the virus may have been present in the United States as early as 1966,[238] the vast majority of infections occurring outside sub-Saharan Africa (including the U.S.) can be traced back to a single unknown individual who became infected with HIV in Haiti and then brought the infection to the United States some time around 1969.[239] The epidemic then rapidly spread among high-risk groups (initially, sexually promiscuous men who have sex with men). By 1978, the prevalence of HIV-1 among homosexual male residents of New York City and San Francisco was estimated at 5%, suggesting that several thousand individuals in the country had been infected.[239]

# Society and culture

## Stigma

*Main article: Discrimination against people with HIV/AIDS*

AIDS stigma exists around the world in a variety of ways, including ostracism, rejection, discrimination and avoidance of HIV infected people; compulsory HIV testing without prior consent or protection of confidentiality; violence against HIV infected individuals or people who are perceived to be infected with HIV;

Ryan White became a poster child for HIV after being expelled from school because he was infected.[240]

and the quarantine of HIV infected individuals.[19] Stigma-related violence or the fear of violence prevents many people from seeking HIV testing, returning for their results, or securing treatment, possibly turning what could be a manageable chronic illness into a death sentence and perpetuating the spread of HIV.[241]

AIDS stigma has been further divided into the following three categories:

- *Instrumental AIDS stigma*—a reflection of the fear and apprehension that are likely to be associated with any deadly and transmissible illness.[242]
- *Symbolic AIDS stigma*—the use of HIV/AIDS to express attitudes toward the social groups or lifestyles perceived to be associated with the disease.[242]
- *Courtesy AIDS stigma*—stigmatization of people connected to the issue of HIV/AIDS or HIV-positive people.[243]

Often, AIDS stigma is expressed in conjunction with one or more other stigmas, particularly those associated with homosexuality, bisexuality, promiscuity, prostitution, and intravenous drug use.[244]

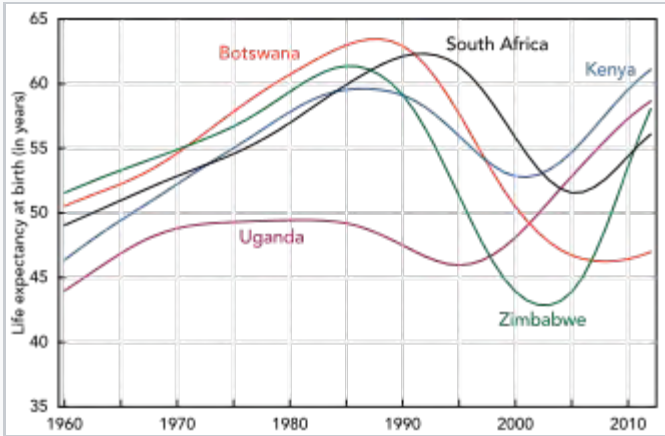
In many developed countries, there is an association between AIDS and homosexuality or bisexuality, and this association is correlated with higher levels of sexual prejudice, such as anti-homosexual/bisexual attitudes.[245] There is also a perceived association between AIDS and all male-male sexual behavior, including sex between uninfected men.[242] However, the dominant mode of spread worldwide for HIV remains heterosexual transmission.[246]

In 2003, as part of an overall reform of marriage and population legislation, it became legal for people with AIDS to marry in China.[247]

## Economic impact

*Main articles: Economic impact of HIV/AIDS and Cost of HIV treatment*

HIV/AIDS affects the economics of both individuals and countries.[202] The gross domestic product of the most affected countries has decreased due to the lack of human capital.[202][248] Without proper nutrition, health care and medicine, large numbers of people die from AIDS-related complications. They will not only be unable to work, but will also require significant medical care. It is estimated that as of 2007 there were 12 million AIDS orphans.[202] Many are cared for by elderly grandparents.[249]



Changes in life expectancy in some African countries, 1960–2012

Returning to work after beginning treatment for HIV/AIDS is difficult, and affected people often work less than the average worker. Unemployment in people with HIV/AIDS also is associated with suicidal ideation, memory problems, and social isolation; employment increases self-esteem, sense of dignity, confidence, and quality of life. A 2015 Cochrane review found low-quality evidence that antiretroviral treatment helps people with HIV/AIDS work more, and increases the chance that a person with HIV/AIDS will be employed.[250]

By affecting mainly young adults, AIDS reduces the taxable population, in turn reducing the resources

available for public expenditures such as education and health services not related to AIDS resulting in increasing pressure for the state's finances and slower growth of the economy. This causes a slower growth of the tax base, an effect that is reinforced if there are growing expenditures on treating the sick, training (to replace sick workers), sick pay and caring for AIDS orphans. This is especially true if the sharp increase in adult mortality shifts the responsibility and blame from the family to the government in caring for these orphans.[249]

At the household level, AIDS causes both loss of income and increased spending on healthcare. A study in Côte d'Ivoire showed that households having a person with HIV/AIDS spent twice as much on medical expenses as other households. This additional expenditure also leaves less income to spend on education and other personal or family investment.[251]

## Religion and AIDS

*Main article: Religion and HIV/AIDS*

The topic of religion and AIDS has become highly controversial in the past twenty years, primarily because some religious authorities have publicly declared their opposition to the use of condoms.[252][253] The religious approach to prevent the spread of AIDS according to a report by American health expert Matthew Hanley titled *The Catholic Church and the Global AIDS Crisis* argues that cultural changes are needed including a re-emphasis on fidelity within marriage and sexual abstinence outside of it.[253]

Some religious organizations have claimed that prayer can cure HIV/AIDS. In 2011, the BBC reported that some churches in London were claiming that prayer would cure AIDS, and the Hackney-based Centre for the Study of Sexual Health and HIV reported that several people stopped taking their medication, sometimes on the direct advice of their pastor, leading to a number of deaths.[254] The Synagogue Church Of All Nations advertise an "anointing water" to promote God's healing, although the group deny advising people to stop taking medication.[254]

## Media portrayal

*Main article: Media portrayal of HIV/AIDS*

One of the first high-profile cases of AIDS was the American Rock Hudson, a gay actor who had been married and divorced earlier in life, who died on October 2, 1985 having announced that he was suffering from the virus on July 25 that year. He had been diagnosed during 1984.[255] A notable British casualty of AIDS that year was Nicholas Eden, a gay politician and son of the late prime minister Anthony Eden.[256] On November 24, 1991, the virus claimed the life of British rock star Freddie Mercury, lead singer of the band Queen, who died from an AIDS-related illness having only revealed the diagnosis on the previous day.[257] However, he had been diagnosed as HIV positive in 1987.[258] One of the first high-profile heterosexual cases of the virus was Arthur Ashe, the American tennis player. He was diagnosed as HIV positive on August 31, 1988, having contracted the virus from blood transfusions during heart surgery earlier in the 1980s. Further tests within 24 hours of the initial diagnosis revealed that Ashe had AIDS, but he did not tell the public about his diagnosis until April 1992.[259] He died as a result on February 6, 1993 at age 49.[260]

Therese Frare's photograph of gay activist David Kirby, as he lay dying from AIDS while surrounded by family, was taken in April 1990. *LIFE magazine* said the photo became the one image "most powerfully identified with the HIV/AIDS epidemic." The photo was displayed in *LIFE magazine*, was the winner of the World Press Photo, and acquired worldwide notoriety after being used in a United Colors of Benetton advertising campaign in 1992.[261] In 1996, Johnson Aziga, a Ugandan-born Canadian was diagnosed with HIV, but subsequently had unprotected sex with 11 women without disclosing his diagnosis. By 2003 seven had contracted HIV, and two died from complications related to AIDS.[262][263] Aziga was convicted of first-degree murder and is liable to a life sentence.[264]

## Criminal transmission

*Main article: Criminal transmission of HIV*

Criminal transmission of HIV is the intentional or reckless infection of a person with the human immunodeficiency virus (HIV). Some countries or jurisdictions, including some areas of the United States, have laws that criminalize HIV transmission or exposure.[265] Others may charge the accused under laws enacted before the HIV pandemic.

### Misconceptions

*Main articles: Misconceptions about HIV/AIDS and Discredited HIV/AIDS origins theories*

There are many misconceptions about HIV and AIDS. Three of the most common are that AIDS can spread through casual contact, that sexual intercourse with a virgin will cure AIDS,[266][267][268] and that HIV can infect only gay men and drug users. In 2014, some among the British public wrongly thought one could get HIV from kissing (16%), sharing a glass (5%), spitting (16%), a public toilet seat (4%), and coughing or sneezing (5%).[269] Other misconceptions are that any act of anal intercourse between two uninfected gay men can lead to HIV infection, and that open discussion of HIV and homosexuality in schools will lead to increased rates of AIDS.[270][271]

A small group of individuals continue to dispute the connection between HIV and AIDS,[272] the existence of HIV itself, or the validity of HIV testing and treatment methods.[273][274] These claims, known as AIDS denialism, have been examined and rejected by the scientific community.[275] However, they have had a significant political impact, particularly in South Africa, where the government's official embrace of AIDS denialism (1999–2005) was responsible for its ineffective response to that country's AIDS epidemic, and has been blamed for hundreds of thousands of avoidable deaths and HIV infections.[276][277][278]

Several discredited conspiracy theories have held that HIV was created by scientists, either inadvertently or deliberately. Operation INFEKTION was a worldwide Soviet active measures operation to spread the claim that the United States had created HIV/AIDS. Surveys show that a significant number of people believed – and continue to believe – in such claims.[279]

## Research

*Main article: HIV/AIDS research*

HIV/AIDS research includes all medical research which attempts to prevent, treat, or cure HIV/AIDS along with fundamental research about the nature of HIV as an infectious agent and AIDS as the disease caused by HIV.

Many governments and research institutions participate in HIV/AIDS research. This research includes behavioral health interventions such as sex education, and drug development, such as research into microbicides for sexually transmitted diseases, HIV vaccines, and antiretroviral drugs. Other medical research areas include the topics of pre-exposure prophylaxis, post-exposure prophylaxis, and circumcision and HIV.

*For the Biblical term and its varied meanings, see Tzaraath. For other uses, see Leprosy (disambiguation).*

**Leprosy**, also known as **Hansen's disease** (**HD**), is a long-term infection by the bacteria *Mycobacterium leprae* or *Mycobacterium lepromatosis*.[2][3] Initially, infections are without symptoms and typically remain this way for 5 to 20 years.[2] Symptoms that develop include granulomas of the nerves, respiratory tract, skin, and eyes.[2] This may result in a lack of ability to feel pain and thus loss of parts of extremities due to repeated injuries or infection due to unnoticed wounds.[4] Weakness and poor eyesight may also be present.[4]

Leprosy is spread between people. This is thought to occur through a cough or contact with fluid from the nose of an infected person.[5] Leprosy occurs more commonly among those living in poverty.[1] Contrary to popular belief, it is not highly contagious.[4] The two main types of disease are based on the number of bacteria present: paucibacillary and multibacillary.[4] The two types are differentiated by the number of poorly pigmented, numb skin patches present, with paucibacillary having five or fewer and multibacillary having more than five.[4] The diagnosis is confirmed by finding acid-fast bacilli in a biopsy of the skin or by detecting the DNA using polymerase chain reaction.[4]

Leprosy is curable with a treatment known as multidrug therapy.[2] Treatment for paucibacillary leprosy is with the medications dapsone and rifampicin for six months.[4] Treatment for multibacillary leprosy consists of rifampicin, dapsone, and clofazimine for 12 months.[4] A number of other antibiotics may also be used.[4] These treatments are provided free of charge by the World Health Organization.[2] Globally in 2012, the number of chronic cases of leprosy was 189,000, down from some 5.2 million in the 1980s.[2][6][7] The number of new cases was 230,000.[2] Most new cases occur in 16 countries, with India accounting for more than half.[2][4] In the past 20 years, 16 million people worldwide have been cured of leprosy.[2] About 200 cases are reported per year in the United States.[8]

Leprosy has affected humanity for thousands of years.[4] The disease takes its name from the Latin word *lepra*, which means "scaly", while the term "Hansen's disease" is named after the physician Gerhard Armauer Hansen.[4] Separating people by placing them in leper colonies still occurs in places such as India,[9] China,[10] and Africa.[11] However, most colonies have closed since leprosy is not very contagious.[11] Social stigma has been associated with leprosy for much of history, which continues to be a barrier to self-reporting and early treatment.[2] Some consider the word "leper" offensive, preferring the phrase "person affected with leprosy".[12] World Leprosy Day was started in 1954 to draw awareness to those affected by leprosy.[13]

## Signs and symptoms [edit]

Leprosy is primarily a granulomatous disease of the peripheral nerves and mucosa of the upper respiratory tract; skin lesions (light or dark patches) are the primary external sign.[14] If untreated, leprosy can progress and cause permanent damage to the skin, nerves, limbs, and eyes. Contrary to folklore, leprosy does not cause body parts to fall off, although they can become numb or diseased as a result of secondary infections; these occur as a result of the body's defenses being compromised by the primary disease.[15][16] Secondary infections, in turn, can result in tissue loss, causing fingers and toes to become shortened and deformed, as cartilage is absorbed into the body.[15][16][17]

## Cause [edit]

### *M. leprae* [edit]

*Main article: Mycobacterium leprae*

*M. leprae*, one of the causative agents of leprosy: As an acid-fast bacterium, *M. leprae* appears red when a Ziehl-Neelsen stain is used.

*M. leprae* and *M. lepromatosis* are the causative agents of leprosy. *M. lepromatosis* is a relatively newly identified mycobacterium isolated from a fatal case of diffuse lepromatous leprosy in 2008.[3][14]

An intracellular, acid-fast bacterium, *M. leprae* is aerobic and rod-shaped, and is surrounded by the waxy cell membrane coating characteristic of the *Mycobacterium* genus.[18]

Due to extensive loss of genes necessary for independent growth, *M. leprae* and *M. lepromatosis* are obligate intracellular pathogens, and unculturable in the laboratory, a factor that leads to difficulty in definitively identifying the organism under a strict interpretation of Koch's postulates.[3][19] The use of nonculture-based techniques such as molecular genetics has allowed for alternative establishment of causation.

While the causative organisms have to date been impossible to culture *in vitro*, it has been possible to grow them in animals such as mice and armadillos.

Naturally occurring infection also has been reported in nonhuman primates, including the African chimpanzee, sooty mangabey, and cynomolgus macaque, as well as in armadillos and red squirrels.[20]

Red squirrels (*Sciurus vulgaris*) - a threatened species - in England were found to have leprosy in November 2016.[21] There have been no squirrel cases spread to a human for hundreds of years, though.[22]

### Risk factors [edit]

The greatest risk factor for developing leprosy is contact with another case of leprosy. Contacts of people with leprosy are five to eight times more likely to develop leprosy than members of the general population.[23] Other risk factors are poorly understood. However, conditions that reduce immune function, such as malnutrition, other illnesses, or host genetic differences, may increase the risk of developing leprosy.[23] Despite this, infection with HIV does not appear to increase the risk of developing leprosy.[24]

### Transmission [edit]

Transmission of leprosy occurs during close contact with those who are infected.[25] Transmission is proposed to be by nasal droplets,[7][25] but many questions remain about its mode of transmission and epidemiology.[26]

Leprosy is not known to be either sexually transmitted or highly infectious. People are no longer infectious after as little as two weeks of treatment.[27]

Leprosy may also be transmitted to humans by armadillos[28]

Two exit routes of *M. leprae* from the human body often described are the skin and the nasal mucosa, although their relative importance is not clear. Lepromatous cases show large numbers of organisms deep in the dermis, but whether they reach the skin surface in sufficient numbers is doubtful.[29]

The skin and the upper respiratory tract are most likely entry route. While older research dealt with the skin route, recent research has increasingly favored the respiratory route. Experimental transmission of leprosy through aerosols containing *M. leprae* in immunosuppressed mice was accomplished, suggesting a similar possibility in humans.[30]

### Genetics [edit]

Several genes have been associated with a susceptibility to leprosy. Often, the immune system is able to eliminate leprosy during the early infection stage before severe symptoms develop.[31] A defect in cell-mediated immunity may cause susceptibility to leprosy. The region of DNA responsible for this variability is also involved in Parkinson's disease, giving rise to current speculation that the two disorders may be linked in some way at the biochemical level.[32] Some evidence indicates not all people who are infected with *M. leprae* develop leprosy, and genetic factors have long been thought to play a role, due to the observation of clustering of leprosy around certain families, and the failure to understand why certain individuals develop lepromatous leprosy while others develop other types of leprosy.[33]

## Pathophysiology [edit]

How the infection produces the symptoms of the disease is not known.[7]

## Diagnosis [edit]

According to the World Health Organization, diagnosis in areas where people are frequently infected is based on one of these main signs:

- Skin lesion consistent with leprosy and with definite sensory loss
- Positive skin smears

Skin lesions can be single or multiple, and usually hypopigmented, although occasionally reddish or copper-colored. The lesions may be macules (flat), papules (raised), or nodular. The sensory loss at the skin lesion is important because this feature can help differentiate it from other causes of skin lesions such as tinea versicolor. Thickened nerves are associated with leprosy and can be accompanied by loss of sensation or muscle weakness. However, without the characteristic skin lesion and sensory loss, muscle weakness is not considered a reliable sign of leprosy.

In some cases, acid-fast leprosy bacilli in skin smears are considered diagnostic; however, the diagnosis is clinical.[34]

Diagnosis in areas where the disease is uncommon, such as the United States, is often delayed because healthcare providers are unaware of leprosy and its symptoms. Early diagnosis and treatment prevent nerve involvement, the hallmark of leprosy, and the disability it causes.[35]

Many kinds of leprosy are known, but some symptoms are common to them, including runny nose, dry scalp, eye problems, skin lesions, muscle weakness, reddish skin, smooth, shiny, diffuse thickening of facial skin, ear, and hand, loss of sensation in fingers and toes, thickening of peripheral nerves, and flat nose due to destruction of nasal cartilage. Also, phonation and resonation of sound occur during speech. Often, atrophy of the testes with resulting impotency occurs.

### Classification [edit]

Several different approaches for classifying leprosy exist, but parallels exist.

- The World Health Organization system distinguishes "paucibacillary" and "multibacillary" based upon the proliferation of bacteria.[36]("pauci-" refers to a low quantity.)
- The SHAY scale provides five gradations.[37][38]
- The ICD-10, though developed by the WHO, uses Ridley-Jopling and not the WHO system. It also adds an indeterminate ("I") entry.[29]
- In MeSH, three groupings are used.

| WHO | Ridley-Jopling | ICD-10 | MeSH | Description | Lepromin test |
|---|---|---|---|---|---|
| Paucibacillary | tuberculoid ("TT"), borderline tuberculoid ("BT") | A30.1, A30.2 | Tuberculoid | It is characterized by one or more hypopigmented skin macules and patches where skin sensations are lost because of damaged peripheral nerves that have been attacked by the human host's immune cells. | Positive |
| Multibacillary | midborderline or borderline ("BB") | A30.3 | Borderline | Borderline leprosy is of intermediate severity and is the most common form. Skin lesions resemble tuberculoid leprosy, but are more numerous and irregular; large patches may affect a whole limb, and peripheral nerve involvement with weakness and loss of sensation is common. This type is unstable and may become more like lepromatous leprosy or may undergo a reversal reaction, becoming more like the tuberculoid form. | |
| Multibacillary | borderline lepromatous ("BL"), and lepromatous ("LL") | A30.4, A30.5 | Lepromatous | It is associated with symmetric skin lesions, nodules, plaques, thickened dermis, and frequent involvement of the nasal mucosa resulting in nasal congestion and nose bleeds, but, typically, detectable nerve damage is late. | Negative |

A difference in immune response to the tuberculoid and lepromatous forms is seen.[39]

Leprosy may also be divided into:[40]:344–346

- Early and indeterminate leprosy
- Tuberculoid leprosy
- Borderline tuberculoid leprosy

- Borderline leprosy
- Borderline lepromatous leprosy
- Lepromatous leprosy
- Histoid leprosy
- Diffuse leprosy of Lucio and Latapí

This disease may also occur with only neural involvement, without skin lesions.[25][41][42][43][44][45]

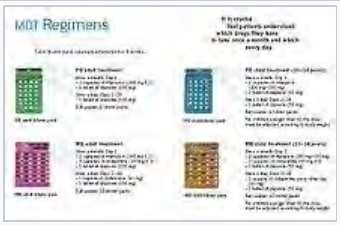
## Prevention [edit]

Early detection of the disease is important, since physical and neurological damage may be irreversible even if cured. Medications can decrease the risk of those living with people with leprosy from acquiring the disease and likely those with whom people with leprosy come into contact outside the home.[46] However, concerns are known of resistance, cost, and disclosure of a person's infection status when doing follow-up of contacts. Therefore, the WHO recommends that people who live in the same household be examined for leprosy and be treated only if symptoms are present.[46]

The Bacillus Calmette–Guérin (BCG) vaccine offers a variable amount of protection against leprosy in addition to tuberculosis.[47] It appears to be 26 to 41% effective (based on controlled trials) and about 60% effective based on observational studies with two doses possibly working better than one.[48][49] Development of a more effective vaccine is ongoing.[46][50][51][52]

## Treatment [edit]

A number of leprostatic agents are available for treatment. For paucibacillary (PB or tuberculoid) cases, treatment with daily dapsone and monthly rifampicin for six months is recommended.[4] While for multibacillary (MB or lepromatous) cases, treatment with daily dapsone and clofazimine along with monthly rifampicin for 12 months is recommended.[4]



MDT antileprosy drugs: standard regimens

Multidrug therapy (MDT) remains highly effective, and people are no longer infectious after the first monthly dose.[25] It is safe and easy to use under field conditions due to its presentation in calendar blister packs.[25] Relapse rates remain low, and no resistance to the combined drugs is seen.[25]

## Epidemiology [edit]

*Main article: Epidemiology of leprosy*

In 2012, the number of cases of leprosy was about 180,000.[6] In 2011, the approximate number of new leprosy cases diagnosed was 220,000.[6]

World distribution of leprosy, 2003

As of 2013, 14 countries contain 95% of the globally reported leprosy cases.[54] Of these, India has the greatest number of cases (59%), followed by Brazil (14%) and Indonesia (8%).[54] Although the number of cases worldwide continues to fall, pockets of high prevalence remain in certain areas such as Brazil, South Asia (India, Nepal, Bhutan), some parts of Africa (Tanzania, Madagascar, Mozambique), and the western Pacific.

The number of cases of leprosy was in the tens of millions in the 1960s, a series of national (the International Federation of Anti-Leprosy Associations) and international (the WHO's "Global Strategy for Reducing Disease Burden Due to Leprosy") initiatives have reduced the total number and the number of new cases of the disease.[7][55] In 1995, two to three million people were estimated to be permanently disabled because of leprosy.[56]

Disability-adjusted life year for leprosy per 100,000 inhabitants in 2004[53]

| | |
|---|---|
| no data | 9–10.5 |
| <1.5 | 10.5–12 |
| 1.5–3 | 12–13.5 |
| 3–4.5 | 13.5–15 |
| 4.5–6 | 15–20 |
| 6–7.5 | >20 |
| 7.5–9 | |

### Disease burden [edit]

Although the number of new leprosy cases occurring each year is important as a measure of transmission, it is difficult to measure due to leprosy's long incubation period, delays in diagnosis after onset of the disease, and the lack of laboratory tools to detect it in the very early stages. Instead, the registered prevalence is used. Registered prevalence is a useful proxy indicator of the disease burden, as it reflects the number of active leprosy cases diagnosed with the disease and receiving treatment with MDT at a given point in time. The prevalence rate is defined as the number of cases registered for MDT treatment among the population in which the cases have occurred, again at a given point in time.[57]

New case detection is another indicator of the disease that is usually reported by countries on an annual basis. It includes cases diagnosed with the onset of disease in the year in question (true incidence) and a large proportion of cases with onset in previous years (termed a backlog prevalence of undetected cases).

Endemic countries also report the number of new cases with established disabilities at the time of detection, as an indicator of the backlog prevalence. Determination of the time of onset of the disease is, in general, unreliable, is very labor-intensive, and is seldom done in recording these statistics.

## History [edit]

*Main article: History of leprosy*

Using comparative genomics, in 2005, geneticists traced the origins and worldwide distribution of leprosy from East Africa or the Near East along human migration routes. They found four strains of *M. leprae* with specific regional locations. Strain 1 occurs predominantly in Asia, the Pacific region, and East Africa; strain 4, in West Africa and the Caribbean; strain 3 in Europe, North Africa, and the Americas; and strain 2 only in Ethiopia, Malawi, Nepal/north India, and New Caledonia.

On the basis of this, they offer a map of the dissemination of leprosy in the world. This confirms the spread of the disease along the migration, colonisation, and slave trade routes taken from East Africa to India, West Africa to the New World, and from Africa into Europe and vice versa.[58]

The oldest skeletal evidence for the disease was found in the human remains from the archaeological sites of Balathal and Harappa, in India and Pakistan, respectively.[59][60]

Although retrospectively identifying descriptions of leprosy-like symptoms is difficult, what appears to be leprosy was discussed by Hippocrates in 460 BC. In 1846, Francis Adams produced *The Seven Books of Paulus Aegineta* which included a commentary on all medical and surgical knowledge and descriptions and remedies to do with leprosy from the Romans, Greeks, and Arabs.[61]

Interpretations of the presence of leprosy have been made on the basis of descriptions in ancient Indian (Atharva Verda and Kausika Sutra), Greek, and Middle Eastern documentary sources that describe skin afflictions.[62]

G. H. A. Hansen, discoverer of *M. leprae*

Skeletal remains from the second millennium BC, discovered in 2009, represent the oldest documented evidence for leprosy. Located at Balathal, in Rajasthan, northwest India, the discoverers suggest that if the disease did migrate from Africa to India, during the third millennium BC "at a time when there was substantial interaction among the Indus Civilization, Mesopotamia, and Egypt, there needs to be additional skeletal and molecular evidence of leprosy in India and Africa so as to confirm the African origin of the disease."[63] A proven human case was verified by DNA taken from the shrouded remains of a man discovered in a tomb next to the Old City of Jerusalem dated by radiocarbon methods to 1–50 AD.[64]

The causative agent of leprosy, *M. leprae*, was discovered by G. H. Armauer Hansen in Norway in 1873, making it the first bacterium to be identified as causing disease in humans.[65] The first effective treatment (promin) became available in the 1940s.[66] In the 1950s, dapsone was introduced. The search for further effective antileprosy drugs led to the use of clofazimine and rifampicin in the 1960s and 1970s.[67] Later, Indian scientist Shantaram Yawalkar and his colleagues formulated a combined therapy using rifampicin and dapsone, intended to mitigate bacterial resistance.[68] MDT combining all three drugs was first recommended by the WHO] in 1981. These three antileprosy drugs are still used in the standard MDT regimens.

Leprosy was once believed to be highly contagious and was treated with mercury—all of which applied to syphilis, which was first described in 1530. Many early cases thought to be leprosy could actually have been syphilis.[69] Resistance has developed to initial treatment. Until the introduction of MDT in the early 1980s, the disease could not be diagnosed and treated successfully within the community.[70]

Japan still has sanatoriums (although Japan's sanatoriums no longer have active leprosy cases, nor are survivors held in them by law).[71]

The importance of the nasal mucosa in the transmission of *M leprae* was recognized as early as 1898 by Schäffer, in particular, that of the ulcerated mucosa.[72]

## Society and culture [edit]

### India [edit]

India was one of the first countries to have acted against leprosy. India enacted the Leprosy Act of 1898 which institutionalized those affected and segregated them by gender to prevent reproduction. The Act was difficult to enforce but was repealed in 1983 only after MDT therapy became widely available. In 1983, the National Leprosy Elimination Programme, previously the National Leprosy Control Programme, changed its methods from surveillance to the treatment of people with leprosy. India still accounts for over half of the global disease burden.[73]

Two lepers denied entrance to town, 14th century

### Treatment cost [edit]

Between 1995 and 1999, the WHO, with the aid of the Nippon Foundation, supplied all endemic countries with free MDT in blister packs, channeled through ministries of health. This free provision was extended in 2000 and again in 2005, 2010 and 2015 with donations by the MDT manufacturer Novartis through the WHO. In the latest agreement signed between the company and the WHO in October 2015, the provision of free MDT by the WHO to all endemic countries will run until the end of 2020. At the national level, nongovernment organizations affiliated with the national program will continue to be provided with an appropriate free supply of this WHO-supplied MDT by the government.

### Historical texts [edit]

Written accounts of leprosy date back thousands of years. Various skin diseases translated as leprosy appear in the ancient Indian text, the *Atharava Veda*, as early as 2000 BC. Another Indian text, the *Laws of Manu* (1500 BC), prohibited contact with those infected with the disease and made marriage to a person infected with leprosy punishable.[74]

Many English translations of the Bible translate *tzaraath* as "leprosy," a confusion that derives from the use of the koine cognate "Λέπρα" (which can mean any disease causing scaly skin) in the Septuagint. Ancient sources such as the Talmud (Sifra 63) make clear that *tzaraath* refers to various types of lesions or stains associated with ritual impurity and occurring on cloth, leather, or houses, as well as skin. It may sometimes be a symptom of the disease described in this article but has many other causes, as well. The New Testament describes instances of Jesus healing people with leprosy (Luke 5:10), although the precise relationship between this, *tzaraath*, and Hansen's disease is not established.

The biblical perception that people with leprosy were unclean may be connected to a passage from Leviticus 13: 44-46. Judeo-Christian belief held that leprosy was a moral disease, and early Christians believed that those affected by leprosy were being punished by God for sinful

behavior. Moral associations have persisted throughout history. Pope Gregory the Great (540-604) and Isidor of Seville (560-636) considered people with the disease to be heretics.[75]

## Middle Ages [edit]

Medieval leper bell

It is believed that a rise in leprosy in Europe occurred in the Middle Ages based on the increased number of hospitals created to treat leprosy patients in the 12th and 13th centuries.[76][77][78] France alone had nearly 2,000 leprosariums during this period.

The social perception in medieval communities was generally one of fear, and those people infected with the disease were thought to be unclean, untrustworthy, and morally corrupt.[75] People with leprosy were also often required to wear clothing that identified them as such or carry a bell announcing their presence. Segregation from mainstream society was common. The third Lateran Council of 1179 and a 1346 edict by King Edward expelled lepers from city limits. Because of the moral stigma of the disease, methods of treatment were both physical and spiritual, and leprosariums were established under the purview of the church.[75][79]

## Nineteenth century [edit]

### Norway [edit]

Norway was the location of a progressive stance on leprosy tracking and treatment and played an influential role in European understanding of the disease. In 1832, Dr. JJ Hjort conducted the first leprosy survey, thus establishing a basis for epidemiological surveys. Subsequent surveys resulted in the establishment of a national leprosy registry to study the causes of leprosy and for tracking of the rate of infection.

Early leprosy research throughout Europe was conducted by Norwegian scientists, Daniel Cornelius Danielssen and C.W. Boeck. Their work resulted in the establishment of the National Leprosy Research and Treatment Center. Danielssen and Boeck believed the cause of leprosy transmission was hereditary. This stance was influential in advocating for the isolation of those infected by gender to prevent reproduction.[80]

## Colonialism and imperialism [edit]

Father Damien on his deathbed in 1889

Though leprosy in Europe was again on the decline by the 1860s, Western countries embraced isolation treatment out of fear of the spread of disease from developing countries, minimal understanding of bacteriology, lack of diagnostic ability or knowledge of how contagious the disease was, and missionary activity.[81] Growing imperialism and pressures of the industrial revolution resulted in a Western presence in countries where leprosy was endemic, namely the British presence in India. Isolation treatment methods were observed by Surgeon-Mayor Henry Vandyke Carter of the British Colony in India while visiting Norway, and these methods were applied in India with the financial and logistical assistance of religious missionaries. Colonial and religious influence and associated stigma continued to be a major factor in the treatment and public perception of leprosy in endemic developing countries until the mid-twentieth century.[81]

## Stigma [edit]

*See also: Leprosy stigma*

Despite effective treatment and education efforts, leprosy stigma continues to be problematic in endemic developing countries. Leprosy is most prevalent amongst impoverished or marginalized populations where social stigma is likely to be compounded by other social inequities. Fears of ostracism, loss of employment, or expulsion from family and society may contribute to a delayed diagnosis and treatment.

Folk models of belief, lack of education, and religious connotations of the disease continue to influence social perceptions of those afflicted in many parts of the world. In Brazil, for example, folklore holds that leprosy is transmitted by dogs, it is a disease associated with sexual promiscuity, and is sometimes thought to be punishment for sins or moral transgressions.[82] Socioeconomic factors also have a direct impact. Lower-class domestic workers who are often employed by those in a higher socioeconomic class may find their employment in jeopardy as physical manifestations of the disease become apparent. Skin discoloration and darker pigmentation resulting from the disease also has social repercussions.

In extreme cases in northern India, leprosy is equated with an "untouchable" status that "often persists long after (individuals with leprosy) have been cured of the disease, creating lifelong prospects of divorce, eviction, loss of employment, and ostracism from family and social networks."[83]

## Programs and treatment [edit]

The WHO states that diagnosis and treatment with MDT are easy and effective, and a 45% decline in disease burden has occurred since MDT has become more widely available. The organization emphasizes the importance of fully integrating leprosy treatment into public health services, effective diagnosis and treatment, and access to information.[84]

In some instances in India, community-based rehabilitation is embraced by local governments and NGOs alike. Often, the identity cultivated by a community environment is preferable to reintegration, and models of self-management and collective agency independent of NGOs and government support have been desirable and successful.[85]

## Notable cases [edit]

- Saint Damien DeVeuster, a Roman Catholic priest from Belgium, himself eventually contracting leprosy, ministered to lepers who had been placed under a government-sanctioned medical quarantine on the island of Moloka'i in the Kingdom of Hawai'i.[86]
- Baldwin IV of Jerusalem was a Christian king of Latin Jerusalem afflicted with leprosy. Baldwin, and the effects of his disease, were portrayed in the film *Kingdom of Heaven*.[87]

- King Henry IV of England (reigned 1399 to 1413) possibly had leprosy.[88]
- Vietnamese poet Hàn Mặc Tử[89]
- Ōtani Yoshitsugu, a Japanese *daimyō*[90]
- Forough Farrokhzad made a 22-minute documentary about a leprosy colony in Iran in 1962 called *The House Is Black*. The film humanizes the people affected and opens by saying that "there is no shortage of ugliness in the world, but by closing our eyes on ugliness, we will intensify it."

## Other animals [edit]

Wild nine-banded armadillos (*Dayspus novemcinctus*) in south central United States often carry Mycobacterium leprae.[91] This is believed to be because armadillos have such a low body temperature. Leprosy lesions appear mainly in cooler body regions such as the skin and mucous membranes of the upper respiratory tract. Because of armadillo's armor, skin lesions are hard to see.[92] Abrasions around the eyes, nose and feet are the most common signs. Infected armadillos make up a large reservoir of *M. leprae* and may be a source of infection for some humans in the United States or other locations in the armadillos' home range. In armadillo leprosy, lesions did not persist at the site of entry in animals, *M. leprae* multiplied in macrophages at the site of inoculation and lymph nodes.[93]

17. ^ "Q and A about leprosy". American Leprosy Missions. Retrieved 2011-01-22. "Do fingers and toes fall off when someone gets leprosy? No. The bacillus attacks nerve endings and destroys the body's ability to feel pain and injury. Without feeling pain, people injure themselves on fire, thorns, rocks, even hot coffee cups. Injuries become infected and result in tissue loss. Fingers and toes become shortened and deformed as the cartilage is absorbed into the body."

# Lyme disease

From Wikipedia, the free encyclopedia

*Not to be confused with photodermatitis, also known as "lime disease".*

**Lyme disease**, also known as **Lyme borreliosis**, is an infectious disease caused by bacteria of the *Borrelia* type.[1] The most common sign of infection is an expanding area of redness, known as erythema migrans, that begins at the site of a tick bite about a week after it has occurred. The rash is typically neither itchy nor painful. Approximately 25–50% of infected people do not develop a rash. Other early symptoms may include fever, headache and feeling tired. If untreated, symptoms may include loss of the ability to move one or both sides of the face, joint pains, severe headaches with neck stiffness, or heart palpitations, among others. Months to years later, repeated episodes of joint pain and swelling may occur. Occasionally, people develop shooting pains or tingling in their arms and legs. Despite appropriate treatment, about 10 to 20% of people develop joint pains, memory problems, and feel tired for at least six months.[2][3]

Lyme disease is transmitted to humans by the bite of infected ticks of the *Ixodes* genus.[4] Usually, the tick must be attached for 36 to 48 hours before the bacteria can spread.[5] In North America, *Borrelia burgdorferi sensu stricto* and *Borrelia mayonii* are the cause.[1][6] In Europe and Asia, the bacteria *Borrelia afzelii* and *Borrelia garinii* are also causes of the disease.[1] The disease does not appear to be transmissible between people, by other animals, or through food.[5] Diagnosis is based upon a combination of symptoms, history of tick exposure, and possibly testing for specific antibodies in the blood.[7][8] Blood tests are often negative in the early stages of the disease.[1] Testing of individual ticks is not typically useful.[9]

Prevention includes efforts to prevent tick bites such as by wearing long pants and using DEET.[1] Using pesticides to reduce tick numbers may also be effective.[1] Ticks can be removed using tweezers.[10] If the removed tick was full of blood, a single dose of doxycycline may be used to prevent development of infection, but is not generally recommended since development of infection is rare.[1] If an infection develops, a number of antibiotics are effective, including doxycycline, amoxicillin, and cefuroxime.[1] Treatment is usually for two or three weeks.[1] Some people develop a

fever and muscle and joint pains from treatment which may last for one or two days.[1] In those who develop persistent symptoms, long-term antibiotic therapy has not been found to be useful.[1][11]

Lyme disease is the most common disease spread by ticks in the Northern Hemisphere.[12] It is estimated to affect 300,000 people a year in the United States and 65,000 people a year in Europe.[1][13] Infections are most common in the spring and early summer.[1] Lyme disease was diagnosed as a separate condition for the first time in 1975 in Old Lyme, Connecticut. It was originally mistaken for juvenile rheumatoid arthritis.[14] The bacterium involved was first described in 1981 by Willy Burgdorfer.[15] Chronic symptoms are well described and are known as post-treatment Lyme disease syndrome, although it is often called chronic Lyme disease.[11] Some healthcare providers claim that it is due to ongoing infection; however, this is not believed to be true.[16] A previous vaccine is no longer available. Research is ongoing to develop new vaccines.[1]

## Signs and symptoms

Lyme disease can affect multiple body systems and produce a broad range of symptoms. Not all patients with Lyme disease have all symptoms, and many of the symptoms are not specific to Lyme disease, but can occur with other diseases, as well. The incubation period from

infection to the onset of symptoms is usually one to two weeks, but can be much shorter (days), or much longer (months to years).[18]

Symptoms most often occur from May to September, because the nymphal stage of the tick is responsible for most cases.[18] Asymptomatic infection exists, but occurs in less than 7% of infected individuals in the United States.[19] Asymptomatic infection may be much more common among those infected in Europe.[20]

## Early localized infection

Early localized infection can occur when the infection has not yet spread throughout the body. Only the site where the infection has first come into contact with the skin is affected. The classic sign of early local infection with Lyme disease is a circular, outwardly expanding rash called erythema chronicum migrans (EM), which occurs at the site of the tick bite three to 32 days after the tick bite.[1] The rash is red, and may be warm, but is generally painless. Classically, the innermost portion remains dark red and becomes indurated (is thicker and firmer), the outer edge remains red, and the portion in between clears, giving the appearance of a bull's eye. However, partial clearing is uncommon, and the bull's-eye pattern more often involves central redness.[1]

This "classic" bull's-eye rash is also called erythema migrans. A rash caused by Lyme does not always look like this and approximately 25% of those infected with Lyme disease may have no rash.[2][17]

The EM rash associated with early infection is found in about 70-80% of people infected.[2] It can have a range of appearances including the classic target bull's-eye lesion and nontarget appearing lesions. The 20-30% without the EM and the nontarget lesions can often cause misidentification of Lyme disease.[21] Affected individuals can also experience flu-like symptoms, such as headache, muscle soreness, fever, and malaise.[22] Lyme disease can progress to later stages even in people who do not develop a rash.[20][23]

Raised, red borders around indurated central portion

## Early disseminated infection

Within days to weeks after the onset of local infection, the *Borrelia* bacteria may begin to spread through the bloodstream. EM may develop at sites across the body that bear no relation to the original tick bite.[24] Another skin condition, apparently absent in North American patients, but found in Europe, is borrelial lymphocytoma, a purplish lump that develops on the ear lobe, nipple, or scrotum.[25] Various acute neurological problems, termed neuroborreliosis, appear in 10–15% of untreated patients.[22][26] These include facial palsy, which is the loss of muscle tone on one or both sides of the face, as well as meningitis, which involves severe headaches, neck stiffness, and sensitivity to light. Inflammation of the spinal cord's nerve roots can cause shooting pains that may interfere with sleep, as well as abnormal skin sensations. Mild encephalitis may lead to memory loss, sleep disturbances, or mood changes. In addition, some case reports have described altered mental status as the only symptom seen in a few cases of early neuroborreliosis.[27] The disease may adversely impact the heart's electrical conduction system and can cause abnormal heart rhythms such as atrioventricular block.[28]

## Late disseminated infection

After several months, untreated or inadequately treated patients may go on to develop severe and chronic symptoms that affect many parts of the body, including the brain, nerves, eyes, joints, and heart. Many disabling symptoms can occur, including permanent impairment of motor or sensory function of the lower extremities in extreme cases.[20] The associated nerve pain radiating out from the spine is termed Bannwarth syndrome,[29] named after Alfred Bannwarth.

The late disseminated stage is where the infection has fully spread throughout the body. Chronic neurologic symptoms occur in up to 5% of untreated patients.[22] A polyneuropathy that involves shooting pains, numbness, and tingling in the hands or feet may develop. A neurologic syndrome called Lyme encephalopathy is associated with subtle cognitive difficulties, insomnia, a general sense of feeling unwell, and changes in personality.[30] Other problems, however, such as depression and fibromyalgia, are no more common in people with Lyme disease than in the general population.[31][32]

Chronic encephalomyelitis, which may be progressive, can involve cognitive impairment, brain fog, migraines, balance issues, weakness in the legs, awkward gait, facial palsy, bladder problems, vertigo, and back pain. In rare cases, untreated Lyme disease may cause frank psychosis, which has been misdiagnosed as schizophrenia or bipolar disorder. Panic attacks and anxiety can occur; also, delusional behavior may be seen, including somatoform delusions, sometimes accompanied by a depersonalization or derealization syndrome, where the patients begin to feel detached from themselves or from reality.[33][34]

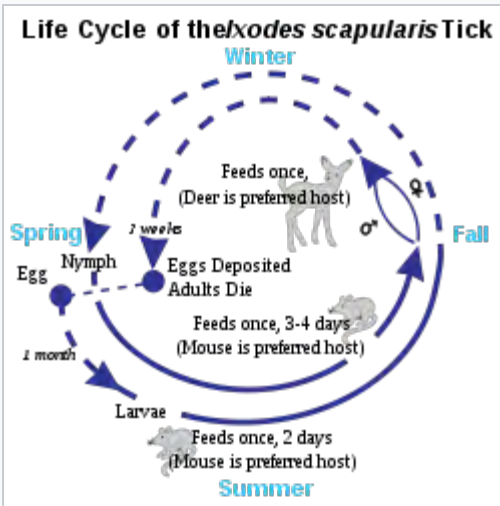
Lyme arthritis usually affects the knees.[35] In a minority of patients, arthritis can occur in other joints, including the ankles, elbows, wrists, hips, and shoulders. Pain is often mild or moderate, usually with swelling at the involved joint. Baker's cysts may form and rupture. In some cases, joint erosion occurs.

*Acrodermatitis chronica atrophicans* (ACA) is a chronic skin disorder observed primarily in Europe among the elderly.[25] ACA begins as a reddish-blue patch of discolored skin, often on the backs of the hands or feet. The lesion slowly atrophies over several weeks or months, with the skin becoming first thin and wrinkled and then, if untreated, completely dry and hairless.[36]

# Cause

*Main article: Lyme disease microbiology*

Lyme disease is caused by spirochetal bacteria from the genus *Borrelia*. Spirochetes are surrounded by peptidoglycan and flagella, along with an outer membrane similar to other Gram-negative bacteria. Because of their double-membrane envelope, *Borrelia* bacteria are often mistakenly described as Gram negative despite the considerable differences in their envelope components from Gram-negative bacteria.[37] The Lyme-related *Borrelia* species are collectively known as *Borrelia burgdorferi sensu lato*, and show a great deal of genetic diversity.



Deer tick life cycle

*B. burgdorferi sensu lato* is made up of 21 closely related species, but only three clearly cause Lyme disease: *B. burgdorferi sensu stricto* (predominant in North America, but also present in Europe), *B. afzelii*, and *B. garinii* (both predominant in Eurasia).[38][39] Some studies have also proposed *B. bissettii* and *B. valaisiana* may sometimes infect humans, but these species do not seem to be important causes of disease.[40][41]

*Further information: Weather and climate effects on Lyme disease exposure*

## Transmission

Lyme disease is classified as a zoonosis, as it is transmitted to humans

*Borrelia* bacteria, the causative agent of Lyme disease, magnified

from a natural reservoir among small mammals and birds by ticks that feed on both sets of hosts.[42] Hard-bodied ticks of the genus *Ixodes* are the main vectors of Lyme disease (also the vector for *Babesia*).[43] Most infections are caused by ticks in the nymphal stage, because they are very small and thus may feed for long periods of time undetected.[42] Larval ticks are very rarely infected.[44] Although deer are the preferred hosts of the adult stage of deer ticks, and tick populations are much lower in the absence of deer, ticks generally do not acquire Lyme disease spirochetes from deer. Rather, deer ticks acquire *Borrelia* microbes from infected small mammals and occasionally birds, including the white-footed mouse, *Peromyscus leucopus*.[45]

Within the tick midgut, the *Borrelia*'s outer surface protein A (OspA) binds to the tick receptor for OspA, known as TROSPA. When the tick feeds, the *Borrelia* downregulates OspA and upregulates OspC, another surface protein. After the bacteria migrate from the midgut to the salivary glands, OspC binds to Salp15, a tick salivary protein that appears to have immunosuppressive effects that enhance infection.[46] Successful infection of the mammalian host depends on bacterial expression of OspC.[47]

*Ixodes scapularis*, the primary vector of Lyme disease in eastern North America

Tick bites often go unnoticed because of the small size of the tick in its nymphal stage, as well as tick secretions that prevent the host from feeling any itch or pain from the bite. However, transmission is quite rare, with only about 1% of recognized tick bites resulting in Lyme disease.

In Europe, the vector is *Ixodes ricinus*, which is also called the sheep tick or castor bean tick.[48] In China, *Ixodes persulcatus* (the taiga tick) is probably the most important vector.[49] In North America, the black-legged tick or deer tick (*Ixodes scapularis*) is the main vector on the East Coast.[44]

The lone star tick (*Amblyomma americanum*), which is found throughout the Southeastern United States as far west as Texas, is unlikely to transmit the Lyme disease spirochetes,[50] though it may be implicated in a related syndrome called southern tick-associated rash illness, which resembles a mild form of Lyme disease.[51]

Tick *ixodes ricinus*, developmental stages

On the West Coast of the United States, the main vector is the western black-legged tick (*Ixodes pacificus*).[52] The tendency of this tick species to feed predominantly on host species such as lizards that are resistant to *Borrelia* infection appears to diminish transmission of Lyme disease in the West.[53][54]

Transmission across the placenta during pregnancy has not been demonstrated, and no consistent pattern of teratogenicity or specific "congenital Lyme borreliosis" has been identified. As with a number of other spirochetal diseases, adverse pregnancy outcomes are possible with untreated infection; prompt treatment with antibiotics reduces or eliminates this risk.[55][56]

While Lyme spirochetes have been found in insects, as well as ticks,[57] reports of actual infectious transmission appear to be rare.[58] Lyme spirochete DNA has been found in semen[59] and breast milk,[60] but transmission has not been known to take place through sexual contact.[61] According to the CDC, live

spirochetes have not been found in breast milk, urine, or semen.[62] However, more recent studies published in 2014, suggest a link might exist.[63]

### Tick-borne coinfections

Ticks that transmit *B. burgdorferi* to humans can also carry and transmit several other parasites, such as *Theileria microti* and *Anaplasma phagocytophilum*, which cause the diseases babesiosis and human granulocytic anaplasmosis (HGA), respectively.[64] Among early Lyme disease patients, depending on their location, 2–12% will also have HGA and 2–40% will have babesiosis.[65] Ticks in certain regions, including the lands along the eastern Baltic Sea, also transmit tick-borne encephalitis.[66]

Coinfections complicate Lyme symptoms, especially diagnosis and treatment. It is possible for a tick to carry and transmit one of the coinfections and not *Borrelia*, making diagnosis difficult and often elusive. The Centers for Disease Control and Prevention studied 100 ticks in rural New Jersey, and found 55% of the ticks were infected with at least one of the pathogens.[67]

## Pathophysiology

*B. burgdorferi* can spread throughout the body during the course of the disease, and has been found in the skin, heart, joints, peripheral nervous system, and central nervous system.[47][68] Many of the signs and symptoms of Lyme disease are a consequence of the immune response to the spirochete in those tissues.[22]

*B. burgdorferi* is injected into the skin by the bite of an infected *Ixodes* tick. Tick saliva, which accompanies the spirochete into the skin during the feeding process, contains substances that disrupt the immune response at the site of the bite.[69] This provides a protective environment where the spirochete can establish infection. The spirochetes multiply and migrate outward within the dermis. The host inflammatory response to the bacteria in the skin causes the characteristic circular EM lesion.[47] Neutrophils, however, which are necessary to eliminate the spirochetes from the skin, fail to appear in the developing EM lesion. This allows the bacteria to survive and eventually spread throughout the body.[70]

Days to weeks following the tick bite, the spirochetes spread via the bloodstream to joints, heart, nervous system, and distant skin sites, where their presence gives rise to the variety of symptoms of the disseminated disease. The spread of *B. burgdorferi* is aided by the attachment of the host protease plasmin to the surface of the spirochete.[71]

If untreated, the bacteria may persist in the body for months or even years, despite the production of *B. burgdorferi* antibodies by the immune system.[72] The spirochetes may avoid the immune response by decreasing expression of surface proteins that are targeted by antibodies, antigenic variation of the VlsE surface protein, inactivating key immune components such as complement, and hiding in the extracellular matrix, which may interfere with the function of immune factors.[73][74]

In the brain, *B. burgdorferi* may induce astrocytes to undergo astrogliosis (proliferation followed by apoptosis), which may contribute to neurodysfunction.[75] The spirochetes may also induce host cells to secrete quinolinic acid, which stimulates the NMDA receptor on nerve cells, which may account for the fatigue and malaise observed with Lyme encephalopathy.[76] In addition, diffuse white matter pathology during Lyme encephalopathy may disrupt gray matter connections, and could account for deficits in attention, memory, visuospatial ability, complex cognition, and emotional status. White matter disease may have a greater potential for recovery than gray matter disease, perhaps because the neuronal loss is less common. Resolution of MRI white matter hyperintensities after antibiotic treatment has been observed.[77]

Tryptophan, a precursor to serotonin, appears to be reduced within the central nervous system in a number of infectious diseases that affect the brain, including Lyme.[78] Researchers are investigating if this neurohormone secretion is the cause of neuropsychiatric disorders developing in some patients with borreliosis.[79]

## Immunological studies

Exposure to the *Borrelia* bacterium during Lyme disease possibly causes a long-lived and damaging inflammatory response,[80] a form of pathogen-induced autoimmune disease.[81] The production of this reaction might be due to a form of molecular mimicry, where *Borrelia* avoids being killed by the immune system by resembling normal parts of the body's tissues.[82][83]

Chronic symptoms from an autoimmune reaction could explain why some symptoms persist even after the spirochetes have been eliminated from the body. This hypothesis may explain why chronic arthritis persists after antibiotic therapy, similar to rheumatic fever, but its wider application is controversial.[84][85]

# Diagnosis

Lyme disease is diagnosed clinically based on symptoms, objective physical findings (such as EM, facial palsy, or arthritis), or a history of possible exposure to infected ticks, as well as serological blood tests. The EM rash is not always a bull's eye, i.e., it can be solid red. When making a diagnosis of Lyme disease, health care providers should consider other diseases that may cause similar illnesses. Not all individuals infected with Lyme disease develop the characteristic bull's-eye rash, and many may not recall a tick bite.[86]

Because of the difficulty in culturing *Borrelia* bacteria in the laboratory, diagnosis of Lyme disease is typically based on the clinical exam findings and a history of exposure to endemic Lyme areas.[43] The EM rash, which does not occur in all cases, is considered sufficient to establish a diagnosis of Lyme disease even when serologic blood tests are negative.[87][88] Serological testing can be used to support a clinically suspected case, but is not diagnostic by itself.[43]

Diagnosis of late-stage Lyme disease is often complicated by a multifaceted appearance and nonspecific symptoms, prompting one reviewer to call Lyme the new "great imitator".[89] Lyme disease may be misdiagnosed as multiple sclerosis, rheumatoid arthritis, fibromyalgia, chronic fatigue syndrome, lupus, Crohn's disease, HIV, or other autoimmune and neurodegenerative diseases. As all people with later-stage infection will have a positive antibody test, simple blood tests can exclude Lyme disease as a possible cause of a person's symptoms.[90]

## Laboratory testing

Several forms of laboratory testing for Lyme disease are available, some of which have not been adequately validated. The most widely used tests are serologies, which measure levels of specific antibodies in a patient's blood. These tests may be negative in early infection as the body may not have produced a significant quantity of antibodies, but they are considered a reliable aid in the diagnosis of later stages of Lyme disease.[91] Serologic tests for Lyme disease are of limited use in people lacking objective signs of Lyme disease because of false positive results and cost.[92]

The serological laboratory tests most widely available and employed are the Western blot and ELISA. A two-tiered protocol is recommended by the Centers for Disease Control and Prevention: the sensitive ELISA test is performed first, and if it is positive or equivocal, then the more specific Western blot is run.[93] The reliability of testing in diagnosis remains controversial.[43] Studies show the Western blot IgM has a specificity of 94–96% for people with clinical symptoms of early Lyme disease.[94][95] The initial ELISA test has a sensitivity of about 70%, and in two-tiered testing, the overall sensitivity is only 64%, although this rises to 100% in the subset of people with disseminated symptoms, such as arthritis.[96]

Erroneous test results have been widely reported in both early and late stages of the disease, and can be caused by several factors, including antibody cross-reactions from other infections, including Epstein–Barr virus and cytomegalovirus,[97] as well as herpes simplex virus.[98] The overall rate of false positives is low, only about 1 to 3%, in comparison to a false-negative rate of up to 36% in the early stages of infection using two-tiered testing.[96]

Polymerase chain reaction (PCR) tests for Lyme disease have also been developed to detect the genetic material (DNA) of the Lyme disease spirochete. PCR tests are susceptible to false positive results from poor laboratory technique.[99] Even when properly performed, PCR often shows false negative results with blood and cerebrospinal fluid specimens.[100] Hence, PCR is not widely performed for diagnosis of Lyme disease, but it may have a role in the diagnosis of Lyme arthritis because it is a highly sensitive way of detecting *ospA* DNA in synovial fluid.[101]

Culture or PCR are the current means for detecting the presence of the organism, as serologic studies only test for antibodies of *Borrelia*. OspA antigens, shedded by live Borrelia bacteria into urine, are a promising technique being studied.[102] The use of nanotrap particles for their detection is being looked at and the OspA has been linked to active symptoms of Lyme.[103][104] High titers of either immunoglobulin G (IgG) or immunoglobulin M (IgM) antibodies to *Borrelia* antigens indicate disease, but lower titers can be misleading, because the IgM antibodies may remain after the initial infection, and IgG antibodies may remain for years.[105]

Western blot, ELISA, and PCR can be performed by either blood test via venipuncture or cerebrospinal fluid (CSF) via lumbar puncture. Though lumbar puncture is more definitive of diagnosis, antigen capture in the CSF is much more elusive; reportedly, CSF yields positive results in only 10–30% of affected individuals cultured. The diagnosis of neurologic infection by *Borrelia* should not be excluded solely on the basis of normal routine CSF or negative CSF antibody analyses.[106]

New techniques for clinical testing of *Borrelia* infection have been developed, such as LTT-MELISA,[107] although the results of studies are contradictory. The first peer reviewed study assessing the diagnostic sensitivity and specificity of the test was presented in 2012 and demonstrated potential for LTT to become a supportive diagnostic tool.[108] In 2014, research of LTT-MELISA concluded that it is "sensible" to include the LTT test in the diagnostic protocol for putative European-acquired Lyme borreliosis infections.[109] Other diagnostic techniques, such as focus floating microscopy, are under investigation.[110] New research indicates chemokine CXCL13 may also be a possible marker for neuroborreliosis.[111]

Some laboratories offer Lyme disease testing using assays whose accuracy and clinical usefulness have not been adequately established. These tests include urine antigen tests, PCR tests on urine, immunofluorescent staining for cell-wall-deficient forms of *B. burgdorferi*, and lymphocyte transformation tests. The CDC does not recommend these tests, and stated their use is "of great concern and is strongly discouraged".[100]

### Imaging

Neuroimaging is controversial in whether it provides specific patterns unique to neuroborreliosis, but may aid in differential diagnosis and in understanding the pathophysiology of the disease.[112] Though controversial, some evidence shows certain neuroimaging tests can provide data that are helpful in the diagnosis of a patient. Magnetic resonance imaging (MRI) and single-photon emission computed tomography (SPECT) are two of the tests that can identify abnormalities in the brain of a patient affected with this disease. Neuroimaging findings in an MRI include lesions in the periventricular white matter, as well as enlarged ventricles and cortical atrophy. The findings are considered somewhat unexceptional because the lesions have been found to be reversible following antibiotic treatment. Images produced using SPECT show numerous areas where an insufficient amount of blood is being delivered the cortex and subcortical white matter. However, SPECT images are known to be nonspecific because they show a heterogeneous pattern in the imaging. The abnormalities seen in the SPECT images are very similar to those seen in people with cerebral vacuities and Creutzfeldt–Jakob disease, which makes them questionable.[113]

## Prevention

Protective clothing includes a hat, long-sleeved shirt, and long pants tucked into socks or boots. Light-colored clothing makes the tick more easily visible before it attaches itself. People should use special care in

handling and allowing outdoor pets inside homes because they can bring ticks into the house. People who work in areas with woods, bushes, leaf litter, and tall grass are at risk of becoming infected with Lyme at work. Employers can reduce the risk for employees by providing education on Lyme transmission and infection risks, and about how to check themselves for ticks on the groin, armpits, and hair. Work clothing used in risky areas should be washed in hot water and dried in a hot dryer to kill any ticks.[114]

Permethrin sprayed on clothing kills ticks on contact, and is sold for this purpose. According to the CDC, only DEET is effective at repelling ticks.[115]

## Management of host animals

Lyme and other deer tick-borne diseases can sometimes be reduced by greatly reducing the deer population on which the adult ticks depend for feeding and reproduction. Lyme disease cases fell following deer eradication on an island, Monhegan, Maine[116] and following deer control in Mumford Cove, Connecticut.[117] It is worth noting that eliminating deer may lead to a temporary increase in tick density.[118]

For example, in the U.S., reducing the deer population to levels of 8 to 10 per square mile (from the current levels of 60 or more deer per square mile in the areas of the country with the highest Lyme disease rates), may reduce tick numbers and reduce the spread of Lyme and other tick-borne diseases.[119] However, such a drastic reduction may be very difficult to implement in many areas, and low to moderate densities of deer or other large mammal hosts may continue to feed sufficient adult ticks to maintain larval densities at high levels. Routine veterinary control of ticks of domestic animals, including livestock, by use of acaricides can contribute to reducing exposure of humans to ticks.

Action can be taken to avoid getting bitten by ticks by using insect repellants, for example, those that contain DEET. DEET-containing repellants are thought to be moderately effective in the prevention of tick bites.[120]

In Europe known reservoirs of *Borrelia burgdorferi* were 9 small mammals, 7 medium-sized mammals and 16 species of birds (including passerines, sea-birds and pheasants).[121] These animals seem to transmit spirochetes to ticks and thus participate in the natural circulation of B. burgdorferi in Europe. The house mouse is also suspected as well as other species of small rodents, particularly in Eastern Europe and Russia.[121]
"The reservoir species that contain the most pathogens are the European roe deer *Capreolus capreolus*;[122] "*it does not appear to serve as a major reservoir of B. burgdorferi*" thought Jaenson & al. (1992)[123] (incompetent host for *B. burgdorferi* and TBE virus) but it is important for feeding the ticks,[124] as red deer and wild boars (*Sus scrofa*),[125] in which one *Rickettsia* and three *Borrelia* species were identified",[122] with high risks of coinfection in roe deer.[126] Nevertheless, in the 2000s, in roe deer in Europe " *two species of Rickettsia and two species of Borrelia were identified*".[125]

## Vaccination

A recombinant vaccine against Lyme disease, based on the outer surface protein A (ospA) of *B. burgdorferi*, was developed by SmithKline Beecham. In clinical trials involving more than 10,000 people, the vaccine, called LYMErix, was found to confer protective immunity to *Borrelia* in 76% of adults and 100% of children with only mild or moderate and transient adverse effects.[127] LYMErix was approved on the basis of these trials by the Food and Drug Administration (FDA) on December 21, 1998.

Following approval of the vaccine, its entry in clinical practice was slow for a variety of reasons, including its cost, which was often not reimbursed by insurance companies.[128] Subsequently, hundreds of vaccine recipients reported they had developed autoimmune side effects. Supported by some patient advocacy groups, a number of class-action lawsuits were filed against GlaxoSmithKline, alleging the vaccine had caused these health problems. These claims were investigated by the FDA and the Centers for Disease Control, which found no connection between the vaccine and the autoimmune complaints.[129]

Despite the lack of evidence that the complaints were caused by the vaccine, sales plummeted and LYMErix

was withdrawn from the U.S. market by GlaxoSmithKline in February 2002,[130] in the setting of negative media coverage and fears of vaccine side effects.[129][131] The fate of LYMErix was described in the medical literature as a "cautionary tale";[131] an editorial in *Nature* cited the withdrawal of LYMErix as an instance in which "unfounded public fears place pressures on vaccine developers that go beyond reasonable safety considerations."[132] The original developer of the OspA vaccine at the Max Planck Institute told *Nature*: "This just shows how irrational the world can be... There was no scientific justification for the first OspA vaccine LYMErix being pulled."[129]

New vaccines are being researched using outer surface protein C (OspC) and glycolipoprotein as methods of immunization.[133][134] Vaccines have been formulated and approved for prevention of Lyme disease in dogs. Currently, three Lyme disease vaccines are available. LymeVax, formulated by Fort Dodge Laboratories, contains intact dead spirochetes which expose the host to the organism. Galaxy Lyme, Intervet-Schering-Plough's vaccine, targets proteins OspC and OspA. The OspC antibodies kill any of the bacteria that have not been killed by the OspA antibodies. Canine Recombinant Lyme, formulated by Merial, generates antibodies against the OspA protein so a tick feeding on a vaccinated dog draws in blood full of anti-OspA antibodies, which kill the spirochetes in the tick's gut before they are transmitted to the dog.[135]

### Tick removal

Removal of a tick using tweezers

Attached ticks should be removed promptly, as removal within 36 hours can reduce transmission rates.[136] Folk remedies for tick removal tend to be ineffective, offer no advantages in preventing the transfer of disease, and may increase the risks of transmission or infection.[137] The best method is simply to pull the tick out with tweezers as close to the skin as possible, without twisting, and avoiding crushing the body of the tick or removing the head from the tick's body.[138] The risk of infection increases with the time the tick is attached, and if a tick is attached for fewer than 24 hours, infection is unlikely. However, since these ticks are very small, especially in the nymph stage, prompt detection is quite difficult.[136] The Australian Society of Clinical Immunology recommends against using tweezers to remove ticks but rather to kill the tick first by using a product to rapidly freeze the tick to prevent it from injecting more allergen-containing saliva. In a tick allergic person, the tick should be killed and removed in a safe place (e.g. an emergency department of a hospital).[139]

### Preventive antibiotics

The risk of infectious transmission increases with the duration of tick attachment.[140] It requires between 36 and 48 hours of attachment for the bacteria that causes Lyme to travel from within the tick into its saliva.[140] If a deer tick that is sufficiently likely to be carrying *Borrelia* is found attached to a person and removed, and if the tick has been attached for 36 hours or is engorged, a single dose of doxycycline administered within the 72 hours after removal may reduce the risk of Lyme disease. It is not generally recommended for all people bitten, as development of infection is rare: about 50 bitten people would have to be treated this way to prevent one case of erythema migrans (i.e. the typical rash found in about 70-80% of people infected).[1][140]

## Treatment

Antibiotics are the primary treatment.[1][140] The specific approach to their use is dependent on the individual affected and the stage of the disease.[140] For most people with early localized infection, oral administration of doxycycline is widely recommended as the first choice, as it is effective against not only *Borrelia* bacteria but also a variety of other illnesses carried by ticks.[140] Doxycycline is contraindicated in children younger than eight years of age and women who are pregnant or breastfeeding;[140] alternatives

to doxycycline are amoxicillin, cefuroxime axetil, and azithromycin.[140] Individuals with early disseminated or late infection may have symptomatic cardiac disease, refractory Lyme arthritis, or neurologic symptoms like meningitis or encephalitis.[140] Intravenous administration of ceftriaxone is recommended as the first choice in these cases;[140] cefotaxime and doxycycline are available as alternatives.[140]

These treatment regimens last from one to four weeks.[140] If joint swelling persists or returns, a second round of antibiotics may be considered.[140] Outside of that, a prolonged antibiotic regimen lasting more than 28 days is not recommended as no clinical evidence shows it to be effective.[140][141] IgM and IgG antibody levels may be elevated for years even after successful treatment with antibiotics.[140] As antibody levels are not indicative of treatment success, testing for them is not recommended.[140]

# Prognosis

For early cases, prompt[*specify*] treatment is usually curative.[142] However, the severity and treatment of Lyme disease may be complicated due to late diagnosis, failure of antibiotic treatment, and simultaneous infection with other tick-borne diseases (coinfections), including ehrlichiosis, babesiosis, and immune suppression[*citation needed*] in the patient.

A meta-analysis published in 2005 found some patients with Lyme disease have fatigue, joint or muscle pain, and neurocognitive symptoms persisting for years, despite antibiotic treatment.[143] Patients with late stage Lyme disease have been shown to experience a level of physical disability equivalent to that seen in congestive heart failure.[144]

In dogs, a serious long-term prognosis may result in glomerular disease,[145] which is a category of kidney damage that may cause chronic kidney disease.[135] Dogs may also experience chronic joint disease if the disease is left untreated. However, the majority of cases of Lyme disease in dogs result in a complete recovery with, and sometimes without, treatment with antibiotics.[146][*verification needed*] In rare cases, Lyme disease can be fatal to both humans and dogs.[147]

# Epidemiology

Lyme disease occurs regularly in Northern Hemisphere temperate regions.[148]

Countries with reported Lyme disease cases.

## Africa

In northern Africa, *B. burgdorferi sensu lato* has been identified in Morocco, Algeria, Egypt and Tunisia.[149][150][151]

Lyme disease in sub-Saharan Africa is presently unknown, but evidence indicates it may occur in humans in this region. The abundance of hosts and tick vectors would favor the establishment of Lyme infection in Africa.[152] In East Africa, two cases of Lyme disease have been reported in Kenya.[153]

## Asia

*B. burgdorferi sensu lato*-infested ticks are being found more frequently in Japan, as well as in northwest China, Nepal, Thailand and far eastern Russia.[154][155] *Borrelia* has also been isolated in Mongolia.[156]

## Europe

In Europe, Lyme disease is caused by infection with one or more pathogenic European genospecies of the spirochaete *B. burgdorferi sensu lato*, mainly transmitted by the tick *Ixodes ricinus*.[157] Cases of *B. burgdorferi sensu lato*-infected ticks are found predominantly in central Europe, particularly in Slovenia and Austria, but have been isolated in almost every country on the continent.[158] Incidence in southern Europe, such as Italy and Portugal, is much lower.[159]

## United Kingdom

In the United Kingdom the number of laboratory confirmed cases of Lyme disease has been rising steadily since voluntary reporting was introduced in 1986[160] when 68 cases were recorded in the UK and Republic of Ireland combined.[161] In the UK there were 23 confirmed cases in 1988 and 19 in 1990,[162] but 973 in 2009[160] and 953 in 2010.[163] Provisional figures for the first 3 quarters of 2011 show a 26% increase on the same period in 2010.[164]

It is thought, however, that the actual number of cases is significantly higher than suggested by the above figures, with the UK's Health Protection Agency estimating that there are between 2,000 and 3,000 cases per year,[163] (with an average of around 15% of the infections acquired overseas[160]), while Dr Darrel Ho-Yen, Director of the Scottish Toxoplasma Reference Laboratory and National Lyme Disease Testing Service, believes that the number of confirmed cases should be multiplied by 10 "to take account of wrongly diagnosed cases, tests giving false results, sufferers who weren't tested, people who are infected but not showing symptoms, failures to notify and infected individuals who don't consult a doctor."[165][166]

Despite Lyme disease (Borrelia burgdorferi infection) being a notifiable disease in Scotland[167] since January 1990[168] which should therefore be reported on the basis of clinical suspicion, it is believed that many GPs are unaware of the requirement.[169] Mandatory reporting, limited to laboratory test results only, was introduced throughout the UK in October 2010, under the Health Protection (Notification) Regulations 2010.[160]

Although there is a greater incidence of Lyme disease in the New Forest, Salisbury Plain, Exmoor, the South Downs, parts of Wiltshire and Berkshire, Thetford Forest[170] and the West coast and islands of Scotland[171] infected ticks are widespread, and can even be found in the parks of London.[162][172] A 1989 report found that 25% of forestry workers in the New Forest were seropositive, as were between 2% and 4-5% of the general local population of the area.[173][174]

Tests on pet dogs, carried out throughout the country in 2009 indicated that around 2.5% of ticks in the UK may be infected, considerably higher than previously thought.[175][176] It is thought that global warming may lead to an increase in tick activity in the future, as well as an increase in the amount of time that people spend in public parks, thus increasing the risk of infection.[177]

## North America

Many studies in North America have examined ecological and environmental correlates of Lyme disease prevalence. A 2005 study using climate suitability modelling of *I. scapularis* projected that climate change would cause an overall 213% increase in suitable vector habitat by the year 2080, with northward expansions in Canada, increased suitability in the central U.S., and decreased suitable habitat and vector retraction in the southern U.S.[178] A 2008 review of published studies concluded that the presence of forests or forested areas was the only variable that consistently elevated the risk of Lyme disease whereas other environmental variables showed little or no concordance between studies.[179] The authors argued that the factors influencing tick density and human risk between sites are still poorly understood, and that future studies should be conducted over longer time periods, become more standardized across regions, and incorporate existing knowledge of regional Lyme disease ecology.[179]

## Canada

Owing to changing climate, the range of ticks able to carry Lyme disease has expanded from a limited area

of Ontario to include areas of southern Quebec, Manitoba, northern Ontario, southern New Brunswick, southwest Nova Scotia and limited parts of Saskatchewan and Alberta, as well as British Columbia. Cases have been reported as far east as the island of Newfoundland.[180][181][182] A model-based prediction by Leighton *et al.* (2012) suggests that the range of the *I. scapularis* tick will expand into Canada by 46 km/year over the next decade, with warming climatic temperatures as the main driver of increased speed of spread.[183]

## Mexico

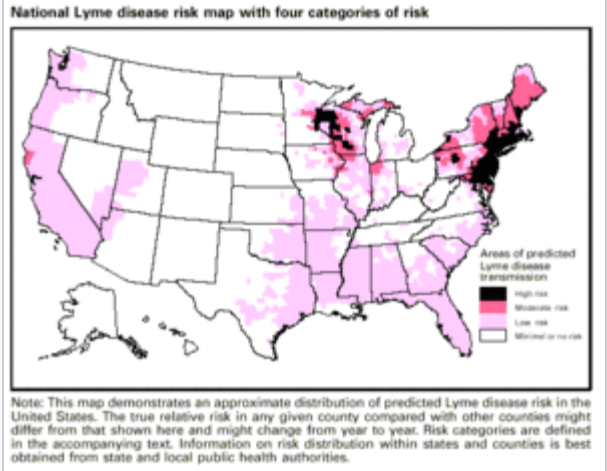
A 2007 study suggests *Borrelia burgdorferi* infections are endemic to Mexico, from four cases reported between 1999 and 2000.[184]

## United States

Each year, approximately 30,000 new cases are reported to the CDC however, this number is likely underestimated. The CDC is currently conducting research on evaluation and diagnostics of the disease and preliminary results suggest the number of new cases to be around 300,000.[185][186]

Lyme disease is the most common tick-borne disease in North America and Europe, and one of the fastest-growing infectious diseases in the United States. Of cases reported to the United States CDC, the ratio of Lyme disease infection is 7.9 cases for every 100,000 persons. In the ten states where Lyme disease is most common, the average was 31.6 cases for every 100,000 persons for the year 2005.[187][188][189]

Although Lyme disease has been reported in all states[185][190] about 99% of all reported cases are confined to just five geographic areas (New England, Mid-Atlantic, East-North Central, South Atlantic, and West North-Central).[191] New 2011 CDC Lyme case definition guidelines are used to determine confirmed CDC surveillance cases.[192]



CDC map showing the risk of Lyme disease in the United States, particularly its concentration in the Northeast Megalopolis and western Wisconsin.

Effective January 2008, the CDC gives equal weight to laboratory evidence from 1) a positive culture for *B. burgdorferi*; 2) two-tier testing (ELISA screening and Western blot confirming); or 3) single-tier IgG (old infection) Western blot.[193] Previously, the CDC only included laboratory evidence based on (1) and (2) in their surveillance case definition. The case definition now includes the use of Western blot without prior ELISA screen.[193]

The number of reported cases of the disease has been increasing, as are endemic regions in North America. For example, *B. burgdorferi sensu lato* was previously thought to be hindered in its ability to be maintained in an enzootic cycle in California, because it was assumed the large lizard population would dilute the prevalence of *B. burgdorferi* in local tick populations; this has since been brought into question, as some evidence has suggested lizards can become infected.[194]

Except for one study in Europe,[195] much of the data implicating lizards is based on DNA detection of the spirochete and has not demonstrated lizards are able to infect ticks feeding upon them.[194][196][197][198] As some experiments suggest lizards are refractory to infection with *Borrelia*, it appears likely their involvement in the enzootic cycle is more complex and species-specific.[54]

While *B. burgdorferi* is most associated with ticks hosted by white-tailed deer and white-footed mice, *Borrelia afzelii* is most frequently detected in rodent-feeding vector ticks, and *Borrelia garinii* and *Borrelia valaisiana* appear to be associated with birds. Both rodents and birds are competent reservoir hosts for *B. burgdorferi sensu stricto*. The resistance of a genospecies of Lyme disease spirochetes to the bacteriolytic activities of the alternative complement pathway of various host species may determine its reservoir host [*citation needed*]

association.

Several similar but apparently distinct conditions may exist, caused by various species or subspecies of *Borrelia* in North America. A regionally restricted condition that may be related to *Borrelia* infection is southern tick-associated rash illness (STARI), also known as Masters' disease. *Amblyomma americanum*, known commonly as the lone-star tick, is recognized as the primary vector for STARI. In some parts of the geographical distribution of STARI, Lyme disease is quite rare (e.g., Arkansas), so patients in these regions experiencing Lyme-like symptoms—especially if they follow a bite from a lone-star tick—should consider STARI as a possibility. It is generally a milder condition than Lyme and typically responds well to antibiotic treatment.[*citation needed*]

In recent years there have been 5 to 10 cases a year of a disease similar to Lyme occurring in Montana. It occurs primarily in pockets along the Yellowstone River in central Montana. People have developed a red bull's-eye rash around a tick bite followed by weeks of fatigue and a fever.[190]

Lyme disease prevalence is comparable among males and females. A wide range of age groups is affected, though the number of cases is highest among 10- to 19-year-olds. For unknown reasons, Lyme disease is seven times more common among Asians.[199]

### South America

In South America, tick-borne disease recognition and occurrence is rising. In Brazil, a Lyme-like disease known as Baggio–Yoshinari syndrome was identified, caused by microorganisms that do not belong to the *B. burgdorferi sensu lato* complex and transmitted by ticks of the *Amblyomma* and *Rhipicephalus* genera.[200] The first reported case of BYS in Brazil was made in 1992 in Cotia, São Paulo.[201] *B. burgdorferi sensu stricto* antigens in patients have been identified in Colombia and Bolivia.[*citation needed*]

## History

The evolutionary history of *Borrelia burgdorferi* genetics has been the subject of recent studies. One study has found that prior to the reforestation that accompanied post-colonial farm abandonment in New England and the wholesale migration into the mid-west that occurred during the early 19th century, Lyme disease was present for thousands of years in America and had spread along with its tick hosts from the Northeast to the Midwest.[202]

John Josselyn, who visited New England in 1638 and again from 1663–1670, wrote "there be infinite numbers of tikes hanging upon the bushes in summer time that will cleave to man's garments and creep into his breeches eating themselves in a short time into the very flesh of a man. I have seen the stockins of those that have gone through the woods covered with them."[203]

This is also confirmed by the writings of Peter Kalm, a Swedish botanist who was sent to America by Linnaeus, and who found the forests of New York "abound" with ticks when he visited in 1749. When Kalm's journey was retraced 100 years later, the forests were gone and the Lyme bacterium had probably become isolated to a few pockets along the northeast coast, Wisconsin, and Minnesota.[204]

Perhaps the first detailed description of what is now known as Lyme disease appeared in the writings of Reverend Dr. John Walker after a visit to the Island of Jura (Deer Island) off the west coast of Scotland in 1764.[205] He gives a good description both of the symptoms of Lyme disease (with "exquisite pain [in] the interior parts of the limbs") and of the tick vector itself, which he describes as a "worm" with a body which is "of a reddish colour and of a compressed shape with a row of feet on each side" that "penetrates the skin". Many people from this area of Great Britain emigrated to North America between 1717 and the end of the 18th century.

The examination of preserved museum specimens has found *Borrelia* DNA in an infected *Ixodes ricinus* tick from Germany that dates back to 1884, and from an infected mouse from Cape Cod that died in 1894.[204] The 2010 autopsy of Ötzi the Iceman, a 5,300-year-old mummy, revealed the presence of the DNA sequence of *Borrelia burgdorferi* making him the earliest known human with Lyme disease.[206]

The early European studies of what is now known as Lyme disease described its skin manifestations. The first study dates to 1883 in Breslau, Germany (now Wrocław, Poland), where physician Alfred Buchwald described a man who had suffered for 16 years with a degenerative skin disorder now known as acrodermatitis chronica atrophicans.[207]

At a 1909 research conference, Swedish dermatologist Arvid Afzelius presented a study about an expanding, ring-like lesion he had observed in an older woman following the bite of a sheep tick. He named the lesion *erythema migrans*.[207] The skin condition now known as borrelial lymphocytoma was first described in 1911.[208]

Neurological problems following tick bites were recognized starting in the 1920s. French physicians Garin and Bujadoux described a farmer with a painful sensory radiculitis accompanied by mild meningitis following a tick bite. A large, ring-shaped rash was also noted, although the doctors did not relate it to the meningoradiculitis. In 1930, the Swedish dermatologist Sven Hellerström was the first to propose EM and neurological symptoms following a tick bite were related.[209] In the 1940s, German neurologist Alfred Bannwarth described several cases of chronic lymphocytic meningitis and polyradiculoneuritis, some of which were accompanied by erythematous skin lesions.

Carl Lennhoff, who worked at the Karolinska Institute in Sweden, believed many skin conditions were caused by spirochetes. In 1948, he used a special stain to microscopically observe what he believed were spirochetes in various types of skin lesions, including EM.[210] Although his conclusions were later shown to be erroneous, interest in the study of spirochetes was sparked. In 1949, Nils Thyresson, who also worked at the Karolinska Institute, was the first to treat ACA with penicillin.[211] In the 1950s, the relationship among tick bite, lymphocytoma, EM and Bannwarth's syndrome was recognized throughout Europe leading to the widespread use of penicillin for treatment in Europe.[212][213]

In 1970, a dermatologist in Wisconsin named Rudolph Scrimenti recognized an EM lesion in a patient after recalling a paper by Hellerström that had been reprinted in an American science journal in 1950. This was the first documented case of EM in the United States. Based on the European literature, he treated the patient with penicillin.[214]

The full syndrome now known as Lyme disease was not recognized until a cluster of cases originally thought to be juvenile rheumatoid arthritis was identified in three towns in southeastern Connecticut in 1975, including the towns Lyme and Old Lyme, which gave the disease its popular name.[215] This was investigated by physicians David Snydman and Allen Steere of the Epidemic Intelligence Service, and by others from Yale University, including Dr. Stephen Malawista, who is credited as a co-discover of the disease.[216] The recognition that the patients in the United States had EM led to the recognition that "Lyme arthritis" was one manifestation of the same tick-borne condition known in Europe.[217]

Before 1976, the elements of *B. burgdorferi sensu lato* infection were called or known as tick-borne meningopolyneuritis, Garin-Bujadoux syndrome, Bannwarth syndrome, Afzelius' disease,[218] Montauk Knee or sheep tick fever. Since 1976 the disease is most often referred to as Lyme disease,[219][220] Lyme borreliosis or simply borreliosis.[*citation needed*]

In 1980, Steere, *et al.*, began to test antibiotic regimens in adult patients with Lyme disease.[221] In the same year, New York State Health Dept. epidemiologist Jorge Benach provided Willy Burgdorfer, a researcher at the Rocky Mountain Biological Laboratory, with collections of *I. dammini* [*scapularis*] from Shelter Island, NY, a known Lyme-endemic area as part of an ongoing investigation of Rocky Mountain spotted fever. In examining the ticks for rickettsiae, Burgdorfer noticed "poorly stained, rather long, irregularly coiled spirochetes." Further examination revealed spirochetes in 60% of the ticks. Burgdorfer credited his familiarity with the European literature for his realization that the spirochetes might be the "long-sought cause of ECM and Lyme disease." Benach supplied him with more ticks from Shelter Island and sera from patients diagnosed with Lyme disease. University of Texas Health Science Center researcher Alan Barbour "offered his expertise to culture and immunochemically characterize the organism." Burgdorfer subsequently confirmed his discovery by isolating, from patients with Lyme disease, spirochetes identical to those found in ticks.[222] In June 1982, he published his findings in Science, and the spirochete was named *Borrelia burgdorferi* in his honor.[223]

After the identification of *B. burgdorferi* as the causative agent of Lyme disease, antibiotics were selected for testing, guided by *in vitro* antibiotic sensitivities, including tetracycline antibiotics, amoxicillin, cefuroxime axetil, intravenous and intramuscular penicillin and intravenous ceftriaxone.[224][225] The mechanism of tick transmission was also the subject of much discussion. *B. burgdorferi* spirochetes were identified in tick saliva in 1987, confirming the hypothesis that transmission occurred via tick salivary glands.[226]

Jonathan Edlow, Professor of Medicine at Harvard Medical School, quotes the late Ed Masters (discoverer of STARI, a Lyme-like illness) in his book *Bull's-Eye*, on the history of Lyme disease. Edlow writes:

> Masters points out that the "track record" of the "conventional wisdom" regarding Lyme disease is not very good: "First off, they said it was a new disease, which it wasn't. Then it was thought to be viral, but it isn't. Then it was thought that sero-negativity didn't exist, which it does. They thought it was easily treated with short courses of antibiotics, which sometimes it isn't. Then it was only the *Ixodes dammini* tick, which we now know is not even a separate valid tick species. If you look throughout the history, almost every time a major dogmatic statement has been made about what we 'know' about this disease, it was subsequently proven wrong or underwent major modifications."[227]

# Society and culture

Urbanization and other anthropogenic factors can be implicated in the spread of Lyme disease to humans. In many areas, expansion of suburban neighborhoods has led to gradual deforestation of surrounding wooded areas and increased border contact between humans and tick-dense areas. Human expansion has also resulted in a reduction of predators that hunt deer as well as mice, chipmunks and other small rodents —the primary reservoirs for Lyme disease. As a consequence of increased human contact with host and vector, the likelihood of transmission of the disease has greatly increased.[228][229] Researchers are investigating possible links between global warming and the spread of vector-borne diseases, including Lyme disease.[230]

## Controversy

*Main article: Lyme disease controversy*

The term "chronic Lyme disease" is controversial and not recognized in the medical literature,[231] and most medical authorities advise against long-term antibiotic treatment for Lyme disease.[92][232][233] Studies have shown that most people diagnosed with "chronic Lyme disease" either have no objective evidence of previous or current infection with *B. burgdorferi* or are people who should be classified as having post-treatment Lyme disease syndrome (PTLDS), which is defined as continuing or relapsing non-specific symptoms (such as fatigue, musculoskeletal pain, and cognitive complaints) in a person previously treated for Lyme disease.[234]

## Notable cases

Singer Avril Lavigne was diagnosed in December 2014 with Lyme disease.[235] In September 2015, billionaire John Caudwell discussed his family's experience with Lyme.[236] *The Punk Singer*, a 2013 documentary film by Sini Anderson, portrays feminist singer Kathleen Hanna's experience with late-stage Lyme disease.[237] Professional basketball player and WNBA MVP Elena Delle Donne has discussed her experience with Lyme.[238]

# Other animals

Prevention of Lyme disease is an important step in keeping dogs safe in endemic areas. Prevention education and a number of preventative measures are available. First, for dog owners who live near or who

often frequent tick-infested areas, routine vaccinations of their dogs is an important step.[239]

Another crucial preventive measure is the use of persistent acaricides, such as topical repellents or pesticides that contain triazapentadienes (Amitraz), phenylpyrazoles (Fipronil), or permethrin (pyrethroids).[240] These acaricides target primarily the adult stages of Lyme-carrying ticks and reduce the number of reproductively active ticks in the environment.[239] Formulations of these ingredients are available in a variety of topical forms, including spot-ons, sprays, powders, impregnated collars, solutions, and shampoos.[240]

Examination of a dog for ticks after being in a tick-infested area is an important precautionary measure to take in the prevention of Lyme disease. Key spots to examine include the head, neck, and ears.[241]

## Research

The National Institutes of Health have supported research into bacterial persistence.[242]

# Malaria

From Wikipedia, the free encyclopedia

**Malaria** is a mosquito-borne infectious disease affecting humans and other animals caused by parasitic protozoans (a group of single-celled microorganisms) belonging to the *Plasmodium* type.[1] Malaria causes symptoms that typically include fever, fatigue, vomiting, and headaches. In severe cases it can cause yellow skin, seizures, coma, or death.[2] Symptoms usually begin ten to fifteen days after being bitten. If not properly treated, people may have recurrences of the disease months later.[1] In those who have recently survived an infection, reinfection usually causes milder symptoms. This partial resistance disappears over months to years if the person has no continuing exposure to malaria.[2]

The disease is most commonly transmitted by an infected female *Anopheles* mosquito. The mosquito bite introduces the parasites from the mosquito's saliva into a person's blood.[1] The parasites travel to the liver where they mature and reproduce. Five species of *Plasmodium* can infect and be spread by humans.[2] Most deaths are caused by *P. falciparum* because *P. vivax*, *P. ovale*, and *P. malariae* generally cause a milder form of malaria.[1][2] The species *P. knowlesi* rarely causes disease in humans.[1] Malaria is typically diagnosed by the microscopic examination of blood using blood films, or with antigen-based rapid diagnostic tests.[2] Methods that use the polymerase chain reaction to detect the parasite's DNA have been developed, but are not widely used in areas where malaria is common due to their cost and complexity.[3]

The risk of disease can be reduced by preventing mosquito bites through the use of mosquito nets and insect repellents, or with mosquito control measures such as spraying insecticides and draining standing water.[2] Several medications are available to prevent malaria in travellers to areas where the disease is common. Occasional doses of the combination medication sulfadoxine/pyrimethamine are recommended in infants and after the first trimester of pregnancy in areas with high rates of malaria. Despite a need, no effective vaccine exists, although efforts to develop one are ongoing.[1] The recommended treatment for malaria is a combination of antimalarial medications that includes an artemisinin.[1][2] The second medication may be either mefloquine, lumefantrine, or sulfadoxine/pyrimethamine.[4] Quinine along with doxycycline may be used if an artemisinin is not available.[4] It is recommended that in areas where the disease is common, malaria is confirmed if possible before treatment is started due to concerns of increasing drug resistance. among the parasites has developed to several antimalarial medications; for example, chloroquine-resistant *P. falciparum* has spread to most malarial areas, and resistance to artemisinin has become a problem in some parts of Southeast Asia.[1]

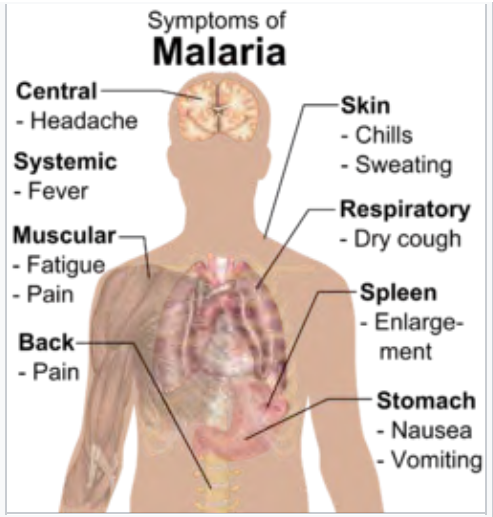
The disease is widespread in the tropical and subtropical regions that exist in a broad band around the equator.[2] This includes much of Sub-Saharan Africa, Asia, and Latin America. In 2015, there were 214 million cases of malaria worldwide resulting in an estimated 438,000 deaths, 90% of which occurred in Africa.[5] Rates of disease have decreased from 2000 to 2015 by 37%,[5] but increased from 2014 during which there were 198 million cases.[6] Malaria is commonly associated with poverty and has a major negative effect on economic development.[7][8] In Africa, it is estimated to result in losses of US$12 billion a year due to increased healthcare costs, lost ability to work, and negative effects on tourism.[9]

**Contents**

# Signs and symptoms

The signs and symptoms of malaria typically begin 8–25 days following infection,[10] however, symptoms may occur later in those who have taken antimalarial medications as prevention.[3] Initial manifestations of the disease—common to all malaria species—are similar to flu-like symptoms,[11] and can resemble other conditions such as sepsis, gastroenteritis, and viral diseases.[3] The presentation may include headache, fever, shivering, joint pain, vomiting, hemolytic anemia, jaundice, hemoglobin in the urine, retinal damage, and convulsions.[12]



Main symptoms of malaria[10]

The classic symptom of malaria is paroxysm—a cyclical occurrence of sudden coldness followed by shivering and then fever and sweating, occurring every two days (tertian fever) in *P. vivax* and *P. ovale* infections, and every three days (quartan fever) for *P. malariae*. *P. falciparum* infection can cause recurrent fever every 36–48 hours, or a less pronounced and almost continuous fever.[13]

Severe malaria is usually caused by *P. falciparum* (often referred to as falciparum malaria). Symptoms of falciparum malaria arise 9–30 days after infection.[11] Individuals with cerebral malaria frequently exhibit neurological symptoms, including abnormal posturing, nystagmus, conjugate gaze palsy (failure of the eyes to turn together in the same direction), opisthotonus, seizures, or coma.[11]

## Complications

Malaria has several serious complications. Among these is the development of respiratory distress, which occurs in up to 25% of adults and 40% of children with severe *P. falciparum* malaria. Possible causes include respiratory compensation of metabolic acidosis, noncardiogenic pulmonary oedema, concomitant pneumonia, and severe anaemia. Although rare in young children with severe malaria, acute respiratory distress syndrome occurs in 5–25% of adults and up to 29% of pregnant women.[14] Coinfection of HIV with malaria increases mortality.[15] Renal failure is a feature of blackwater fever, where hemoglobin from lysed red blood cells leaks into the urine.[11]

Infection with *P. falciparum* may result in cerebral malaria, a form of severe malaria that involves encephalopathy. It is associated with retinal whitening, which may be a useful clinical sign in distinguishing malaria from other causes of fever.[16] Enlarged spleen, enlarged liver or both of these, severe headache, low blood sugar, and hemoglobin in the urine with renal failure may occur.[11] Complications may include spontaneous bleeding, coagulopathy, and shock.[17]

Malaria in pregnant women is an important cause of stillbirths, infant mortality, abortion and low birth weight,[18] particularly in *P. falciparum* infection, but also with *P. vivax*.[19]

## Cause

*Main article: Plasmodium*

Malaria parasites belong to the genus *Plasmodium* (phylum Apicomplexa). In humans, malaria is caused by *P. falciparum*, *P. malariae*, *P. ovale*, *P. vivax* and *P. knowlesi*.[20][21] Among those infected, *P. falciparum* is the most common species identified (~75%) followed by *P. vivax* (~20%).[3] Although *P. falciparum* traditionally accounts for the majority of deaths,[22] recent evidence suggests that *P. vivax* malaria is associated with potentially life-threatening conditions about as often as with a diagnosis of *P. falciparum* infection.[23] *P. vivax* proportionally is more common outside Africa.[24] There have been documented human infections with several species of *Plasmodium* from higher apes; however, except for *P. knowlesi*—a zoonotic species that causes malaria in macaques[21]—these are mostly of limited public health importance.[25]

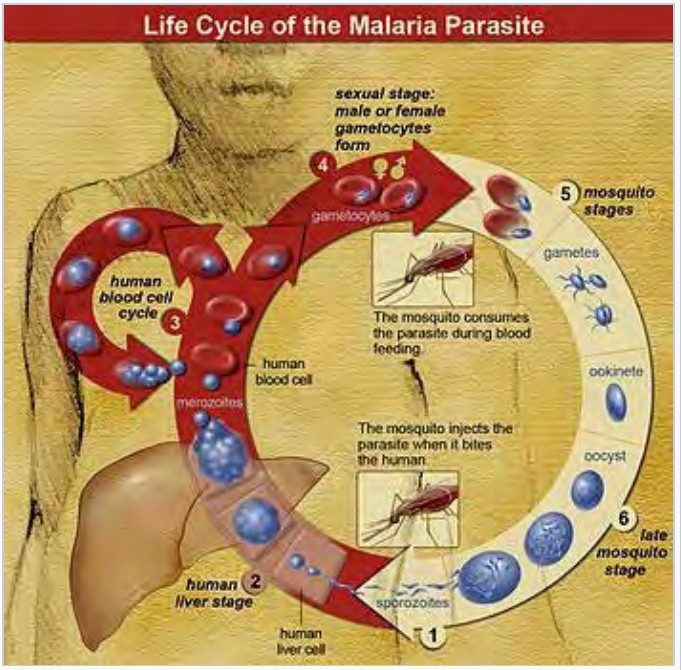
Global warming is likely to affect malaria transmission, but the severity and geographic distribution of such effects is uncertain.[26][27]

## Life cycle

In the life cycle of *Plasmodium*, a female *Anopheles* mosquito (the definitive host) transmits a motile infective form (called the sporozoite) to a vertebrate host such as a human (the secondary host), thus acting as a transmission vector. A sporozoite travels through the blood vessels to liver cells (hepatocytes), where it reproduces asexually (tissue schizogony), producing thousands of merozoites. These infect new red blood cells and initiate a series of asexual multiplication cycles (blood schizogony) that produce 8 to 24 new infective merozoites, at which point the cells burst and the infective cycle begins anew.[28]

Other merozoites develop into immature gametocytes, which are the precursors of male and female gametes. When a fertilized mosquito bites an infected person, gametocytes are taken up with the blood and mature in the mosquito gut. The male and female gametocytes fuse and form an ookinete—a fertilized, motile zygote. Ookinetes develop into new sporozoites that migrate to the insect's salivary glands, ready to infect a new vertebrate host. The sporozoites are injected into the skin, in the saliva, when the mosquito takes a subsequent blood meal.[29]

Only female mosquitoes feed on blood; male mosquitoes feed on plant nectar and do not transmit the disease. The females of the *Anopheles* genus of mosquito prefer to feed at night. They usually start searching for a meal at dusk and will continue throughout the night until taking a meal.[30] Malaria parasites can also be transmitted by blood transfusions, although this is rare.[31]



The life cycle of malaria parasites. A mosquito causes an infection by a bite. First, sporozoites enter the bloodstream, and migrate to the liver. They infect liver cells, where they multiply into merozoites, rupture the liver cells, and return to the bloodstream. The merozoites infect red blood cells, where they develop into ring forms, trophozoites and schizonts that in turn produce further merozoites. Sexual forms are also produced, which, if taken up by a mosquito, will infect the insect and continue the life cycle.

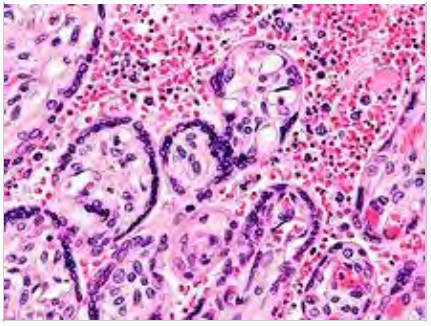
## Recurrent malaria

Symptoms of malaria can recur after varying symptom-free periods. Depending upon the cause, recurrence can be classified as either recrudescence, relapse, or reinfection. Recrudescence is when symptoms return after a symptom-free period. It is caused by parasites surviving in the blood as a result of inadequate or ineffective treatment.[32] Relapse is when symptoms reappear after the parasites have been eliminated from blood but persist as dormant hypnozoites in liver cells. Relapse commonly occurs between 8–24 weeks and is commonly seen with *P. vivax* and *P. ovale* infections.[3] *P. vivax* malaria cases in temperate areas often involve overwintering by hypnozoites, with relapses beginning the year after the mosquito bite.[33] Reinfection means the parasite that caused the past infection was eliminated from the body but a new parasite was introduced. Reinfection cannot readily be distinguished from recrudescence, although recurrence of infection within two weeks of treatment for the initial infection is typically attributed to treatment failure.[34] People may develop some immunity when exposed to frequent infections.[35]

# Pathophysiology

*Further information:* Plasmodium falciparum *biology*

Malaria infection develops via two phases: one that involves the liver (exoerythrocytic phase), and one that involves red blood cells, or erythrocytes (erythrocytic phase). When an infected mosquito pierces a person's skin to take a blood meal, sporozoites in the mosquito's saliva enter the bloodstream and migrate to the liver where they infect hepatocytes, multiplying asexually and asymptomatically for a period of 8–30 days.[36]



Micrograph of a placenta from a stillbirth due to maternal malaria. H&E stain. Red blood cells are anuclear; blue/black staining in bright red structures (red blood cells) indicate foreign nuclei from the parasites.

After a potential dormant period in the liver, these organisms differentiate to yield thousands of merozoites, which, following rupture of their host cells, escape into the blood and infect red blood cells to begin the erythrocytic stage of the life cycle.[36] The parasite escapes from the liver undetected by wrapping itself in the cell membrane of the infected host liver cell.[37]

Within the red blood cells, the parasites multiply further, again asexually, periodically breaking out of their host cells to invade fresh red blood cells. Several such amplification cycles occur. Thus, classical descriptions of waves of fever arise from simultaneous waves of merozoites escaping and infecting red blood cells.[36]

Some *P. vivax* sporozoites do not immediately develop into exoerythrocytic-phase merozoites, but instead, produce hypnozoites that remain dormant for periods ranging from several months (7–10 months is typical) to several years. After a period of dormancy, they reactivate and produce merozoites. Hypnozoites are responsible for long incubation and late relapses in *P. vivax* infections,[33] although their existence in *P. ovale* is uncertain.[38]

The parasite is relatively protected from attack by the body's immune system because for most of its human life cycle it resides within the liver and blood cells and is relatively invisible to immune surveillance. However, circulating infected blood cells are destroyed in the spleen. To avoid this fate, the *P. falciparum* parasite displays adhesive proteins on the surface of the infected blood cells, causing the blood cells to stick to the walls of small blood vessels, thereby sequestering the parasite from passage through the general circulation and the spleen.[39] The blockage of the microvasculature causes symptoms such as in placental malaria.[40] Sequestered red blood cells can breach the blood–brain barrier and cause cerebral malaria.[41]

## Genetic resistance

*Main article: Human genetic resistance to malaria*

According to a 2005 review, due to the high levels of mortality and morbidity caused by malaria—especially the *P. falciparum* species—it has placed the greatest selective pressure on the human genome in recent history. Several genetic factors provide some resistance to it including sickle cell trait, thalassaemia traits, glucose-6-phosphate dehydrogenase deficiency, and the absence of Duffy antigens on red blood cells.[42][43]

The impact of sickle cell trait on malaria immunity illustrates some evolutionary trade-offs that have occurred because of endemic malaria. Sickle cell trait causes a change in the hemoglobin molecule in the blood. Normally, red blood cells have a very flexible, biconcave shape that allows them to move through narrow capillaries; however, when the modified hemoglobin S molecules are exposed to low amounts of oxygen, or crowd together due to dehydration, they can stick together forming strands that cause the cell to sickle or distort into a curved shape. In these strands the molecule is not as effective in taking or releasing oxygen, and the cell is not flexible enough to circulate freely. In the early stages of malaria, the parasite can cause infected red cells to sickle, and so they are removed from circulation sooner. This reduces the frequency with which malaria parasites complete their life cycle in the cell. Individuals who are homozygous (with two copies of the abnormal hemoglobin beta allele) have sickle-cell anaemia, while those who are heterozygous (with one abnormal allele and one normal allele) experience resistance to malaria without severe anemia. Although the shorter life expectancy for those with the homozygous condition would tend to disfavor the trait's survival, the trait is preserved in malaria-prone regions because of the benefits provided by the heterozygous form.[43][44]

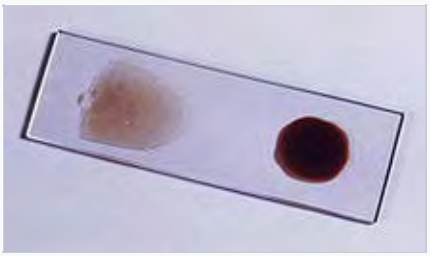
## Liver dysfunction

Liver dysfunction as a result of malaria is uncommon and usually only occurs in those with another liver condition such as viral hepatitis or chronic liver disease. The syndrome is sometimes called *malarial hepatitis*.[45] While it has been considered a rare occurrence, malarial hepatopathy has seen an increase, particularly in Southeast Asia and India. Liver compromise in people with malaria correlates with a greater likelihood of complications and death.[45]

# Diagnosis

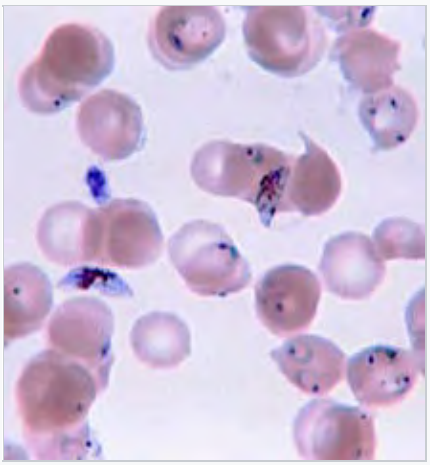
*Main article: Diagnosis of malaria*

Owing to the non-specific nature of the presentation of symptoms, diagnosis of malaria in non-endemic areas requires a high degree of suspicion, which might be elicited by any of the following: recent travel history, enlarged spleen, fever, low number of platelets in the blood, and higher-than-normal levels of bilirubin in the blood combined with a normal level of white blood cells.[3]



The blood film is the gold standard for malaria diagnosis.

Malaria is usually confirmed by the microscopic examination of blood films or by antigen-based rapid diagnostic tests (RDT).[46][47] In some areas, RDTs need to be able to distinguish whether the malaria symptoms are caused by Plasmodium falciparum or by other species of parasites since treatment strategies could differ for non-falciparum infections.[48] Microscopy is the most commonly used method to detect the malarial parasite—about 165 million blood films were examined for malaria in 2010.[49] Despite its widespread usage, diagnosis by microscopy suffers from two main drawbacks: many settings (especially rural) are not equipped to perform the test, and the accuracy of the results depends on both the skill of the person examining the blood film and the levels of the parasite in the blood. The sensitivity of blood films ranges from 75–90% in optimum conditions, to as low as 50%. Commercially available RDTs are often more accurate than blood films at predicting the presence of malaria parasites, but they are widely variable in diagnostic sensitivity and specificity depending on manufacturer, and are unable to tell how many parasites are present.[49]



Ring-forms and gametocytes of *Plasmodium falciparum* in human blood

In regions where laboratory tests are readily available, malaria should be suspected, and tested for, in any unwell person who has been in an area where malaria is endemic. In areas that cannot afford laboratory diagnostic tests, it has become common to use only a history of fever as the indication to treat for malaria—thus the common teaching "fever equals malaria unless proven otherwise". A drawback of this practice is overdiagnosis of malaria and mismanagement of non-malarial fever, which wastes limited resources, erodes confidence in the health care system, and contributes to drug resistance.[50] Although polymerase chain reaction-based tests have been developed, they are not widely used in areas where malaria is common as of 2012, due to their complexity.[3]

## Classification

Malaria is classified into either "severe" or "uncomplicated" by the World Health Organization (WHO).[3] It is deemed severe when *any* of the following criteria are present, otherwise it is considered uncomplicated.[51]

- Decreased consciousness
- Significant weakness such that the person is unable to walk
- Inability to feed
- Two or more convulsions
- Low blood pressure (less than 70 mmHg in adults and 50 mmHg in children)
- Breathing problems
- Circulatory shock
- Kidney failure or hemoglobin in the urine

Bleeding problems, or hemoglobin less than 50 g/L (5 g/dL)
- Pulmonary oedema
- Blood glucose less than 2.2 mmol/L (40 mg/dL)
- Acidosis or lactate levels of greater than 5 mmol/L
- A parasite level in the blood of greater than 100,000 per microlitre (μL) in low-intensity transmission areas, or 250,000 per μL in high-intensity transmission areas

Cerebral malaria is defined as a severe *P. falciparum*-malaria presenting with neurological symptoms, including coma (with a Glasgow coma scale less than 11, or a Blantyre coma scale greater than 3), or with a coma that lasts longer than 30 minutes after a seizure.[52]

Various types of malaria have been called by the names below:[53]

| Name | Pathogen | Notes |
|---|---|---|
| algid malaria | *Plasmodium falciparum* | severe malaria affecting the cardiovascular system and causing chills and circulatory shock |
| bilious malaria | *Plasmodium falciparum* | severe malaria affecting the liver and causing vomiting and jaundice |
| cerebral malaria | *Plasmodium falciparum* | severe malaria affecting the cerebrum |
| congenital malaria | various plasmodia | plasmodium introduced from the mother via the fetal circulation |
| falciparum malaria, *Plasmodium falciparum* malaria, pernicious malaria | *Plasmodium falciparum* | |
| ovale malaria, *Plasmodium ovale* malaria | *Plasmodium ovale* | |
| quartan malaria, malariae malaria, *Plasmodium malariae* malaria | *Plasmodium malariae* | paroxysms every fourth day (quartan), counting the day of occurrence as the first day |
| quotidian malaria | *Plasmodium falciparum*, *Plasmodium vivax* | paroxysms daily (quotidian) |
| tertian malaria | *Plasmodium falciparum*, *Plasmodium ovale*, *Plasmodium vivax* | paroxysms every third day (tertian), counting the day of occurrence as the first |
| transfusion malaria | various plasmodia | plasmodium introduced by blood transfusion, needle sharing, or needlestick injury |
| vivax malaria, *Plasmodium vivax* malaria | *Plasmodium vivax* | |

# Prevention

Methods used to prevent malaria include medications, mosquito elimination and the prevention of bites. There is no vaccine for malaria. The presence of malaria in an area requires a combination of high human population density, high anopheles mosquito population density and high rates of transmission from humans to mosquitoes and from mosquitoes to humans. If any of these is lowered sufficiently, the parasite will eventually disappear from that area, as happened in North America, Europe and parts of the Middle East. However, unless the parasite is eliminated from the whole world, it could become re-established if conditions revert to a combination that favors the parasite's reproduction. Furthermore, the cost per person of eliminating anopheles mosquitoes rises with decreasing population density, making it

An *Anopheles stephensi*

economically unfeasible in some areas.[54]

Prevention of malaria may be more cost-effective than treatment of the disease in the long run, but the initial costs required are out of reach of many of the world's poorest people. There is a wide difference in the costs of control (i.e. maintenance of low endemicity) and elimination programs between countries. For example, in China—whose government in 2010 announced a strategy to pursue malaria elimination in the Chinese provinces—the required investment is a small proportion of public expenditure on health. In contrast, a similar program in Tanzania would cost an estimated one-fifth of the public health budget.[55]

mosquito shortly after obtaining blood from a human (the droplet of blood is expelled as a surplus). This mosquito is a vector of malaria, and mosquito control is an effective way of reducing its incidence.

In areas where malaria is common, children under five years old often have anemia which is sometimes due to malaria. Giving children with anemia in these areas preventive antimalarial medication improves red blood cell levels slightly but did not affect the risk of death or need for hospitalization.[56]

## Mosquito control

*Further information: Mosquito control*

Man spraying kerosene oil in standing water, Panama Canal Zone 1912

Vector control refers to methods used to decrease malaria by reducing the levels of transmission by mosquitoes. For individual protection, the most effective insect repellents are based on DEET or picaridin.[57] Insecticide-treated mosquito nets (ITNs) and indoor residual spraying (IRS) have been shown to be highly effective in preventing malaria among children in areas where malaria is common.[58][59] Prompt treatment of confirmed cases with artemisinin-based combination therapies (ACTs) may also reduce transmission.[60]

Mosquito nets help keep mosquitoes away from people and reduce infection rates and transmission of malaria. Nets are not a perfect barrier and are often treated with an insecticide designed to kill the mosquito before it has time to find a way past the net. Insecticide-treated nets are estimated to be twice as effective as untreated nets and offer greater than 70% protection compared with no net.[61] Between 2000 and 2008, the use of ITNs saved the lives of an estimated 250,000 infants in Sub-Saharan Africa.[62] About 13% of households in Sub-Saharan countries owned ITNs in 2007[63] and 31% of African households were estimated to own at least one ITN in 2008. In 2000, 1.7 million (1.8%) African children living in areas of the world where malaria is common were protected by an ITN. That number increased to 20.3 million (18.5%) African children using ITNs in 2007, leaving 89.6 million children unprotected[64] and to 68% African children using mosquito nets in 2015.[65] Most nets are impregnated with pyrethroids, a class of insecticides with low toxicity. They are most effective when used from dusk to dawn.[66] It is recommended to hang a large "bed net" above the center of a bed and either tuck the edges under the mattress or make sure it is large enough such that it touches the ground.[67]

Walls where indoor residual spraying of DDT has been applied. The mosquitoes remain on the wall until they fall down dead on the floor.

Indoor residual spraying is the spraying of insecticides on the walls inside a home. After feeding, many mosquitoes rest on a nearby surface while digesting the bloodmeal, so if the walls of houses have been coated with insecticides, the resting mosquitoes can be killed before they can bite another [68]

A mosquito net in use.

person and transfer the malaria parasite. As of 2006, the World Health Organization recommends 12 insecticides in IRS operations, including DDT and the pyrethroids cyfluthrin and deltamethrin.[69] This public health use of small amounts of DDT is permitted under the Stockholm Convention, which prohibits its agricultural use.[70] One problem with all forms of IRS is insecticide resistance. Mosquitoes affected by IRS tend to rest and live indoors, and due to the irritation caused by spraying, their descendants tend to rest and live outdoors, meaning that they are less affected by the IRS.[71]

There are a number of other methods to reduce mosquito bites and slow the spread of malaria. Efforts to decrease mosquito larva by decreasing the availability of open water in which they develop or by adding substances to decrease their development is effective in some locations.[72] Electronic mosquito repellent devices which make very high-frequency sounds that are supposed to keep female mosquitoes away, do not have supporting evidence.[73]

## Other methods

Community participation and health education strategies promoting awareness of malaria and the importance of control measures have been successfully used to reduce the incidence of malaria in some areas of the developing world.[74] Recognizing the disease in the early stages can stop the disease from becoming fatal. Education can also inform people to cover over areas of stagnant, still water, such as water tanks that are ideal breeding grounds for the parasite and mosquito, thus cutting down the risk of the transmission between people. This is generally used in urban areas where there are large centers of population in a confined space and transmission would be most likely in these areas.[75] Intermittent preventive therapy is another intervention that has been used successfully to control malaria in pregnant women and infants,[76] and in preschool children where transmission is seasonal.[77]

## Medications

*Main article: Malaria prophylaxis*

There are a number of drugs that can help prevent or interrupt malaria in travelers to places where infection is common. Many of these drugs are also used in treatment. Chloroquine may be used where chloroquine-resistant parasites are not common.[78] In places where *Plasmodium* is resistant to one or more medications, three medications—mefloquine (*Lariam*), doxycycline (available generically), or the combination of atovaquone and proguanil hydrochloride (*Malarone*)—are frequently used when prophylaxis is needed.[78] Doxycycline and the atovaquone plus proguanil combination are the best tolerated; mefloquine is associated with death, suicide, and neurological and psychiatric symptoms.[78]

The protective effect does not begin immediately, and people visiting areas where malaria exists usually start taking the drugs one to two weeks before arriving and continue taking them for four weeks after leaving (except for atovaquone/proguanil, which only needs to be started two days before and continued for seven days afterward).[79] The use of preventative drugs is often not practical for those who live in areas where malaria exists, and their use is usually only in pregnant women and short-term visitors. This is due to the cost of the drugs, side effects from long-term use, and the difficulty in obtaining anti-malarial drugs outside of wealthy nations.[80] During pregnancy, medication to prevent malaria has been found to improve the weight of the baby

at birth and decrease the risk of anemia in the mother.[81] The use of preventative drugs where malaria-bearing mosquitoes are present may encourage the development of partial resistance.[82]

# Treatment

Malaria is treated with antimalarial medications; the ones used depends on the type and severity of the disease. While medications against fever are commonly used, their effects on outcomes are not clear.[83]

Simple or uncomplicated malaria may be treated with oral medications. The most effective treatment for *P. falciparum* infection is the use of artemisinins in combination with other antimalarials (known as artemisinin-combination therapy, or ACT), which decreases resistance to any single drug component.[84] These additional antimalarials include: amodiaquine, lumefantrine, mefloquine or sulfadoxine/pyrimethamine.[85] Another recommended combination is dihydroartemisinin and piperaquine.[86][87] ACT is about 90% effective when used to treat uncomplicated malaria.[62] To treat malaria during pregnancy, the WHO recommends the use of quinine plus clindamycin early in the pregnancy (1st trimester), and ACT in later stages (2nd and 3rd trimesters).[88] In the 2000s (decade), malaria with partial resistance to artemisins emerged in Southeast Asia.[89][90] Infection with *P. vivax*, *P. ovale* or *P. malariae* usually do not require hospitalization. Treatment of *P. vivax* requires both treatment of blood stages (with chloroquine or ACT) and clearance of liver forms with primaquine.[91] Treatment with tafenoquine prevents relapses after confirmed *P. vivax* malaria.[92]

An advertisement for quinine as a malaria treatment from 1927.

Severe and complicated malaria are almost always caused by infection with *P. falciparum*. The other species usually cause only febrile disease.[93] Severe and complicated malaria are medical emergencies since mortality rates are high (10% to 50%).[94] Cerebral malaria is the form of severe and complicated malaria with the worst neurological symptoms.[95] Recommended treatment for severe malaria is the intravenous use of antimalarial drugs. For severe malaria, parenteral artesunate was superior to quinine in both children and adults.[96] In another systematic review, artemisinin derivatives (artemether and arteether) were as efficacious as quinine in the treatment of cerebral malaria in children.[97] Treatment of severe malaria involves supportive measures that are best done in a critical care unit. This includes the management of high fevers and the seizures that may result from it. It also includes monitoring for poor breathing effort, low blood sugar, and low blood potassium.[22]

## Resistance

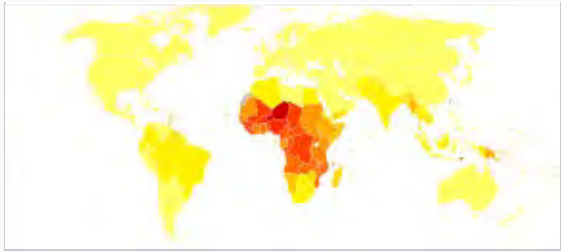
Drug resistance poses a growing problem in 21st-century malaria treatment.[98] Resistance is now common against all classes of antimalarial drugs apart from artemisinins. Treatment of resistant strains became increasingly dependent on this class of drugs. The cost of artemisinins limits their use in the developing world.[99] Malaria strains found on the Cambodia–Thailand border are resistant to combination therapies that include artemisinins, and may, therefore, be untreatable.[100] Exposure of the parasite population to artemisinin monotherapies in subtherapeutic doses for over 30 years and the availability of substandard artemisinins likely drove the selection of the resistant phenotype.[101] Resistance to artemisinin has been detected in Cambodia, Myanmar, Thailand, and Vietnam,[102] and there has been emerging resistance in Laos.[103][104]

# Prognosis

When properly treated, people with malaria can usually expect a complete recovery.[105] However, severe malaria can progress extremely rapidly and cause death within hours or days.[106] In the

most severe cases of the disease, fatality rates can reach 20%, even with intensive care and treatment.[3] Over the longer term, developmental impairments have been documented in children who have suffered episodes of severe malaria.[107] Chronic infection without severe disease can occur in an immune-deficiency syndrome associated with a decreased responsiveness to *Salmonella* bacteria and the Epstein–Barr virus.[108]

During childhood, malaria causes anemia during a period of rapid brain development, and also direct brain damage resulting from cerebral malaria.[107] Some survivors of cerebral malaria have an increased risk of neurological and cognitive deficits, behavioural disorders, and epilepsy.[109] Malaria prophylaxis was shown to improve cognitive function and school performance in clinical trials when compared to placebo groups.[107]



Disability-adjusted life year for malaria per 100,000 inhabitants in 2004

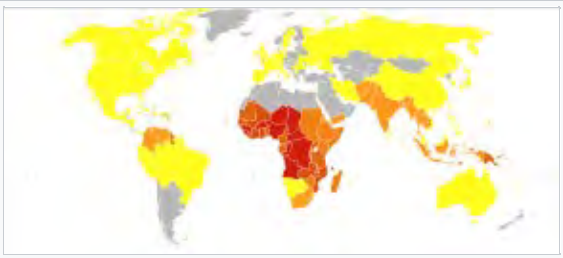
## Epidemiology

Distribution of malaria in the world:[110]

- Elevated occurrence of chloroquine- or multi-resistant malaria
- Occurrence of chloroquine-resistant malaria
- No *Plasmodium falciparum* or chloroquine-resistance
- No malaria



Deaths due to malaria per million persons in 2012

| | | |
|---|---|---|
| 0–0 | 55–325 | 950–1,358 |
| 1–2 | 326–679 | |
| 3–54 | 680–949 | |

The WHO estimates that in 2015 there were 214 million new cases of malaria resulting in 438,000 deaths.[111] Others have estimated the number of cases at between 350 and 550 million for falciparum malaria[112] The majority of cases (65%) occur in children under 15 years old.[113] About 125 million pregnant women are at risk of infection each year; in Sub-Saharan Africa, maternal malaria is associated with up to 200,000 estimated infant deaths yearly.[18] There are about 10,000 malaria cases per year in Western Europe, and 1300–1500 in the United States.[14] About 900 people died from the disease in Europe between 1993 and 2003.[57] Both the global incidence of disease and resulting mortality have declined in recent years. According to the WHO and UNICEF, deaths attributable to malaria in 2015 were reduced by 60%[65] from a 2000 estimate of 985,000, largely due to the widespread use of insecticide-treated nets and artemisinin-based combination therapies.[62] In 2012, there were 207 million cases of malaria. That year, the disease is estimated to have killed between 473,000 and 789,000 people, many of whom were children in Africa.[1] Efforts at decreasing the disease in Africa since the turn of millennium have been partially effective, with rates of the disease dropping by an estimated forty percent on the continent.[114]

Malaria is presently endemic in a broad band around the equator, in areas of the Americas, many parts of Asia, and much of Africa; in Sub-Saharan Africa, 85–90% of malaria fatalities occur.[115] An estimate for 2009 reported that countries with the highest death rate per 100,000 of population were Ivory Coast (86.15), Angola (56.93) and Burkina Faso (50.66).[116] A 2010 estimate indicated the deadliest countries per population were Burkina Faso, Mozambique and Mali.[113] The Malaria Atlas Project aims to map global endemic levels of malaria, providing a means with which to determine the global spatial limits of the disease and to assess disease burden.[117][118] This effort led to the publication of a map of *P. falciparum* endemicity in 2010.[119] As of 2010, about 100 countries have endemic malaria.[120][121] Every

year, 125 million international travellers visit these countries, and more than 30,000 contract the disease.[57]

The geographic distribution of malaria within large regions is complex, and malaria-afflicted and malaria-free areas are often found close to each other.[122] Malaria is prevalent in tropical and subtropical regions because of rainfall, consistent high temperatures and high humidity, along with stagnant waters in which mosquito larvae readily mature, providing them with the environment they need for continuous breeding.[123] In drier areas, outbreaks of malaria have been predicted with reasonable accuracy by mapping rainfall.[124] Malaria is more common in rural areas than in cities. For example, several cities in the Greater Mekong Subregion of Southeast Asia are essentially malaria-free, but the disease is prevalent in many rural regions, including along international borders and forest fringes.[125] In contrast, malaria in Africa is present in both rural and urban areas, though the risk is lower in the larger cities.[126]

## History

*Main articles: History of malaria and Mosquito-malaria theory*

Although the parasite responsible for *P. falciparum* malaria has been in existence for 50,000–100,000 years, the population size of the parasite did not increase until about 10,000 years ago, concurrently with advances in agriculture[127] and the development of human settlements. Close relatives of the human malaria parasites remain common in chimpanzees. Some evidence suggests that the *P. falciparum* malaria may have originated in gorillas.[128]

Ancient malaria oocysts preserved in Dominican amber

References to the unique periodic fevers of malaria are found throughout recorded history.[129] Hippocrates described periodic fevers, labelling them tertian, quartan, subtertian and quotidian.[130] The Roman Columella associated the disease with insects from swamps.[130] Malaria may have contributed to the decline of the Roman Empire,[131] and was so pervasive in Rome that it was known as the "Roman fever".[132] Several regions in ancient Rome were considered at-risk for the disease because of the favourable conditions present for malaria vectors. This included areas such as southern Italy, the island of Sardinia, the Pontine Marshes, the lower regions of coastal Etruria and the city of Rome along the Tiber River. The presence of stagnant water in these places was preferred by mosquitoes for breeding grounds. Irrigated gardens, swamp-like grounds, runoff from agriculture, and drainage problems from road construction led to the increase of standing water.[133]

British doctor Ronald Ross received the Nobel Prize for

The term malaria originates from Medieval Italian: *mala aria*—"bad air"; the disease was formerly called *ague* or *marsh fever* due to its association with swamps and marshland.[134] The term first appeared in the English literature about 1829.[130] Malaria was once common in most of Europe and North America,[135] where it is no longer endemic,[136] though imported cases do occur.[137]

Scientific studies on malaria made their first significant advance in 1880, when Charles Louis Alphonse Laveran—a French army doctor working in the military hospital of Constantine in Algeria—observed parasites inside the red blood cells of infected people for the first time. He, therefore, proposed that malaria is caused by this organism, the first time a protist was identified as causing disease.[138] For this and later discoveries, he was awarded the 1907 Nobel Prize for Physiology or Medicine. A year later, Carlos Finlay, a Cuban doctor treating people with yellow fever in Havana, provided strong evidence that mosquitoes were transmitting disease to and from humans.[139] This work followed earlier suggestions by Josiah C. Nott,[140] and work by Sir Patrick Manson, the "father of tropical medicine", on the transmission of filariasis.[141]

In April 1894, a Scottish physician Sir Ronald Ross visited Sir Patrick Manson at his house on Queen Anne Street, London. This visit was the start of four

Physiology or Medicine in 1902 for his work on malaria.

Chinese traditional Chinese medicine researcher Tu Youyou received the Nobel Prize for Physiology or Medicine in 2015 for her work on antimalarial drug artemisin.

years of collaboration and fervent research that culminated in 1898 when Ross, who was working in the Presidency General Hospital in Calcutta, proved the complete life-cycle of the malaria parasite in mosquitoes. He thus proved that the mosquito was the vector for malaria in humans by showing that certain mosquito species transmit malaria to birds. He isolated malaria parasites from the salivary glands of mosquitoes that had fed on infected birds.[142] For this work, Ross received the 1902 Nobel Prize in Medicine. After resigning from the Indian Medical Service, Ross worked at the newly established Liverpool School of Tropical Medicine and directed malaria-control efforts in Egypt, Panama, Greece and Mauritius.[143] The findings of Finlay and Ross were later confirmed by a medical board headed by Walter Reed in 1900. Its recommendations were implemented by William C. Gorgas in the health measures undertaken during construction of the Panama Canal. This public-health work saved the lives of thousands of workers and helped develop the methods used in future public-health campaigns against the disease.[144]

*Artemisia annua*, source of the antimalarial drug artemisin

The first effective treatment for malaria came from the bark of cinchona tree, which contains quinine. This tree grows on the slopes of the Andes, mainly in Peru. The indigenous peoples of Peru made a tincture of cinchona to control fever. Its effectiveness against malaria was found and the Jesuits introduced the treatment to Europe around 1640; by 1677, it was included in the London Pharmacopoeia as an antimalarial treatment.[145] It was not until 1820 that the active ingredient, quinine, was extracted from the bark, isolated and named by the French chemists Pierre Joseph Pelletier and Joseph Bienaimé Caventou.[146][147]

Quinine became the predominant malarial medication until the 1920s when other medications began to be developed. In the 1940s, chloroquine replaced quinine as the treatment of both uncomplicated and severe malaria until resistance supervened, first in Southeast Asia and South America in the 1950s and then globally in the 1980s.[148]

The medicinal value of Artemisia annua has been used by Chinese herbalists in traditional Chinese medicines for 2,000 years. In 1596, Li Shizhen recommended tea made from qinghao specifically to treat malaria symptoms in his "Compendium of Materia Medica". Artemisinins, discovered by Chinese scientist Tu Youyou and colleagues in the 1970s from the plant *Artemisia annua*, became the recommended treatment for *P. falciparum* malaria, administered in combination with other antimalarials as well as in severe disease.[149] Tu says she was influenced by a traditional Chinese herbal medicine source, *The Handbook of Prescriptions for Emergency Treatments*, written in 340 by Ge Hong[150] For her work on malaria, Tu Youyou received the 2015 Nobel Prize in Physiology or Medicine[151]

*Plasmodium vivax* was used between 1917 and the 1940s for malariotherapy—deliberate injection of malaria parasites to induce a fever to combat certain diseases such as tertiary syphilis. In 1927, the inventor of this technique, Julius Wagner-Jauregg, received the Nobel Prize in Physiology or Medicine for his discoveries. The technique was dangerous, killing about 15% of patients, so it is no longer in use.[152]

The first pesticide used for indoor residual spraying was DDT.[153] Although it was initially used exclusively to combat malaria, its use quickly spread to agriculture. In time, pest control, rather than disease control, came to dominate DDT use, and this large-scale agricultural use led to the evolution of resistant mosquitoes in many regions. The DDT resistance shown by *Anopheles* mosquitoes can be compared to antibiotic resistance shown by bacteria. During the 1960s, awareness of the negative consequences of its indiscriminate use increased, ultimately leading to bans on agricultural applications of DDT in many countries in the 1970s.[70] Before DDT, malaria

U.S. Marines with malaria in a rough field hospital on Guadalcanal, October 1942

was successfully eliminated or controlled in tropical areas like Brazil and Egypt by removing or poisoning the breeding grounds of the mosquitoes or the aquatic habitats of the larva stages, for example by applying the highly toxic arsenic compound Paris Green to places with standing water.[154]

Malaria vaccines have been an elusive goal of research. The first promising studies demonstrating the potential for a malaria vaccine were performed in 1967 by immunizing mice with live, radiation-attenuated sporozoites, which provided significant protection to the mice upon subsequent injection with normal, viable sporozoites. Since the 1970s, there has been a considerable effort to develop similar vaccination strategies for humans.[155] The first vaccine, called RTS,S, was approved by European regulators in 2015.[156]

## Economic impact

Malaria clinic in Tanzania

Malaria is not just a disease commonly associated with poverty: some evidence suggests that it is also a cause of poverty and a major hindrance to economic development.[7][8] Although tropical regions are most affected, malaria's furthest influence reaches into some temperate zones that have extreme seasonal changes. The disease has been associated with major negative economic effects on regions where it is widespread. During the late 19th and early 20th centuries, it was a major factor in the slow economic development of the American southern states.[157]

A comparison of average per capita GDP in 1995, adjusted for parity of purchasing power, between countries with malaria and countries without malaria gives a fivefold difference ($1,526 USD versus $8,268 USD). In the period 1965 to 1990, countries where malaria was common had an average per capita GDP that increased only 0.4% per year, compared to 2.4% per year in other countries.[158]

Poverty can increase the risk of malaria since those in poverty do not have the financial capacities to prevent or treat the disease. In its entirety, the economic impact of malaria has been estimated to cost Africa US$12 billion every year. The economic impact includes costs of health care, working days lost due to sickness, days lost in education, decreased productivity due to brain damage from cerebral malaria, and loss of investment and tourism.[9] The disease has a heavy burden in some countries, where it may be responsible for 30–50% of hospital admissions, up to 50% of outpatient visits, and up to 40% of public health spending.[159]

Cerebral malaria is one of the leading causes of neurological disabilities in African children.[109] Studies comparing cognitive functions before and after treatment for severe malarial illness continued to show significantly impaired school performance and cognitive abilities even after recovery.[107] Consequently, severe and cerebral malaria have far-reaching socioeconomic consequences that extend beyond the immediate effects of the disease.[160]

## Counterfeit and substandard drugs

Child with malaria in Ethiopia

Sophisticated counterfeits have been found in several Asian countries such as Cambodia,[161] China,[162] Indonesia, Laos, Thailand, and Vietnam, and are an important cause of avoidable death in those countries.[163] The WHO said that studies indicate that up to 40% of artesunate-based malaria medications are counterfeit, especially in the Greater Mekong region and have established a rapid alert system to enable information about counterfeit drugs to be rapidly reported to the relevant authorities in participating countries.[164] There is no reliable way for doctors or lay people to detect counterfeit drugs without help from a laboratory. Companies are attempting to combat the persistence of counterfeit drugs by using new technology to provide security from source to distribution.[165]

Another clinical and public health concern is the proliferation of substandard antimalarial medicines resulting from inappropriate concentration of ingredients, contamination with other drugs or toxic impurities, poor quality ingredients, poor stability and inadequate packaging.[166] A 2012 study demonstrated that roughly one-third of antimalarial medications in Southeast Asia and Sub-Saharan Africa failed chemical analysis, packaging analysis, or were falsified.[167]

## War

World War II poster

Throughout history, the contraction of malaria has played a prominent role in the fates of government rulers, nation-states, military personnel, and military actions.[168] In 1910, Nobel Prize in Medicine-winner Ronald Ross (himself a malaria survivor), published a book titled *The Prevention of Malaria* that included a chapter titled "The Prevention of Malaria in War." The chapter's author, Colonel C. H. Melville, Professor of Hygiene at Royal Army Medical College in London, addressed the prominent role that malaria has historically played during wars: "The history of malaria in war might almost be taken to be the history of war itself, certainly the history of war in the Christian era. ... It is probably the case that many of the so-called camp fevers, and probably also a considerable proportion of the camp dysentery, of the wars of the sixteenth, seventeenth and eighteenth centuries were malarial in origin."[169]

Malaria was the most important health hazard encountered by U.S. troops in the South Pacific during World War II, where about 500,000 men were infected.[170] According to Joseph Patrick Byrne, "Sixty thousand American soldiers died of malaria during the African and South Pacific campaigns."[171]

Significant financial investments have been made to procure existing and create new anti-malarial agents. During World War I and World War II, inconsistent supplies of the natural anti-malaria drugs cinchona bark and quinine prompted substantial funding into research and development of other drugs and vaccines. American military organizations conducting such research initiatives include the Navy Medical Research Center, Walter Reed Army Institute of Research, and the U.S. Army Medical Research Institute of Infectious Diseases of the US Armed Forces.[172]

Additionally, initiatives have been founded such as Malaria Control in War Areas (MCWA), established in 1942, and its successor, the Communicable Disease Center (now known as the Centers for Disease Control and Prevention, or CDC) established in 1946. According to the CDC, MCWA "was established to control malaria around military training bases in the southern United States and its territories, where malaria was still problematic".[173]

## Eradication efforts

Several notable attempts are being made to eliminate the parasite from sections of the world, or to eradicate it worldwide. In 2006, the organization Malaria No More set a public goal of eliminating malaria from Africa by 2015, and the organization plans to dissolve if that goal is accomplished.[174] Several malaria vaccines are in clinical trials, which are intended to provide protection for children in endemic areas and reduce the speed of transmission of the disease. As of 2012, The Global Fund to Fight AIDS, Tuberculosis and Malaria has distributed 230 million insecticide-treated nets intended to stop

Members of the Malaria Commission of the League of Nations collecting larvae on the Danube delta, 1929

mosquito-borne transmission of malaria.[175] The U.S.-based Clinton Foundation has worked to manage demand and stabilize prices in the artemisinin market.[176] Other efforts, such as the Malaria Atlas Project, focus on analysing climate and weather information required to accurately predict the spread of malaria based on the availability of habitat of malaria-carrying parasites.[117] The Malaria Policy Advisory Committee (MPAC) of the World Health Organization (WHO) was formed in 2012, "to provide strategic advice and technical input to WHO on all aspects of malaria control and elimination".[177] In November 2013, WHO and the malaria vaccine funders group set a goal to develop vaccines designed to interrupt malaria transmission with the long-term goal of malaria eradication.[178]

Malaria has been successfully eliminated or greatly reduced in certain areas. Malaria was once common in the United States and southern Europe, but vector control programs, in conjunction with the monitoring and treatment of infected humans, eliminated it from those regions. Several factors contributed, such as the draining of wetland breeding grounds for agriculture and other changes in water management practices, and advances in sanitation, including greater use of glass windows and screens in dwellings.[179] Malaria was eliminated from most parts of the USA in the early 20th century by such methods, and the use of the pesticide DDT and other means eliminated it from the remaining pockets in the South in the 1950s as part of the National Malaria Eradication Program.[180] Bill Gates has said that he thinks global eradication is possible by 2040.[181]

# Research

The Malaria Eradication Research Agenda (malERA) initiative was a consultative process to identify which areas of research and development (R&D) needed to be addressed for the worldwide eradication of malaria.[182][183]

## Vaccine

*See also: Malaria vaccine*

A vaccine against malaria called RTS,S, was approved by European regulators in 2015.[156] It is undergoing pilot trials in select countries in 2016.

Immunity (or, more accurately, tolerance) to *P. falciparum* malaria does occur naturally, but only in response to years of repeated infection.[35] An individual can be protected from a *P. falciparum* infection if they receive about a thousand bites from mosquitoes that carry a version of the parasite rendered non-infective by a dose of X-ray irradiation.[184] The highly polymorphic nature of many *P. falciparum* proteins results in significant challenges to vaccine design. Vaccine candidates that target antigens on gametes, zygotes, or ookinetes in the mosquito midgut aim to block the transmission of malaria. These transmission-blocking vaccines induce antibodies in the human blood; when a mosquito takes a blood meal from a protected individual, these antibodies prevent the parasite from completing its development in the mosquito.[185] Other vaccine candidates, targeting the blood-stage of the parasite's life cycle, have been inadequate on their own.[186] For example, SPf66 was tested extensively in areas where the disease is common in the 1990s, but trials showed it to be insufficiently effective.[187]

## Medications

Malaria parasites contain apicoplasts, organelles usually found in plants, complete with their own genomes. These apicoplasts are thought to have originated through the endosymbiosis of algae and play a crucial role in various aspects of parasite metabolism, such as fatty acid biosynthesis. Over 400 proteins have been found to be produced by apicoplasts and these are now being investigated as possible targets for novel anti-malarial

drugs.[188]

With the onset of drug-resistant *Plasmodium* parasites, new strategies are being developed to combat the widespread disease. One such approach lies in the introduction of synthetic pyridoxal-amino acid adducts, which are taken up by the parasite and ultimately interfere with its ability to create several essential B vitamins.[189][190] Antimalarial drugs using synthetic metal-based complexes are attracting research interest.[191][192]

- (+)-SJ733: Part of a wider class of experimental drugs called spiroindolone. It inhibits the ATP4 protein of infected red blood cells that cause the cells to shrink and become rigid like the aging cells. This triggers the immune system to eliminate the infected cells from the system as demonstrated in a mouse model. As of 2014, a Phase 1 clinical trial to assess the safety profile in human is planned by the Howard Hughes Medical Institute.[193]
- NITD246 and NITD609: Also belonged to the class of spiroindolone and target the ATP4 protein.[193]

### Other

A non-chemical vector control strategy involves genetic manipulation of malaria mosquitoes. Advances in genetic engineering technologies make it possible to introduce foreign DNA into the mosquito genome and either decrease the lifespan of the mosquito, or make it more resistant to the malaria parasite. Sterile insect technique is a genetic control method whereby large numbers of sterile male mosquitoes are reared and released. Mating with wild females reduces the wild population in the subsequent generation; repeated releases eventually eliminate the target population.[61]

Genomics is central to malaria research. With the sequencing of *P. falciparum*, one of its vectors *Anopheles gambiae*, and the human genome, the genetics of all three organisms in the malaria lifecycle can be studied.[194] Another new application of genetic technology is the ability to produce genetically modified mosquitoes that do not transmit malaria, potentially allowing biological control of malaria transmission.[195]

In one study, a genetically-modified strain of *Anopheles stephensi* was created that no longer supported malaria transmission, and this resistance was passed down to mosquito offspring.[196]

Gene drive is a technique for changing wild populations, for instance to combat insects so they cannot transmit diseases (in particular mosquitoes in the cases of malaria and zika).[197]

## Other animals

Nearly 200 parasitic *Plasmodium* species have been identified that infect birds, reptiles, and other mammals,[198] and about 30 species naturally infect non-human primates.[199] Some malaria parasites that affect non-human primates (NHP) serve as model organisms for human malarial parasites, such as *P. coatneyi* (a model for *P. falciparum*) and *P. cynomolgi* (*P. vivax*). Diagnostic techniques used to detect parasites in NHP are similar to those employed for humans.[200] Malaria parasites that infect rodents are widely used as models in research, such as *P. berghei*.[201] Avian malaria primarily affects species of the order Passeriformes, and poses a substantial threat to birds of Hawaii, the Galapagos, and other archipelagoes. The parasite *P. relictum* is known to play a role in limiting the distribution and abundance of endemic Hawaiian birds. Global warming is expected to increase the prevalence and global distribution of avian malaria, as elevated temperatures provide optimal conditions for parasite reproduction.[202]

# Meningitis

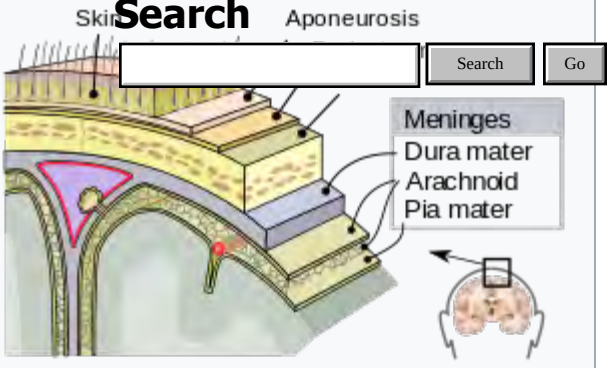
From Wikipedia, the free encyclopedia

**Meningitis** is an acute inflammation of the protective membranes covering the brain and spinal cord, known collectively as the meninges.[1] The most common symptoms are fever, headache and neck stiffness. Other symptoms include confusion or altered consciousness, vomiting, and an inability to tolerate light or loud noises. Young children often exhibit only nonspecific symptoms, such as irritability, drowsiness, or poor feeding.[2] If a rash is present, it may indicate a particular cause of meningitis; for instance, meningitis caused by meningococcal bacteria may be accompanied by a characteristic rash.[1][3]

The inflammation may be caused by infection with viruses, bacteria, or other microorganisms, and less commonly by certain drugs.[4] Meningitis can be life-threatening because of the inflammation's proximity to the brain and spinal cord; therefore, the condition is classified as a medical emergency.[1][5] A lumbar puncture diagnoses or excludes meningitis.[2] A needle is inserted into the spinal canal to collect a sample of cerebrospinal fluid (CSF), that envelops the brain and spinal cord. The CSF is examined in a medical laboratory.[5]

Some forms of meningitis are preventable by immunization with the meningococcal, mumps, pneumococcal, and Hib vaccines.[1] Giving antibiotics to people with significant exposure to certain types of meningitis may also be useful.[2] The first treatment in acute meningitis consists of promptly giving antibiotics and sometimes antiviral drugs.[2][6] Corticosteroids can also be used to prevent complications from excessive inflammation.[3][5] Meningitis can lead to serious long-term consequences such as deafness, epilepsy, hydrocephalus, or cognitive deficits, especially if not treated quickly.[1][3]

## Variants



Meninges of the central nervous system: dura mater, arachnoid mater, and pia mater.

[edit on Wikidata]

In 2013 meningitis occurred in about 16 million people worldwide.[7] This resulted in 303,000 deaths – down from 464,000 deaths in 1990.[8] With appropriate treatment the risk of death in bacterial meningitis is less than 15%.[2] Outbreaks of bacterial meningitis occur between December and June each year in an area of sub-Saharan Africa known as the meningitis belt.[9] Smaller outbreaks may also occur in other areas of the world.[9] The word meningitis is from Greek μῆνιγξ *méninx*, "membrane" and the medical suffix *-itis*, "inflammation".[10][11]

Contents

# Signs and symptoms [edit]

## Clinical features [edit]

Neck stiffness, Texas meningitis epidemic of 1911–12

In adults, the most common symptom of meningitis is a severe headache, occurring in almost 90% of cases of bacterial meningitis, followed by nuchal rigidity (the inability to flex the neck forward passively due to increased neck muscle tone and stiffness).[12] The classic triad of diagnostic signs consists of nuchal rigidity, sudden high fever, and altered mental status; however, all three features are present in only 44–46% of bacterial meningitis cases.[12][13] If none of the three signs are present, acute meningitis is extremely unlikely.[13] Other signs commonly associated with meningitis include photophobia (intolerance to bright light) and phonophobia (intolerance to loud noises). Small children often do not exhibit the aforementioned symptoms, and may only be irritable and look unwell.[1] The fontanelle (the soft spot on the top of a baby's head) can bulge in infants aged up to 6 months. Other features that distinguish meningitis from less severe illnesses in young children are leg pain, cold extremities, and an abnormal skin color.[14][15]

Nuchal rigidity occurs in 70% of bacterial meningitis in adults.[13] Other signs of meningism include the presence of positive Kernig's sign or Brudziński sign. Kernig's sign is assessed with the person lying supine, with the hip and knee flexed to 90 degrees. In a person with a positive Kernig's sign, pain limits passive extension of the knee. A positive Brudzinski's sign occurs when flexion of the neck causes involuntary flexion of the knee and hip. Although Kernig's sign and Brudzinski's sign are both commonly used to screen for meningitis, the sensitivity of these tests is limited.[13][16] They do, however, have very good specificity

for meningitis: the signs rarely occur in other diseases.[13] Another test, known as the "jolt accentuation maneuver" helps determine whether meningitis is present in those reporting fever and headache. A person is asked to rapidly rotate the head horizontally; if this does not make the headache worse, meningitis is unlikely.[13]

Meningitis caused by the bacterium *Neisseria meningitidis* (known as "meningococcal meningitis") can be differentiated from meningitis with other causes by a rapidly spreading petechial rash, which may precede other symptoms.[14] The rash consists of numerous small, irregular purple or red spots ("petechiae") on the trunk, lower extremities, mucous membranes, conjuctiva, and (occasionally) the palms of the hands or soles of the feet. The rash is typically non-blanching; the redness does not disappear when pressed with a finger or a glass tumbler. Although this rash is not necessarily present in meningococcal meningitis, it is relatively specific for the disease; it does, however, occasionally occur in meningitis due to other bacteria.[1] Other clues on the cause of meningitis may be the skin signs of hand, foot and mouth disease and genital herpes, both of which are associated with various forms of viral meningitis.[17]

## Early complications [edit]

Additional problems may occur in the early stage of the illness. These may require specific treatment, and sometimes indicate severe illness or worse prognosis. The infection may trigger sepsis, a systemic inflammatory response syndrome of falling blood pressure, fast heart rate, high or abnormally low temperature, and rapid breathing. Very low blood pressure may occur at an early stage, especially but not exclusively in meningococcal meningitis; this may lead to insufficient blood supply to other organs.[1] Disseminated intravascular coagulation, the excessive activation of blood clotting, may obstruct blood flow to organs and paradoxically increase the bleeding risk. Gangrene of limbs can occur in meningococcal disease.[1] Severe meningococcal and pneumococcal infections may result in hemorrhaging of the adrenal glands, leading to Waterhouse-Friderichsen syndrome, which is often fatal.[18]

Charlotte Cleverley-Bisman developed severe meningococcal meningitis as a young child; in her case, the petechial rash progressed to gangrene and required amputation of all limbs. She survived the disease and became a poster child for a meningitis vaccination campaign in New Zealand.

The brain tissue may swell, pressure inside the skull may increase and the swollen brain may herniate through the skull base. This may be noticed by a decreasing level of consciousness, loss of the pupillary light reflex, and abnormal posturing.[3] The inflammation of the brain tissue may also obstruct the normal flow of CSF around the brain (hydrocephalus).[3] Seizures may occur for various reasons; in children, seizures are common in the early stages of meningitis (in 30% of cases) and do not necessarily indicate an underlying cause.[5] Seizures may result from increased pressure and from areas of inflammation in the brain tissue.[3] Focal seizures (seizures that involve one limb or part of the body), persistent seizures, late-onset seizures and those that are difficult to control with medication indicate a poorer long-term outcome.[1]

Inflammation of the meninges may lead to abnormalities of the cranial nerves, a group of nerves arising from the brain stem that supply the head and neck area and which control, among other functions, eye movement, facial muscles, and hearing.[1][13] Visual symptoms and hearing loss may persist after an episode of meningitis.[1] Inflammation of the brain (encephalitis) or its blood vessels (cerebral vasculitis), as well as the formation of blood clots in the veins (cerebral venous thrombosis), may all lead to weakness, loss of sensation, or abnormal movement or function of the part of the body supplied by the affected area of the brain.[1][3]

## Causes [edit]

Meningitis is typically caused by an infection with microorganisms. Most infections are due to viruses,[13]

with bacteria, fungi, and protozoa being the next most common causes.[4] It may also result from various non-infectious causes.[4] The term *aseptic meningitis* refers to cases of meningitis in which no bacterial infection can be demonstrated. This type of meningitis is usually caused by viruses but it may be due to bacterial infection that has already been partially treated, when bacteria disappear from the meninges, or pathogens infect a space adjacent to the meninges (e.g. sinusitis). Endocarditis (an infection of the heart valves which spreads small clusters of bacteria through the bloodstream) may cause aseptic meningitis. Aseptic meningitis may also result from infection with spirochetes, a type of bacteria that includes *Treponema pallidum* (the cause of syphilis) and *Borrelia burgdorferi* (known for causing Lyme disease). Meningitis may be encountered in cerebral malaria (malaria infecting the brain) or amoebic meningitis, meningitis due to infection with amoebae such as *Naegleria fowleri*, contracted from freshwater sources.[4]

## Bacterial [edit]

*See also: Neonatal infection*

The types of bacteria that cause bacterial meningitis vary according to the infected individual's age group.

- In premature babies and newborns up to three months old, common causes are *group B streptococci* (subtypes III which normally inhabit the vagina and are mainly a cause during the first week of life) and bacteria that normally inhabit the digestive tract such as *Escherichia coli* (carrying the K1 antigen). *Listeria monocytogenes* (serotype IVb) is transmitted by the mother before birth and may cause meningitis in the newborn.[19]
- Older children are more commonly affected by *Neisseria meningitidis* (meningococcus) and *Streptococcus pneumoniae* (serotypes 6, 9, 14, 18 and 23) and those under five by *Haemophilus influenzae* type B (in countries that do not offer vaccination).[1][5]
- In adults, *Neisseria meningitidis* and *Streptococcus pneumoniae* together cause 80% of bacterial meningitis cases. Risk of infection with *Listeria monocytogenes* is increased in persons over 50 years old.[3][5] The introduction of pneumococcal vaccine has lowered rates of pneumococcal meningitis in both children and adults.[20]

Recent skull trauma potentially allows nasal cavity bacteria to enter the meningeal space. Similarly, devices in the brain and meninges, such as cerebral shunts, extraventricular drains or Ommaya reservoirs, carry an increased risk of meningitis. In these cases, the persons are more likely to be infected with Staphylococci, Pseudomonas, and other Gram-negative bacteria.[5] These pathogens are also associated with meningitis in people with an impaired immune system.[1] An infection in the head and neck area, such as otitis media or mastoiditis, can lead to meningitis in a small proportion of people.[5] Recipients of cochlear implants for hearing loss are more at risk for pneumococcal meningitis.[21]

Tuberculous meningitis, which is meningitis caused by *Mycobacterium tuberculosis*, is more common in people from countries in which tuberculosis is endemic, but is also encountered in persons with immune problems, such as AIDS.[22]

Recurrent bacterial meningitis may be caused by persisting anatomical defects, either congenital or acquired, or by disorders of the immune system.[23] Anatomical defects allow continuity between the external environment and the nervous system. The most common cause of recurrent meningitis is a skull fracture,[23] particularly fractures that affect the base of the skull or extend towards the sinuses and petrous pyramids.[23] Approximately 59% of recurrent meningitis cases are due to such anatomical abnormalities, 36% are due to immune deficiencies (such as complement deficiency, which predisposes especially to recurrent meningococcal meningitis), and 5% are due to ongoing infections in areas adjacent to the meninges.[23]

## Viral [edit]

Viruses that cause meningitis include enteroviruses, herpes simplex virus (generally type 2, which produces most genital sores; less commonly type 1), varicella zoster virus (known for causing chickenpox and shingles), mumps virus, HIV, and LCMV.[17] Mollaret's meningitis is a chronic recurrent form of herpes [24]

meningitis; it is thought to be caused by herpes simplex virus type 2.

### Fungal [edit]

There are a number of risk factors for fungal meningitis, including the use of immunosuppressants (such as after organ transplantation), HIV/AIDS,[25] and the loss of immunity associated with aging.[26] It is uncommon in those with a normal immune system[27] but has occurred with medication contamination.[28] Symptom onset is typically more gradual, with headaches and fever being present for at least a couple of weeks before diagnosis.[26] The most common fungal meningitis is cryptococcal meningitis due to *Cryptococcus neoformans*.[29] In Africa, cryptococcal meningitis is now the most common cause of meningitis in multiple studies,[30][31] and it accounts for 20–25% of AIDS-related deaths in Africa.[32] Other less common fungal pathogens which can cause meningitis include: *Coccidioides immitis*, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Candida* species.[26]

### Parasitic [edit]

A parasitic cause is often assumed when there is a predominance of eosinophils (a type of white blood cell) in the CSF. The most common parasites implicated are *Angiostrongylus cantonensis*, *Gnathostoma spinigerum*, *Schistosoma*, as well as the conditions cysticercosis, toxocariasis, baylisascariasis, paragonimiasis, and a number of rarer infections and noninfective conditions.[33]

### Non-infectious [edit]

Meningitis may occur as the result of several non-infectious causes: spread of cancer to the meninges (*malignant or neoplastic meningitis*)[34] and certain drugs (mainly non-steroidal anti-inflammatory drugs, antibiotics and intravenous immunoglobulins).[35] It may also be caused by several inflammatory conditions, such as sarcoidosis (which is then called neurosarcoidosis), connective tissue disorders such as systemic lupus erythematosus, and certain forms of vasculitis (inflammatory conditions of the blood vessel wall), such as Behçet's disease.[4] Epidermoid cysts and dermoid cysts may cause meningitis by releasing irritant matter into the subarachnoid space.[4][23] Rarely, migraine may cause meningitis, but this diagnosis is usually only made when other causes have been eliminated.[4]

## Mechanism [edit]

The meninges comprise three membranes that, together with the cerebrospinal fluid, enclose and protect the brain and spinal cord (the central nervous system). The pia mater is a very delicate impermeable membrane that firmly adheres to the surface of the brain, following all the minor contours. The arachnoid mater (so named because of its spider-web-like appearance) is a loosely fitting sac on top of the pia mater. The subarachnoid space separates the arachnoid and pia mater membranes and is filled with cerebrospinal fluid. The outermost membrane, the dura mater, is a thick durable membrane, which is attached to both the arachnoid membrane and the skull.

In bacterial meningitis, bacteria reach the meninges by one of two main routes: through the bloodstream or through direct contact between the meninges and either the nasal cavity or the skin. In most cases, meningitis follows invasion of the bloodstream by organisms that live upon mucous surfaces such as the nasal cavity. This is often in turn preceded by viral infections, which break down the normal barrier provided by the mucous surfaces. Once bacteria have entered the bloodstream, they enter the subarachnoid space in places where the blood–brain barrier is vulnerable—such as the choroid plexus. Meningitis occurs in 25% of newborns with bloodstream infections due to group B streptococci; this phenomenon is less common in adults.[1] Direct contamination of the cerebrospinal fluid may arise from indwelling devices, skull fractures, or infections of the nasopharynx or the nasal sinuses that have formed a tract with the subarachnoid space (see above); occasionally, congenital defects of the dura mater can be identified.[1]

The large-scale inflammation that occurs in the subarachnoid space during meningitis is not a direct result

of bacterial infection but can rather largely be attributed to the response of the immune system to the entry of bacteria into the central nervous system. When components of the bacterial cell membrane are identified by the immune cells of the brain (astrocytes and microglia), they respond by releasing large amounts of cytokines, hormone-like mediators that recruit other immune cells and stimulate other tissues to participate in an immune response. The blood–brain barrier becomes more permeable, leading to "vasogenic" cerebral edema (swelling of the brain due to fluid leakage from blood vessels). Large numbers of white blood cells enter the CSF, causing inflammation of the meninges and leading to "interstitial" edema (swelling due to fluid between the cells). In addition, the walls of the blood vessels themselves become inflamed (cerebral vasculitis), which leads to decreased blood flow and a third type of edema, "cytotoxic" edema. The three forms of cerebral edema all lead to increased intracranial pressure; together with the lowered blood pressure often encountered in acute infection, this means that it is harder for blood to enter the brain, consequently brain cells are deprived of oxygen and undergo apoptosis (programmed cell death).[1]

It is recognized that administration of antibiotics may initially worsen the process outlined above, by increasing the amount of bacterial cell membrane products released through the destruction of bacteria. Particular treatments, such as the use of corticosteroids, are aimed at dampening the immune system's response to this phenomenon.[1][3]

# Diagnosis [edit]

## Blood tests and imaging [edit]

In someone suspected of having meningitis, blood tests are performed for markers of inflammation (e.g. C-reactive protein, complete blood count), as well as blood cultures.[5][37]

**CSF findings in different forms of meningitis**[36]

| Type of meningitis | Glucose | Protein | Cells |
|---|---|---|---|
| **Acute bacterial** | low | high | PMNs, often > 300/mm³ |
| **Acute viral** | normal | normal or high | mononuclear, < 300/mm³ |
| **Tuberculous** | low | high | mononuclear and PMNs, < 300/mm³ |
| **Fungal** | low | high | < 300/mm³ |
| **Malignant** | low | high | usually mononuclear |

The most important test in identifying or ruling out meningitis is analysis of the cerebrospinal fluid through lumbar puncture (LP, spinal tap).[38] However, lumbar puncture is contraindicated if there is a mass in the brain (tumor or abscess) or the intracranial pressure (ICP) is elevated, as it may lead to brain herniation. If someone is at risk for either a mass or raised ICP (recent head injury, a known immune system problem, localizing neurological signs, or evidence on examination of a raised ICP), a CT or MRI scan is recommended prior to the lumbar puncture.[5][37][39] This applies in 45% of all adult cases.[3] If a CT or MRI is required before LP, or if LP proves difficult, professional guidelines suggest that antibiotics should be administered first to prevent delay in treatment,[5] especially if this may be longer than 30 minutes.[37][39] Often, CT or MRI scans are performed at a later stage to assess for complications of meningitis.[1]

In severe forms of meningitis, monitoring of blood electrolytes may be important; for example, hyponatremia is common in bacterial meningitis, due to a combination of factors, including dehydration, the inappropriate secretion of the antidiuretic hormone (SIADH), or overly aggressive intravenous fluid administration.[3][40]

## Lumbar puncture [edit]

A lumbar puncture is done by positioning the person, usually lying on the side, applying local anesthetic, and inserting a needle into the dural sac (a sac around the spinal cord) to collect cerebrospinal fluid (CSF). When this has been achieved, the "opening pressure" of the CSF is measured using a manometer. The pressure is normally between 6 and 18 cm water ($cmH_2O$);[38] in bacterial meningitis the pressure is usually

Gram stain of meningococci from a culture showing Gram negative (pink) bacteria, often in pairs

elevated.[5][37] In cryptococcal meningitis, intracranial pressure is markedly elevated.[41] The initial appearance of the fluid may prove an indication of the nature of the infection: cloudy CSF indicates higher levels of protein, white and red blood cells and/or bacteria, and therefore may suggest bacterial meningitis.[5]

The CSF sample is examined for presence and types of white blood cells, red blood cells, protein content and glucose level.[5] Gram staining of the sample may demonstrate bacteria in bacterial meningitis, but absence of bacteria does not exclude bacterial meningitis as they are only seen in 60% of cases; this figure is reduced by a further 20% if antibiotics were administered before the sample was taken. Gram staining is also less reliable in particular infections such as listeriosis. Microbiological culture of the sample is more sensitive (it identifies the organism in 70–85% of cases) but results can take up to 48 hours to become available.[5] The type of white blood cell predominantly present (see table) indicates whether meningitis is bacterial (usually neutrophil-predominant) or viral (usually lymphocyte-predominant),[5] although at the beginning of the disease this is not always a reliable indicator. Less commonly, eosinophils predominate, suggesting parasitic or fungal etiology, among others.[33]

The concentration of glucose in CSF is normally above 40% of that in blood. In bacterial meningitis it is typically lower; the CSF glucose level is therefore divided by the blood glucose (CSF glucose to serum glucose ratio). A ratio ≤0.4 is indicative of bacterial meningitis;[38] in the newborn, glucose levels in CSF are normally higher, and a ratio below 0.6 (60%) is therefore considered abnormal.[5] High levels of lactate in CSF indicate a higher likelihood of bacterial meningitis, as does a higher white blood cell count.[38] If lactate levels are less than 35 mg/dl and the person has not previously received antibiotics then this may rule out bacterial meningitis.[42]

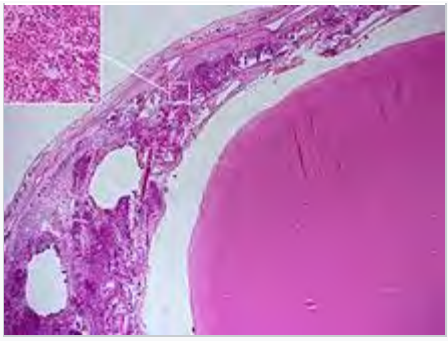
Various other specialized tests may be used to distinguish between different types of meningitis. A latex agglutination test may be positive in meningitis caused by *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*, *Escherichia coli* and *group B streptococci*; its routine use is not encouraged as it rarely leads to changes in treatment, but it may be used if other tests are not diagnostic. Similarly, the limulus lysate test may be positive in meningitis caused by Gram-negative bacteria, but it is of limited use unless other tests have been unhelpful.[5] Polymerase chain reaction (PCR) is a technique used to amplify small traces of bacterial DNA in order to detect the presence of bacterial or viral DNA in cerebrospinal fluid; it is a highly sensitive and specific test since only trace amounts of the infecting agent's DNA is required. It may identify bacteria in bacterial meningitis and may assist in distinguishing the various causes of viral meningitis (enterovirus, herpes simplex virus 2 and mumps in those not vaccinated for this).[17] Serology (identification of antibodies to viruses) may be useful in viral meningitis.[17] If tuberculous meningitis is suspected, the sample is processed for Ziehl-Neelsen stain, which has a low sensitivity, and tuberculosis culture, which takes a long time to process; PCR is being used increasingly.[22] Diagnosis of cryptococcal meningitis can be made at low cost using an India ink stain of the CSF; however, testing for cryptococcal antigen in blood or CSF is more sensitive, particularly in people with AIDS.[43][44]

A diagnostic and therapeutic difficulty is "partially treated meningitis", where there are meningitis symptoms after receiving antibiotics (such as for presumptive sinusitis). When this happens, CSF findings may resemble those of viral meningitis, but antibiotic treatment may need to be continued until there is definitive positive evidence of a viral cause (e.g. a positive enterovirus PCR).[17]

## Postmortem [edit]

Meningitis can be diagnosed after death has occurred. The findings from

a post mortem are usually a widespread inflammation of the pia mater and arachnoid layers of the meninges. Neutrophil granulocytes tend to have migrated to the cerebrospinal fluid and the base of the brain, along with cranial nerves and the spinal cord, may be surrounded with pus – as may the meningeal vessels.[45]



Histopathology of bacterial meningitis: autopsy case of a person with pneumococcal meningitis showing inflammatory infiltrates of the pia mater consisting of neutrophil granulocytes (inset, higher magnification).

## Prevention [edit]

For some causes of meningitis, protection can be provided in the long term through vaccination, or in the short term with antibiotics. Some behavioral measures may also be effective.

### Behavioral [edit]

Bacterial and viral meningitis are contagious, but neither is as contagious as the common cold or flu.[46] Both can be transmitted through droplets of respiratory secretions during close contact such as kissing, sneezing or coughing on someone, but cannot be spread by only breathing the air where a person with meningitis has been.[46] Viral meningitis is typically caused by enteroviruses, and is most commonly spread through fecal contamination.[46] The risk of infection can be decreased by changing the behavior that led to transmission.

### Vaccination [edit]

Since the 1980s, many countries have included immunization against *Haemophilus influenzae* type B in their routine childhood vaccination schemes. This has practically eliminated this pathogen as a cause of meningitis in young children in those countries. In the countries in which the disease burden is highest, however, the vaccine is still too expensive.[47][48] Similarly, immunization against mumps has led to a sharp fall in the number of cases of mumps meningitis, which prior to vaccination occurred in 15% of all cases of mumps.[17]

Meningococcus vaccines exist against groups A, B, C, W135 and Y.[49][50][51] In countries where the vaccine for meningococcus group C was introduced, cases caused by this pathogen have decreased substantially.[47] A quadrivalent vaccine now exists, which combines four vaccines with the exception of B; immunization with this ACW135Y vaccine is now a visa requirement for taking part in Hajj.[52] Development of a vaccine against group B meningococci has proved much more difficult, as its surface proteins (which would normally be used to make a vaccine) only elicit a weak response from the immune system, or cross-react with normal human proteins.[47][49] Still, some countries (New Zealand, Cuba, Norway and Chile) have developed vaccines against local strains of group B meningococci; some have shown good results and are used in local immunization schedules.[49] Two new vaccines, both approved in 2014, are effective against a wider range of group B meningococci strains.[50][51] In Africa, until recently, the approach for prevention and control of meningococcal epidemics was based on early detection of the disease and emergency reactive mass vaccination of the at-risk population with bivalent A/C or trivalent A/C/W135 polysaccharide vaccines,[53] though the introduction of MenAfriVac (meningococcus group A vaccine) has demonstrated effectiveness in young people and has been described as a model for product development partnerships in resource-limited settings.[54][55]

Routine vaccination against *Streptococcus pneumoniae* with the pneumococcal conjugate vaccine (PCV), which is active against seven common serotypes of this pathogen, significantly reduces the incidence of pneumococcal meningitis.[47][56] The pneumococcal polysaccharide vaccine, which covers 23 strains, is only administered to certain groups (e.g. those who have had a splenectomy, the surgical removal of the spleen); it does not elicit a significant immune response in all recipients, e.g. small children.[56] Childhood vaccination with Bacillus Calmette-Guérin has been reported to significantly reduce the rate of tuberculous meningitis, but its waning effectiveness in adulthood has prompted a search for a better vaccine.[47]

### Antibiotics [edit]

Short-term antibiotic prophylaxis is another method of prevention, particularly of meningococcal meningitis. In cases of meningococcal meningitis, preventative treatment in close contacts with antibiotics (e.g. rifampicin, ciprofloxacin or ceftriaxone) can reduce their risk of contracting the condition, but does not protect against future infections.[37][57] Resistance to rifampicin has been noted to increase after use, which has caused some to recommend considering other agents.[57] While antibiotics are frequently used in an attempt to prevent meningitis in those with a basilar skull fracture there is not enough evidence to determine whether this is beneficial or harmful.[58] This applies to those with or without a CSF leak.[58]

## Management [edit]

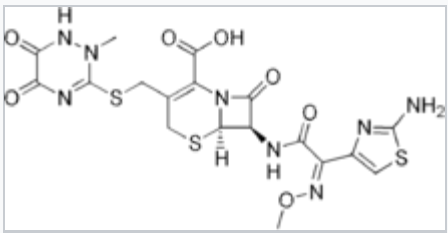
Meningitis is potentially life-threatening and has a high mortality rate if untreated;[5] delay in treatment has been associated with a poorer outcome.[3] Thus, treatment with wide-spectrum antibiotics should not be delayed while confirmatory tests are being conducted.[39] If meningococcal disease is suspected in primary care, guidelines recommend that benzylpenicillin be administered before transfer to hospital.[14] Intravenous fluids should be administered if hypotension (low blood pressure) or shock are present.[39] In children routine intravenous fluids for two days may improve outcomes in those who arrive at hospital after being sick for some time.[59] Given that meningitis can cause a number of early severe complications, regular medical review is recommended to identify these complications early[39] and to admit the person to an intensive care unit if deemed necessary.[3]

Mechanical ventilation may be needed if the level of consciousness is very low, or if there is evidence of respiratory failure. If there are signs of raised intracranial pressure, measures to monitor the pressure may be taken; this would allow the optimization of the cerebral perfusion pressure and various treatments to decrease the intracranial pressure with medication (e.g. mannitol).[3] Seizures are treated with anticonvulsants.[3] Hydrocephalus (obstructed flow of CSF) may require insertion of a temporary or long-term drainage device, such as a cerebral shunt.[3]

### Bacterial meningitis [edit]

#### Antibiotics [edit]

Empiric antibiotics (treatment without exact diagnosis) should be started immediately, even before the results of the lumbar puncture and CSF analysis are known. The choice of initial treatment depends largely on the kind of bacteria that cause meningitis in a particular place and population. For instance, in the United Kingdom empirical treatment consists of a third-generation cefalosporin such as cefotaxime or ceftriaxone.[37][39] In the USA, where resistance to cefalosporins is increasingly found in streptococci, addition of vancomycin to the initial treatment is recommended.[3][5][37] Chloramphenicol, either alone or in combination with ampicillin, however, appears to work equally well.[60]



Structural formula of ceftriaxone, one of the third-generation cefalosporin antibiotics recommended for the initial treatment of bacterial meningitis.

Empirical therapy may be chosen on the basis of the person's age, whether the infection was preceded by a head injury, whether the person has undergone recent neurosurgery and whether or not a cerebral shunt is present.[5] In young children and those over 50 years of age, as well as those who are immunocompromised, the addition of ampicillin is recommended to cover *Listeria monocytogenes*.[5][37] Once the Gram stain results become available, and the broad type of bacterial cause is known, it may be possible to change the antibiotics to those likely to deal with the presumed group of pathogens.[5] The results of the CSF culture generally take longer to become available

(24–48 hours). Once they do, empiric therapy may be switched to specific antibiotic therapy targeted to the specific causative organism and its sensitivities to antibiotics.[5] For an antibiotic to be effective in meningitis it must not only be active against the pathogenic bacterium but also reach the meninges in adequate quantities; some antibiotics have inadequate penetrance and therefore have little use in meningitis. Most of the antibiotics used in meningitis have not been tested directly on people with meningitis in clinical trials. Rather, the relevant knowledge has mostly derived from laboratory studies in rabbits.[5] Tuberculous meningitis requires prolonged treatment with antibiotics. While tuberculosis of the lungs is typically treated for six months, those with tuberculous meningitis are typically treated for a year or longer.[22]

### Steroids [edit]

Additional treatment with corticosteroids (usually dexamethasone) has shown some benefits, such as a reduction of hearing loss, and better short term neurological outcomes[61] in adolescents and adults from high-income countries with low rates of HIV.[62] Some research has found reduced rates of death[62] while other research has not.[61] They also appear to be beneficial in those with tuberculosis meningitis, at least in those who are HIV negative.[63]

Professional guidelines therefore recommend the commencement of dexamethasone or a similar corticosteroid just before the first dose of antibiotics is given, and continued for four days.[37][39] Given that most of the benefit of the treatment is confined to those with pneumococcal meningitis, some guidelines suggest that dexamethasone be discontinued if another cause for meningitis is identified.[5][37] The likely mechanism is suppression of overactive inflammation.[64]

Additional treatment with corticosteroids have a different role in children than in adults. Though the benefit of corticosteroids has been demonstrated in adults as well as in children from high-income countries, their use in children from low-income countries is not supported by the evidence; the reason for this discrepancy is not clear.[61] Even in high-income countries, the benefit of corticosteroids is only seen when they are given prior to the first dose of antibiotics, and is greatest in cases of *H. influenzae* meningitis,[5][65] the incidence of which has decreased dramatically since the introduction of the Hib vaccine. Thus, corticosteroids are recommended in the treatment of pediatric meningitis if the cause is *H. influenzae*, and only if given prior to the first dose of antibiotics; other uses are controversial.[5]

### Viral meningitis [edit]

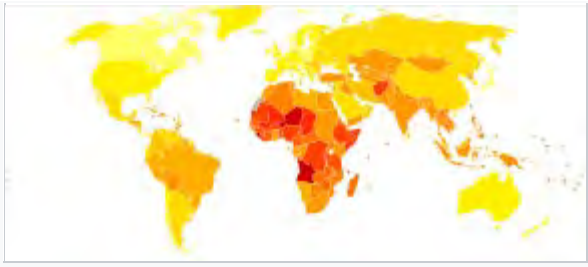
Viral meningitis typically only requires supportive therapy; most viruses responsible for causing meningitis are not amenable to specific treatment. Viral meningitis tends to run a more benign course than bacterial meningitis. Herpes simplex virus and varicella zoster virus may respond to treatment with antiviral drugs such as aciclovir, but there are no clinical trials that have specifically addressed whether this treatment is effective.[17] Mild cases of viral meningitis can be treated at home with conservative measures such as fluid, bedrest, and analgesics.[66]

### Fungal meningitis [edit]

Fungal meningitis, such as cryptococcal meningitis, is treated with long courses of high dose antifungals, such as amphotericin B and flucytosine.[43][67] Raised intracranial pressure is common in fungal meningitis, and frequent (ideally daily) lumbar punctures to relieve the pressure are recommended,[43] or alternatively a lumbar drain.[41]

## Prognosis [edit]

Untreated, bacterial meningitis is almost always fatal. Viral meningitis, in contrast, tends to resolve spontaneously and is rarely fatal. With treatment, mortality (risk of death) from



Disability-adjusted life year for meningitis per 100,000 inhabitants in 2004.[68]

| | |
|---|---|
| no data | 200-300 |
| <10 | 300-400 |
| 10-25 | 400-500 |
| 25-50 | 500-750 |
| 50-75 | 750–1000 |
| 75-100 | >1000 |
| 100-200 | |

bacterial meningitis depends on the age of the person and the underlying cause. Of newborns, 20–30% may die from an episode of bacterial meningitis. This risk is much lower in older children, whose mortality is about 2%, but rises again to about 19–37% in adults.[1][3] Risk of death is predicted by various factors apart from age, such as the pathogen and the time it takes for the pathogen to be cleared from the cerebrospinal fluid,[1] the severity of the generalized illness, a decreased level of consciousness or an abnormally low count of white blood cells in the CSF.[3] Meningitis caused by *H. influenzae* and meningococci has a better prognosis than cases caused by group B streptococci, coliforms and *S. pneumonia*.[1] In adults, too, meningococcal meningitis has a lower mortality (3–7%) than pneumococcal disease.[3]

In children there are several potential disabilities which may result from damage to the nervous system, including sensorineural hearing loss, epilepsy, learning and behavioral difficulties, as well as decreased intelligence.[1] These occur in about 15% of survivors.[1] Some of the hearing loss may be reversible.[69] In adults, 66% of all cases emerge without disability. The main problems are deafness (in 14%) and cognitive impairment (in 10%).[3]

Tuberculous meningitis in children continues to be associated with a significant risk of death even with treatment (19%), and a significant proportion of the surviving children have ongoing neurological problems. Just over a third of all cases survives with no problems.[70]

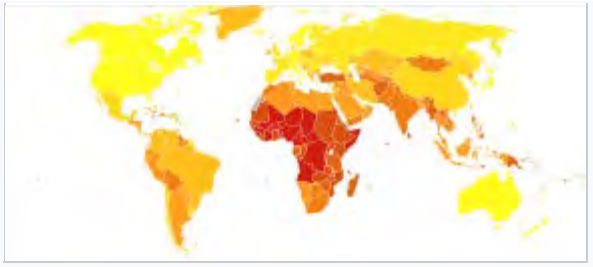
## Epidemiology [edit]

Demography of meningococcal meningitis.

- meningitis belt
- epidemic zones
- sporadic cases only

Although meningitis is a notifiable disease in many countries, the exact incidence rate is unknown.[17] In 2013 meningitis resulted in 303,000 deaths – down from 464,000 deaths in 1990.[8] In 2010 it was estimated that meningitis resulted in 420,000 deaths,[71] excluding cryptococcal meningitis.[72]

Bacterial meningitis occurs in about 3 people per 100,000 annually in Western countries. Population-wide studies have shown that viral meningitis is more common, at 10.9 per 100,000, and occurs more often in the summer. In Brazil, the rate of bacterial meningitis is higher, at 45.8 per 100,000 annually.[13] Sub-Saharan Africa has been plagued by large epidemics of meningococcal meningitis for over a century,[73] leading to it being labeled the "meningitis belt". Epidemics typically occur in the dry season (December to June), and an epidemic wave can last two to three years, dying out during the intervening rainy seasons.[74] Attack rates of 100–800 cases per 100,000 are encountered in this area,[75] which is poorly served by medical care. These cases are predominantly caused by meningococci.[13] The largest epidemic ever recorded in history swept across the entire region in 1996–1997, causing over 250,000 cases and 25,000 deaths.[76]



Deaths from meningitis per million persons in 2012

| | | |
|---|---|---|
| 0-2 | 7-9 | 32-61 |
| 3-3 | 10-20 | 62-153 |
| 4-6 | 21-31 | 154-308 |
| | | 309-734 |

Meningococcal disease occurs in epidemics in areas where many people live together for the first time, such as army barracks during mobilization, college campuses[1] and the annual Hajj pilgrimage.[52] Although the pattern of epidemic cycles in Africa is not well understood, several factors have been associated with the development of epidemics in the meningitis belt. They include: medical conditions (immunological susceptibility of the population), demographic conditions (travel and large population displacements), socioeconomic conditions (overcrowding and poor living conditions), climatic conditions (drought and dust storms), and concurrent infections (acute respiratory infections).[75]

There are significant differences in the local distribution of causes for bacterial meningitis. For instance, while *N. meningitides* groups B and C cause most disease episodes in Europe, group A is found in Asia and continues to predominate in Africa, where it causes most of the major epidemics in the meningitis belt, accounting for about 80% to 85% of documented meningococcal meningitis cases.[75]

## History [edit]

Some suggest that Hippocrates may have realized the existence of meningitis,[13] and it seems that meningism was known to pre-Renaissance physicians such as Avicenna.[77] The description of tuberculous meningitis, then called "dropsy in the brain", is often attributed to Edinburgh physician Sir Robert Whytt in a posthumous report that appeared in 1768, although the link with tuberculosis and its pathogen was not made until the next century.[77][78]

It appears that epidemic meningitis is a relatively recent phenomenon.[79] The first recorded major outbreak occurred in Geneva in 1805.[79][80] Several other epidemics in Europe and the United States were described shortly afterward, and the first report of an epidemic in Africa appeared in 1840. African epidemics became much more common in the 20th century, starting with a major epidemic sweeping Nigeria and Ghana in 1905–1908.[79]

The first report of bacterial infection underlying meningitis was by the Austrian bacteriologist Anton Weichselbaum, who in 1887 described the *meningococcus*.[81] Mortality from meningitis was very high (over 90%) in early reports. In 1906, antiserum was produced in horses; this was developed further by the American scientist Simon Flexner and markedly decreased mortality from meningococcal disease.[82][83] In 1944, penicillin was first reported to be effective in meningitis.[84] The introduction in the late 20th century of *Haemophilus* vaccines led to a marked fall in cases of meningitis associated with this pathogen,[48] and in 2002, evidence emerged that treatment with steroids could improve the prognosis of bacterial meningitis.[61][64][83] World Meningitis Day is celebrated on the 24th of April each year.

# Rabies

From Wikipedia, the free encyclopedia

*"Rabid" redirects here. For the 1977 film, see Rabid (film). For the punk rock band, see Rabid (band). For other uses, see Rabies (disambiguation).*

**Rabies** is a viral disease that causes inflammation of the brain in humans and other mammals.[1] Early symptoms can include fever and tingling at the site of exposure.[1] These symptoms are followed by one or more of the following symptoms: violent movements, uncontrolled excitement, fear of water, an inability to move parts of the body, confusion, and loss of consciousness.[1] Once symptoms appear, the result is nearly always death.[1] The time period between contracting the disease and the start of symptoms is usually one to three months; however, this time period can vary from less than one week to more than one year.[1] The time is dependent on the distance the virus must travel to reach the central nervous system.[2]

Rabies is caused by *lyssaviruses*, including rabies virus and Australian bat lyssavirus.[3] Rabies is spread when an infected animal scratches or bites another animal or human.[1] Saliva from an infected animal can also transmit rabies if the saliva comes into contact with the eyes, mouth, or nose.[1] Globally, dogs are the most common animal involved.[1] More than 99% of rabies cases in countries where dogs commonly have the disease are caused by dog bites.[4] In the Americas, bat bites are the most common source of rabies infections in humans, and less than 5% of cases are from dogs.[1][4] Rodents are very rarely infected with rabies.[4] The rabies virus travels to the brain by following the peripheral nerves. The disease can only be diagnosed after the start of symptoms.[1]

Animal control and vaccination programs have decreased the risk of rabies from dogs in a number of regions of the world.[1] Immunizing people before they are exposed is recommended for those who are at high risk. The high-risk group includes people who work with bats or who spend prolonged periods in areas of the world where rabies is common.[1] In people who have been exposed to rabies, the rabies vaccine and sometimes rabies immunoglobulin are effective in preventing the disease if the person receives the treatment before the start of rabies symptoms.[1] Washing bites and scratches for 15 minutes with soap and water, povidone iodine, or detergent may reduce the number of viral

particles and may be somewhat effective at preventing transmission.[1][5] Only five people have survived a rabies infection after showing symptoms, and this was with extensive treatment known as the Milwaukee protocol.[6][7]

Rabies causes about 24,000 to 60,000 deaths worldwide per year.[8][9] More than 95% of human deaths caused by rabies occur in Africa and Asia.[1] Rabies is present in more than 150 countries and on all continents but Antarctica.[1] More than 3 billion people live in regions of the world where rabies occurs.[1] A number of countries, including Australia, Canada, Japan, and the United States, and Western Europe, do not have rabies among dogs.[10][11] Many small island nations do not have rabies at all.[12]

## Signs and symptoms [edit]

A person with rabies, 1959

The period between infection and the first symptoms (incubation period) is typically 1–3 months in humans.[8] Incubation periods as short as four days and longer than six years have been documented, depending on the location and severity of the contaminated wound and the amount of virus introduced.[8] Initial signs and symptoms of rabies are often nonspecific such as fever and headache.[8] As rabies progresses and causes inflammation of the brain and/or meninges, signs and symptoms can include slight or partial paralysis, anxiety, insomnia, confusion, agitation, abnormal behavior, paranoia, terror, and hallucinations, progressing to delirium, and coma.[2][8] The person may also have hydrophobia.[1]

Death usually occurs 2 to 10 days after first symptoms. Survival is rare once symptoms have presented,[8] even with the administration of proper and intensive care.[13] Jeanna Giese, who in 2004 was the first patient treated with the Milwaukee protocol,[14] became the first person ever recorded to have survived rabies without receiving successful post-exposure prophylaxis. An intention-to-treat analysis has since found this protocol has a survival rate of about 8%.[15]

### Hydrophobia [edit]

Hydrophobia ("fear of water") is the historic name for rabies.[16] It refers to a set of symptoms in the later stages of an infection in which the person has difficulty swallowing, shows panic when presented with liquids to drink, and cannot quench his or her thirst. Any mammal infected with the virus may demonstrate hydrophobia.[17]

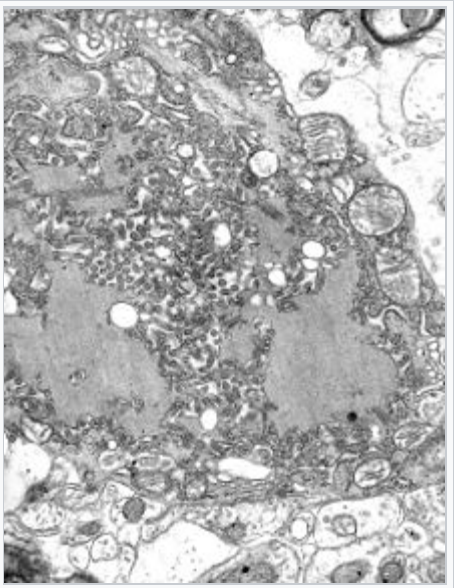
A rabid dog

Saliva production is greatly increased, and attempts to drink, or even the intention or suggestion of drinking, may cause excruciatingly painful spasms of the muscles in the throat and larynx. This can be attributed to the fact that the virus multiplies and assimilates in the salivary glands of the infected animal for the purpose of further transmission through biting. The ability to transmit the virus would decrease significantly if the infected individual could swallow saliva and water.[18]

Hydrophobia is commonly associated with furious rabies, which affects 80% of rabies-infected people. The remaining 20% may experience a paralytic form of rabies that is marked by muscle weakness, loss of sensation, and paralysis; this form of rabies does not usually cause fear of water.[17]

## Cause [edit]

Rabies is caused by a number of *lyssaviruses* including: rabies virus and Australian bat lyssavirus.[3]



TEM micrograph with numerous rabies virions (small, dark grey, rodlike particles) and Negri bodies (the larger pathognomonic cellular inclusions of rabies infection)

The rabies virus is the type species of the *Lyssavirus* genus, in the family *Rhabdoviridae*, order *Mononegavirales*. Lyssavirions have helical symmetry, with a length of about 180 nm and a cross-section of about 75 nm.[19] These virions are enveloped and have a single-stranded RNA genome with negative sense. The genetic information is packed as a ribonucleoprotein complex in which RNA is tightly bound by the viral nucleoprotein. The RNA genome of the virus encodes five genes whose order is highly conserved: nucleoprotein (N), phosphoprotein (P), matrix protein (M), glycoprotein (G), and the viral RNA polymerase (L).[20]

Once within a muscle or nerve cell, the virus undergoes replication. The trimeric spikes on the exterior of the membrane of the virus interact with a specific cell receptor, the most likely one being the acetylcholine receptor. The cellular membrane pinches in a procession known as pinocytosis and allows entry of the virus into the cell by way of an endosome. The virus then uses the acidic environment, which is necessary, of that endosome and binds to its membrane simultaneously, releasing its five proteins and single strand RNA into the cytoplasm.[21]

The L protein then transcribes five mRNA strands and a positive strand of RNA all from the original negative strand RNA using free nucleotides in the cytoplasm. These five mRNA strands are then translated into their corresponding proteins (P, L, N, G and M proteins) at free ribosomes in the cytoplasm. Some proteins require post-translative modifications. For example, the G protein travels through the rough endoplasmic reticulum, where it undergoes further folding, and is then transported to the Golgi apparatus, where a sugar group is added to it (glycosylation).[21]

Where there are enough proteins, the viral polymerase will begin to synthesize new negative strands of RNA from the template of the positive strand RNA. These negative strands will then form complexes with the N, P, L and M proteins and then travel to the inner membrane of the cell, where a G protein has embedded itself in the membrane. The G protein then coils around the N-P-L-M complex of proteins taking some of the host cell membrane with it, which will form the new outer envelope of the virus particle. The virus then buds from the cell.[21]

From the point of entry, the virus is neurotropic, traveling quickly along the neural pathways into the central nervous system. The virus usually first infects muscle cells close to the site of infection, where they are able to replicate without being 'noticed' by the host's immune system. Once enough virus has been replicated, they begin to bind to acetylcholine receptors (p75NR) at the neuromuscular junction.[22] The virus then travels through the nerve cell axon via retrograde transport, as its P protein interacts with dynein, a protein present in the cytoplasm of nerve cells. Once the virus reaches the cell body it travels rapidly to the Central Nervous System (CNS), replicating in motor neurons and eventually reaching the brain.[2] After the brain is infected, the virus travels centrifugally to the peripheral and autonomic nervous systems, eventually migrating to the salivary glands, where it is ready to be transmitted to the next host.[23]:317

## Transmission [edit]

*Main article: Rabies transmission*

All warm-blooded species, including humans, may become infected with the rabies virus and develop symptoms. Birds were first artificially infected with rabies in 1884; however, infected birds are largely if not wholly asymptomatic, and recover.[24] Other bird species have been known to develop rabies antibodies, a sign of infection, after feeding on rabies-infected mammals.[25][26]

The virus has also adapted to grow in cells of poikilothermic ("cold-blooded") vertebrates.[27][28] Most animals can be infected by the virus and can transmit the disease to humans. Infected bats,[29][30] monkeys, raccoons, foxes, skunks, cattle, wolves, coyotes, dogs, mongooses (normally yellow mongoose)[31] and cats present the greatest risk to humans.

Rabies may also spread through exposure to infected bears, domestic farm animals, groundhogs, weasels, and other wild carnivorans. Lagomorphs, such as hares and rabbits, and small rodents such as chipmunks, gerbils, guinea pigs, hamsters, mice, rats, and squirrels, are almost never found to be infected with rabies and are not known to transmit rabies to humans.[32] Bites from mice, rats, or squirrels rarely require rabies prevention because these rodents are typically killed by any encounter with a larger, rabid animal, and would, therefore, not be carriers.[33] The Virginia opossum is resistant but not immune to rabies.[34]

The virus is usually present in the nerves and saliva of a symptomatic rabid animal.[35][36] The route of infection is usually, but not always, by a bite. In many cases, the infected animal is exceptionally aggressive, may attack without provocation, and exhibits otherwise uncharacteristic behavior.[37] This is an example of a viral pathogen modifying the behavior of its host to facilitate its transmission to other hosts.

Transmission between humans is extremely rare. A few cases have been recorded through transplant surgery.[38] The only well-documented cases of rabies caused by human-to-human transmission occurred among eight recipients of transplanted corneas and among three recipients of solid organs.[39] In addition to transmission from cornea and organ transplants, bite and non-bite exposures inflicted by infected humans could theoretically transmit rabies, but no such cases have been documented, since infected humans are usually hospitalized and necessary precautions taken. Casual contact, such as touching a person with rabies or contact with non-infectious fluid or tissue (urine, blood, feces) does not constitute an exposure and does not require post-exposure prophylaxis. Additionally, as the virus is present in sperm or vaginal secretions, spread through sex may be possible.[40]

After a typical human infection by bite, the virus enters the peripheral nervous system. It then travels along the afferent nerves toward the central nervous system.[41] During this phase, the virus cannot be easily detected within the host, and vaccination may still confer cell-mediated immunity to prevent symptomatic rabies. When the virus reaches the brain, it rapidly causes encephalitis, the prodromal phase, which is the beginning of the symptoms. Once the patient becomes symptomatic, treatment is almost never effective and mortality is over 99%. Rabies may also inflame the spinal cord, producing transverse myelitis.[42][43]

## Diagnosis [edit]

Rabies can be difficult to diagnose, because, in the early stages, it is easily confused with other diseases or

with aggressiveness.[44] The reference method for diagnosing rabies is the fluorescent antibody test (FAT), an immunohistochemistry procedure, which is recommended by the World Health Organization (WHO).[45] The FAT relies on the ability of a detector molecule (usually fluorescein isothiocyanate) coupled with a rabies-specific antibody, forming a conjugate, to bind to and allow the visualisation of rabies antigen using fluorescent microscopy techniques. Microscopic analysis of samples is the only direct method that allows for the identification of rabies virus-specific antigen in a short time and at a reduced cost, irrespective of geographical origin and status of the host. It has to be regarded as the first step in diagnostic procedures for all laboratories. Autolysed samples can, however, reduce the sensitivity and specificity of the FAT.[46] The RT PCR assays proved to be a sensitive and specific tool for routine diagnostic purposes,[47] particularly in decomposed samples[48] or archival specimens.[49] The diagnosis can be reliably made from brain samples taken after death. The diagnosis can also be made from saliva, urine, and cerebrospinal fluid samples, but this is not as sensitive and reliable as brain samples.[46] Cerebral inclusion bodies called Negri bodies are 100% diagnostic for rabies infection but are found in only about 80% of cases.[19] If possible, the animal from which the bite was received should also be examined for rabies.[50]

Some light microscopy techniques may also be used to diagnose rabies at a tenth of the cost of traditional fluorescence microscopy techniques, allowing identification of the disease in less-developed countries.[51]

### Differential diagnosis [edit]

The differential diagnosis in a case of suspected human rabies may initially include any cause of encephalitis, in particular infection with viruses such as herpesviruses, enteroviruses, and arboviruses such as West Nile virus. The most important viruses to rule out are herpes simplex virus type one, varicella zoster virus, and (less commonly) enteroviruses, including coxsackieviruses, echoviruses, polioviruses, and human enteroviruses 68 to 71.[52]

New causes of viral encephalitis are also possible, as was evidenced by the 1999 outbreak in Malaysia of 300 cases of encephalitis with a mortality rate of 40% caused by Nipah virus, a newly recognized paramyxovirus.[53] Likewise, well-known viruses may be introduced into new locales, as is illustrated by the outbreak of encephalitis due to West Nile virus in the eastern United States.[54] Epidemiologic factors, such as season, geographic location, and the patient's age, travel history, and possible exposure to bites, rodents, and ticks, may help direct the diagnosis.

## Prevention [edit]

Almost all human cases of rabies were fatal until a vaccine was developed in 1885 by Louis Pasteur and Émile Roux. Their original vaccine was harvested from infected rabbits, from which the virus in the nerve tissue was weakened by allowing it to dry for five to ten days.[55] Similar nerve tissue-derived vaccines are still used in some countries, as they are much cheaper than modern cell culture vaccines.[56]

The human diploid cell rabies vaccine was started in 1967. Less expensive purified chicken embryo cell vaccine and purified vero cell rabies vaccine are now available.[50] A recombinant vaccine called V-RG has been used in Belgium, France, Germany, and the United States to prevent outbreaks of rabies in undomesticated animals.[57] Immunization before exposure has been used in both human and nonhuman populations, where, as in many jurisdictions, domesticated animals are required to be vaccinated.[58]

The number of recorded human deaths from rabies in the United States has dropped from 100 or more annually in the early 20th century to one or two per year due to widespread vaccination of domestic dogs and cats and the development of human vaccines and immunoglobulin treatments. Most deaths now result from bat bites, which may go unnoticed by the victim and hence untreated.[59]

The Missouri Department of Health and Senior Services Communicable Disease Surveillance 2007 Annual Report states the following can help reduce the risk of contracting rabies:[60]

- Vaccinating dogs, cats, and ferrets against rabies
- Keeping pets under supervision

- Not handling wild animals or strays
- Contacting an animal control officer upon observing a wild animal or a stray, especially if the animal is acting strangely
- If bitten by an animal, washing the wound with soap and water for 10 to 15 minutes and contacting a healthcare provider to determine if post-exposure prophylaxis is required

September 28 is World Rabies Day, which promotes the information, prevention, and elimination of the disease.[61]

## Treatment [edit]

Treatment after exposure can prevent the disease if administered promptly, generally within 10 days of infection.[19] Thoroughly washing the wound as soon as possible with soap and water for approximately five minutes is effective in reducing the number of viral particles.[62] Povidone-iodine or alcohol is then recommended to reduce the virus further.[63]

In the US, the Centers for Disease Control and Prevention recommends people receive one dose of human rabies immunoglobulin (HRIG) and four doses of rabies vaccine over a 14-day period.[64] The immunoglobulin dose should not exceed 20 units per kilogram body weight. HRIG is expensive and constitutes most of the cost of post exposure treatment, ranging as high as several thousand dollars.[65] As much as possible of this dose should be injected around the bites, with the remainder being given by deep intramuscular injection at a site distant from the vaccination site.[21]

The first dose of rabies vaccine is given as soon as possible after exposure, with additional doses on days three, seven and 14 after the first. Patients who have previously received pre-exposure vaccination do not receive the immunoglobulin, only the postexposure vaccinations on days 0 and 3.[66]

The pain and side effects of modern cell-based vaccines are similar to flu shots. The old nerve-tissue-based vaccinations that require multiple painful injections into the abdomen with a large needle are inexpensive, but are being phased out and replaced by affordable World Health Organization intradermal-vaccination regimens.[50]

Intramuscular vaccination should be given into the deltoid, not the gluteal area, which has been associated with vaccination failure due to injection into fat rather than muscle. In infants, the lateral thigh is recommended.[67]

Awakening to find a bat in the room, or finding a bat in the room of a previously unattended child or mentally disabled or intoxicated person, is regarded as an indication for post-exposure prophylaxis (PEP). The recommendation for the precautionary use of PEP in occult bat encounters where no contact is recognized has been questioned in the medical literature, based on a cost–benefit analysis.[68] However, a 2002 study has supported the protocol of precautionary administering of PEP where a child or mentally compromised individual has been alone with a bat, especially in sleep areas, where a bite or exposure may occur without the victim being aware.[69] Begun with little or no delay, PEP is 100% effective against rabies.[14] In the case in which there has been a significant delay in administering PEP, the treatment should be administered regardless, as it may still be effective.[21]

### Induced coma [edit]

*See also: Milwaukee protocol*

In 2004, American teenager Jeanna Giese survived an infection of rabies unvaccinated. She was placed into an induced coma upon onset of symptoms and given ketamine, midazolam, ribavirin, and amantadine. Her doctors administered treatment based on the hypothesis that detrimental effects of rabies were caused by temporary dysfunctions in the brain and could be avoided by inducing a temporary partial halt in brain function that would protect the brain from damage while giving the immune system time to defeat the virus. After 31 days of isolation and 76 days of hospitalization, Giese was released from the hospital.[70] She survived with all higher level brain functions, but an inability to walk and balance.[71] On a podcast of

NPR's *Radiolab*, Giese recounted: "I had to learn how to stand and then to walk, turn around, move my toes. I was really, after rabies, a new born baby who couldn't do anything. I had to relearn that all...mentally I knew how to do stuff but my body wouldn't cooperate with what I wanted it to do. It definitely took a toll on me psychologically. You know I'm still recovering. I'm not completely back. Stuff like balance, and I can't run normally."[72]

Giese's treatment regimen became known as the Milwaukee protocol, which has since undergone revision with the second version omitting the use of ribavirin. Two of 25 patients survived when treated under the first protocol. A further 10 patients have been treated under the revised protocol, with a further two survivors.[15]

On June 12, 2011, Precious Reynolds, an eight-year-old girl from Humboldt County, California, became the third reported person in the United States to have recovered from rabies without receiving PEP.[73]

## Prognosis [edit]

In unvaccinated humans, rabies is almost always fatal after neurological symptoms have developed.[74]

Vaccination after exposure, PEP, is highly successful in preventing the disease if administered promptly, in general within 6 days of infection. Begun with little or no delay, PEP is 100% effective against rabies.[14] In the case of significant delay in administering PEP, the treatment still has a chance of success.[21]

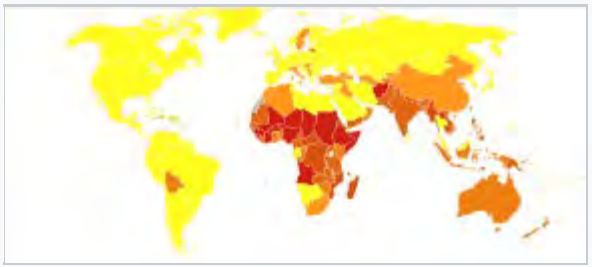
Five of the first 43 patients (12%) treated with the Milwaukee protocol survived, and those receiving treatment survived longer than those not receiving the treatment.[75]

## Epidemiology [edit]

*Main article: Prevalence of rabies*

In 2010, an estimated 26,000 people died from rabies, down from 54,000 in 1990.[76] The majority of the deaths occurred in Asia and Africa.[74] India has the highest rate of human rabies in the world, primarily because of stray dogs,[77] whose number has greatly increased since a 2001 law forbade the killing of dogs.[78] Effective control and treatment of rabies in India is also hindered by a form of mass hysteria known as puppy pregnancy syndrome (PPS). Dog bite victims with PPS (both male and female) become convinced that puppies are growing inside them, and often seek help from faith healers rather than from conventional medical services. In cases where the bite was from a rabid dog, this decision can prove fatal. Dr. Nitai Kishore Marik, former district medical officer of West Midnapur, states "I have seen scores of cases of rabies that reached our hospitals very late because of the intervention of faith healers. We could not save those lives."[79] An estimated 20,000 people die every year from rabies in India — more than a third of the global toll.[78] As of 2015, China had the second-highest number of cases (approximately 6,000), followed by the Democratic Republic of the Congo (5,600).[80]

The rabies virus survives in widespread, varied, rural animal reservoirs. Despite Australia's official rabies-free status,[81] Australian bat lyssavirus (ABLV), discovered in 1996, is a strain of rabies prevalent in native bat populations. There have been three human cases of ABLV in Australia, all of them fatal.



Deaths from rabies per million persons in 2012

Rabies-free countries (in green) as of 2013. always rabies-free

rabies eliminated before 1990
rabies eliminated in or after 1990
year of rabies elimination unknown

In Asia and in parts of the Americas and Africa, dogs remain the principal host. Mandatory vaccination of animals is less effective in rural areas. Especially in developing countries, pets may not be privately kept and their destruction may be unacceptable. Oral vaccines can be safely distributed in baits, a practice that has successfully reduced rabies in rural areas of Canada, France, and the United States. In Montréal, Quebec, Canada, baits are successfully used on raccoons in the Mont-Royal Park area. Vaccination campaigns may be expensive, and cost-benefit analysis suggests baits may be a cost-effective method of control.[82] In Ontario, a dramatic drop in rabies was recorded when an aerial bait-vaccination campaign was launched.[83]

Rabies is common among wild animals in the US. Bats, raccoons, skunks and foxes account for almost all reported cases (98% in 2009). Rabid bats are found in all 48 contiguous states. Other reservoirs are more limited geographically; for example, the raccoon rabies virus variant is only found in a relatively narrow band along the East Coast. Due to a high public awareness of the virus, efforts at vaccination of domestic animals and curtailment of feral populations, and availability of postexposure prophylaxis, incidents of rabies in humans are very rare. A total of 49 cases of the disease was reported in the country between 1995 and 2011; of these, 11 are thought to have been acquired abroad. Almost all domestically acquired cases are attributed to bat bites.[84]

In Switzerland, the disease has been virtually eliminated after scientists placed chicken heads laced with live attenuated vaccine in the Swiss Alps.[83] The foxes of Switzerland, proven to be the main source of rabies in the country, ate the chicken heads and immunized themselves.[83]

Italy, after being declared rabies-free from 1997 to 2008, has witnessed a reemergence of the disease in wild animals in the Triveneto regions (Trentino-Alto Adige/Südtirol, Veneto and Friuli-Venezia Giulia), due to the spreading of an epidemic in the Balkans that hit Austria too. An extensive wild animals vaccination campaign eliminated the virus from Italy again, and it regained the rabies-free country status in 2013, the last reported case of rabies being reported in a red fox in early 2011.[85][86]

## History [edit]

Rabies has been known since around 2000 B.C.[87] The first written record of rabies is in the Mesopotamian Codex of Eshnunna (circa 1930 BC), which dictates that the owner of a dog showing symptoms of rabies should take preventive measure against bites. If another person were bitten by a rabid dog and later died, the owner was heavily fined.[88]

A woodcut from the Middle Ages showing a rabid dog.

Ineffective folk remedies abounded in the medical literature of the ancient world. The physician Scribonius Largus prescribed a poultice of cloth and hyena skin; Antaeus recommended a preparation made from the skull of a hanged man.[89]

Rabies appears to have originated in the Old World, the first epizootic in the New World occurring in Boston in 1768.[90] It spread from there, over the next few years, to various other states, as well as to the French West Indies, eventually becoming common all across North America.

Rabies was considered a scourge for its prevalence in the 19th century. In France and Belgium, where Saint Hubert was venerated, the "St Hubert's Key" was heated and applied to cauterize the wound. By an application of magical thinking, dogs were branded with the key in hopes of protecting them from rabies. The fear of rabies was almost irrational, due to the insignificant number of vectors (mostly rabid dogs) and the absence of any efficacious treatment. It was not uncommon for

François Boissier de Sauvages de Lacroix, *Della natura e causa della rabbia* (*Dissertation sur la nature et la cause de la Rage*), 1777

a person bitten by a dog but merely suspected of being rabid, to commit suicide or to be killed by others.[91] This gave Louis Pasteur ample opportunity to test postexposure treatments from 1885.[8] In ancient times, the attachment of the tongue (the lingual frenulum, a mucous membrane) was cut and removed as this is where rabies was thought to originate. This practice ceased with the discovery of the actual cause of rabies.[23]

In modern times, the fear of rabies has not diminished, and the disease and its symptoms, particularly agitation has served as an inspiration for several works of zombie or similarly-themed fiction, often portraying rabies as having mutated into a stronger virus which fills humans with murderous rage or uncurable illness, bringing about a devastating, widespread pandemic.[92]

## Etymology [edit]

The term is derived from the Latin *rabies*, "madness".[93] This, in turn, may be related to the Sanskrit *rabhas*, "to do violence".[*citation needed*][94] The Greeks derived the word *lyssa*, from *lud* or "violent"; this root is used in the genus name of the rabies virus, *Lyssavirus*.[91]

# Other animals [edit]

*Main article: Rabies in animals*

Rabies is infectious to mammals; three stages of central nervous system infection are recognized. The first stage is a one- to three-day period characterized by behavioral changes and is known as the prodromal stage. The second is the excitative stage, which lasts three to four days. This stage is often known as "furious rabies" for the tendency of the affected animal to be hyper-reactive to external stimuli and bite at anything near. The third is the paralytic stage and is caused by damage to motor neurons. Incoordination is seen, owing to rear limb paralysis, and drooling and difficulty swallowing is caused by paralysis of facial and throat muscles. Death is usually caused by respiratory arrest.[95]

# Research [edit]

Rabies has the advantage over other pseudotyping methods for gene delivery in that the cell-targeting (tissue tropism) is more specific for difficult-to-reach sites, such as the central nervous system without invasive delivery methods, as well as being capable of retrograde tracing (i.e., going against the flow of information at synapses) in neuronal circuits.[96]

Evidence indicates artificially increasing the permeability of the blood–brain barrier, which normally does not allow most immune cells across, promotes viral clearance.[97][98]

# Syphilis

From Wikipedia, the free encyclopedia

**Syphilis** is a sexually transmitted infection caused by the bacterium *Treponema pallidum* subspecies *pallidum*.[1] The signs and symptoms of syphilis vary depending in which of the four stages it presents (primary, secondary, latent, and tertiary). The primary stage classically presents with a single chancre (a firm, painless, non-itchy skin ulceration) but there may be multiple sores. In secondary syphilis a diffuse rash occurs, which frequently involves the palms of the hands and soles of the feet. There may also be sores in the mouth or vagina. In latent syphilis, which can last for years, there are little to no symptoms.[2] In tertiary syphilis there are gummas (soft non-cancerous growths), neurological, or heart symptoms.[3] Syphilis has been known as "the great imitator" as it may cause symptoms similar to many other diseases.[2][3]

Syphilis is most commonly spread through sexual activity.[2] It may also be transmitted from mother to baby during pregnancy or at birth, resulting in congenital syphilis.[2][4] Other human diseases caused by related *Treponema pallidum* subspecies include yaws (subspecies *pertenue*), pinta (subspecies *carateum*), and bejel (subspecies *endemicum*).[3] Diagnosis is usually made by using blood tests; the bacteria can also be detected using dark field microscopy. The Center for Disease Control recommends all pregnant women be tested.[2]

The risk of syphilis can be decreased by latex condom use, or not having sex.[2] Syphilis can be effectively treated with antibiotics. The preferred antibiotic for most cases is benzathine penicillin G injected into a muscle. In those who have a severe penicillin allergy, doxycycline or tetracycline may be used. In those with neurosyphilis, intravenous penicillin G potassium or ceftriaxone is recommended. During treatment people may develop fever, headache, and muscle pains, a reaction known as Jarisch-Herxheimer.[1]

In 2012, about 0.5% of adults were infected with syphilis with 6 million new cases.[5] During 2010, it caused about 113,000 deaths, down from 202,000 in 1990.[6] After decreasing dramatically with the availability of penicillin in the 1940s, rates of infection have increased since the turn of the millennium in many countries, often in combination with human immunodeficiency virus (HIV).[3][7] This is believed to be partly due to increased promiscuity, prostitution, decreasing use of condoms, and unsafe sexual practices among men who have sex with men.[8][9][10] In 2015, Cuba became the first country in the world to eliminate mother-to-child transmission of syphilis.[11]

# Signs and symptoms

Syphilis can present in one of four different stages: primary, secondary, latent, and tertiary,[3] and may also occur congenitally.[12] It was referred to as "the great imitator" by Sir William Osler due to its varied presentations.[3][13]

## Primary

Primary syphilis is typically acquired by direct sexual contact with the infectious lesions of another person.[14] Approximately 3 to 90 days after the initial exposure (average 21 days) a skin lesion, called a chancre, appears at the point of contact. This is classically (40% of the time) a single, firm, painless, non-itchy skin ulceration with a clean base and sharp borders 0.3–3.0 cm in size.[3] The lesion may take on almost any form. In the classic form, it evolves from a macule to a papule and finally to an erosion or ulcer.[15] Occasionally, multiple lesions may be present (~40%),[3] with multiple lesions more common when coinfected with HIV. Lesions may be painful or tender (30%), and they may occur in places other than the genitals (2–7%). The most common location in women is the cervix (44%), the penis in heterosexual men (99%), and anally and rectally relatively commonly in men who have sex with men (34%).[15] Lymph node enlargement frequently (80%) occurs around the area of infection,[3] occurring seven to 10 days after chancre formation.[15] The lesion may persist for three to six weeks without treatment.[3]

Primary chancre of syphilis at the site of infection on the penis

## Secondary

Secondary syphilis occurs approximately four to ten weeks after the primary infection.[3] While secondary disease is known for the many different ways it can manifest, symptoms most commonly involve the skin, mucous membranes, and lymph nodes.[16] There may be a symmetrical, reddish-pink, non-itchy rash on the trunk and extremities, including the palms and soles.[3][17] The rash may become maculopapular or pustular. It may form flat, broad, whitish, wart-like lesions known as condyloma latum on mucous membranes. All of these lesions harbor bacteria and are infectious. Other symptoms may include fever, sore throat, malaise, weight loss, hair loss, and headache.[3] Rare manifestations include liver inflammation, kidney disease, joint inflammation, periostitis, inflammation of the optic nerve, uveitis, and interstitial keratitis.[3][18] The acute symptoms usually resolve after three to six weeks;[18] about 25% of people may present with a recurrence of secondary symptoms. Many people who present with secondary syphilis (40–85% of women, 20–65% of men) do not report previously having had the classic chancre of primary syphilis.[16]

Typical presentation of secondary syphilis with a rash on the palms of the hands

Reddish papules and nodules over much of the body due to secondary syphilis

## Latent

Latent syphilis is defined as having serologic proof of infection without symptoms of disease.[14] It is further described as either early (less than 1 year after secondary syphilis) or late (more than 1 year after secondary syphilis) in the United States.[18] The United Kingdom uses a cut-off of two years for early and late latent syphilis.[15] Early latent syphilis may have a relapse of symptoms. Late latent syphilis is asymptomatic, and not as contagious as early latent syphilis.[18]

## Tertiary

Tertiary syphilis may occur approximately 3 to 15 years after the initial infection, and may be divided into three different forms: gummatous syphilis (15%), late neurosyphilis (6.5%), and cardiovascular syphilis (10%).[3][18] Without treatment, a third of infected people develop tertiary disease.[18] People with tertiary syphilis are not infectious.[3]

Gummatous syphilis or late benign syphilis usually occurs 1 to 46 years after the initial infection, with an average of 15 years. This stage is characterized by the formation of chronic gummas, which are soft, tumor-like balls of inflammation which may vary considerably in size. They typically affect the skin, bone, and liver, but can occur anywhere.[3]

Neurosyphilis refers to an infection involving the central nervous system. It may occur early, being either asymptomatic or in the form of syphilitic meningitis, or late as meningovascular syphilis, general paresis, or tabes dorsalis, which is associated with poor balance and lightning pains in the lower extremities. Late neurosyphilis typically occurs 4 to 25 years after the initial infection. Meningovascular syphilis typically presents with apathy and seizure, and general paresis with dementia and tabes dorsalis.[3] Also, there may be Argyll Robertson pupils, which are bilateral small pupils that constrict when the person focuses on near objects but do not constrict when exposed to bright light.

Person with tertiary (gummatous) syphilis. Bust in Musée de l'Homme, Paris.

Cardiovascular syphilis usually occurs 10–30 years after the initial infection. The most common complication is syphilitic aortitis, which may result in aneurysm formation.[3]

### Congenital

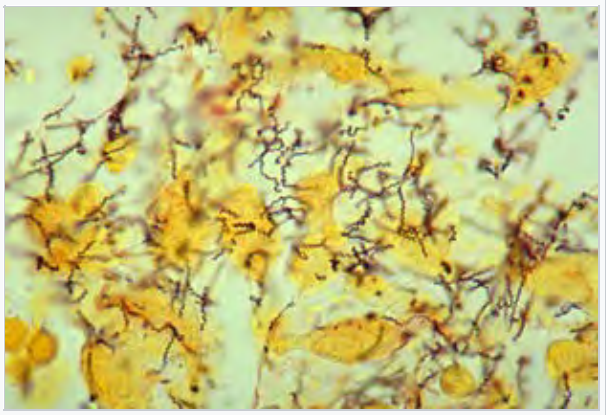
Congenital syphilis is that which is transmitted during pregnancy or during birth. Two-thirds of syphilitic infants are born without symptoms. Common symptoms that develop over the first couple of years of life include enlargement of the liver and spleen (70%), rash (70%), fever (40%), neurosyphilis (20%), and lung inflammation (20%). If untreated, late congenital syphilis may occur in 40%, including saddle nose deformation, Higoumenakis sign, saber shin, or Clutton's joints among others.[4]

## Cause

### Bacteriology

*Main article: Treponema pallidum*

*Treponema pallidum* subspecies *pallidum* is a spiral-shaped, Gram-negative, highly mobile bacterium.[7][15] Three other human diseases are caused by related *Treponema pallidum* subspecies, including yaws (subspecies *pertenue*), pinta (subspecies *carateum*) and bejel (subspecies *endemicum*).[3] Unlike subtype *pallidum*, they do not cause neurological disease.[4] Humans are the only known natural reservoir for subspecies *pallidum*.[12] It is unable to survive without a host for more than a few days. This is due to its small genome (1.14 MDa) failing to encode the metabolic pathways necessary to make most of its macronutrients. It has a slow doubling time of greater than 30 hours.[15]



Histopathology of *Treponema pallidum* spirochetes using a modified Steiner silver stain

### Transmission

Syphilis is transmitted primarily by sexual contact or during pregnancy from a mother to her fetus; the spirochete is able to pass through intact mucous membranes or compromised skin.[3][12] It is thus transmissible by kissing near a lesion, as well as oral, vaginal, and anal sex.[3] Approximately 30% to 60% of those exposed to primary or secondary syphilis will get the disease.[18] Its infectivity is exemplified by the fact that an individual inoculated with only 57 organisms has a 50% chance of being infected.[15] Most (60%) of new cases in the United States occur in men who have sex with men. Syphilis can be transmitted by blood products, but the risk is low due to blood testing in many countries. The risk of transmission from sharing needles appears limited.[3]

It is not generally possible to contract syphilis through toilet seats, daily activities, hot tubs, or sharing eating utensils or clothing.[19] This is mainly because the bacteria die very quickly outside of the body, making transmission by objects extremely difficult.[20]

## Diagnosis

Syphilis is difficult to diagnose clinically early in its presentation.[15] Confirmation is either via blood tests or direct visual inspection using microscopy. Blood tests are more commonly used, as they are easier to perform.[3] Diagnostic tests are unable to distinguish between the stages of the disease.[21]

### Blood tests

This poster acknowledges the social stigma of syphilis, while urging those who possibly have the disease to be tested (circa 1936).

Blood tests are divided into nontreponemal and treponemal tests.[15]

Nontreponemal tests are used initially, and include venereal disease research laboratory (VDRL) and rapid plasma reagin (RPR) tests. False positives on the nontreponemal tests can occur with some viral infections, such as varicella (chickenpox) and measles. False positives can also occur with lymphoma, tuberculosis, malaria, endocarditis, connective tissue disease, and pregnancy.[14]

Because of the possibility of false positives with nontreponemal tests, confirmation is required with a treponemal test, such as treponemal pallidum particle agglutination (TPHA) or fluorescent treponemal antibody absorption test (FTA-Abs).[3] Treponemal antibody tests usually become positive two to five weeks after the initial infection.[15] Neurosyphilis is diagnosed by finding high numbers of leukocytes (predominately lymphocytes) and high protein levels in the cerebrospinal fluid in the setting of a known syphilis infection.[3][14]

### Direct testing

Dark ground microscopy of serous fluid from a chancre may be used to make an immediate diagnosis. Hospitals do not always have equipment or experienced staff members, and testing must be done within 10 minutes of acquiring the sample. Sensitivity has been reported to be nearly 80%; therefore the test can only be used to confirm a diagnosis, but not to rule one out. Two other tests can be carried out on a sample from the chancre: direct fluorescent antibody testing and nucleic acid amplification tests. Direct fluorescent testing uses antibodies tagged with fluorescein, which attach to specific syphilis proteins, while nucleic acid amplification uses techniques, such as the polymerase chain reaction, to detect the presence of specific syphilis genes. These tests are not as time-sensitive, as they do not require living bacteria to make the diagnosis.[15]

## Prevention

### Vaccine

As of 2010, there is no vaccine effective for prevention.[12] Several vaccines based on treponemal proteins reduce lesion development in an animal model, and research is ongoing.[22]

### Sex

Condom use reduces the likelihood of transmission during sex, but does not completely eliminate the risk.[23] The Centers for Disease Control and Prevention states, "Correct and consistent use of latex condoms can reduce the risk of syphilis only when the infected area or site of potential exposure is protected. However, a syphilis sore outside of the area covered by a latex condom can still allow transmission, so caution should be exercised even when using a condom."[24]

Abstinence from intimate physical contact with an infected person is effective at reducing the transmission of syphilis. The CDC states, "The surest way to avoid transmission of sexually transmitted diseases, including syphilis, is to abstain from sexual contact or to be in a long-term mutually monogamous relationship with a partner who has been tested and is known to be uninfected."[24]

### Congenital disease

Congenital syphilis in the newborn can be prevented by screening mothers during early pregnancy and treating those who are infected.[25] The United States Preventive Services Task Force (USPSTF) strongly recommends universal screening of all pregnant women,[26] while the World Health Organization recommends all women be tested at their first antenatal visit and again in the third trimester. If they are positive, they recommend their partners also be treated.[27] Congenital syphilis is still common in the developing world, as many women do not receive antenatal care at all, and the antenatal care others receive does not include screening, and it still occasionally occurs in the developed world, as those most likely to acquire syphilis (through drug use, etc.) are least likely to receive care during pregnancy.[25] Several measures to increase access to testing appear effective at reducing rates of congenital syphilis in low- to middle-income countries.[27] Point-of-care testing to detect syphilis appeared to be good although more research is needed to assess its effectiveness and into improving outcomes in mothers and babies.[28]

### Screening

The CDC recommends that sexually active men who have sex with men be tested at least yearly.[29] The USPSTF also recommends screening among those at high risk.[30]

Syphilis is a notifiable disease in many countries, including Canada[31] the European Union,[32] and the United States.[33] This means health care providers are required to notify public health authorities, which will then ideally provide partner notification to the person's partners.[34] Physicians may also encourage patients to send their partners to seek care.[35] Several strategies have been found to improve follow-up for STI testing including email and text messaging as reminders of appointments.[36]

## Treatment

### Early infections

The first-choice treatment for uncomplicated syphilis remains a single dose of intramuscular benzathine penicillin G.[37] Doxycycline and tetracycline are alternative choices for those allergic to penicillin; due to the risk of birth defects these are not recommended for pregnant women.[37] Resistance to macrolides, rifampin, and clindamycin is often present.[12] Ceftriaxone, a third-generation cephalosporin antibiotic, may be as effective as penicillin-based treatment.[3] It is recommended that a treated person avoid sex until the sores are healed.[19]

### Late infections

For neurosyphilis, due to the poor penetration of penicillin G into the central nervous system, those affected are recommended to be given large doses of intravenous penicillin for a minimum of 10 days.[3][12] If a person is allergic, ceftriaxone may be used or penicillin desensitization attempted. Other late presentations may be treated with once-weekly intramuscular penicillin G for three weeks. If allergic, as in the case of early disease, doxycycline or tetracycline may be used, albeit for a longer duration. Treatment at this stage limits further progression but has only slight effect on damage which has already occurred.[3]

### Jarisch-Herxheimer reaction

One of the potential side effects of treatment is the Jarisch-Herxheimer reaction. It frequently starts within one hour and lasts for 24 hours, with symptoms of fever, muscle pains, headache, and a fast heart rate.[3] It is caused by cytokines released by the immune system in response to lipoproteins released from rupturing syphilis bacteria.[38]

### Pregnancy

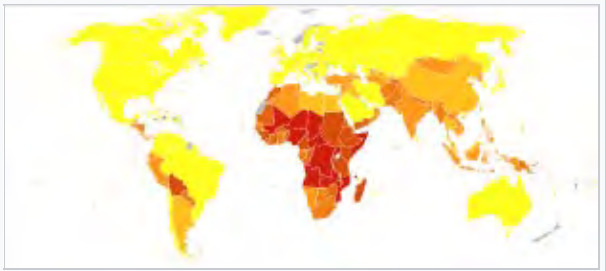
Penicillin is an effective treatment for syphilis in pregnancy[39] but there is no agreement on which dose or way of giving it is most effective.[40] More research is needed into how much antibiotic to give and when to give

it.[40]

# Epidemiology

*Main article: Epidemiology of syphilis*

In 2012 about 0.5% of adults were infected with syphilis with 6 million new cases.[5] In 1999 it is believed to have infected 12 million additional people, with greater than 90% of cases in the developing world.[12] It affects between 700,000 and 1.6 million pregnancies a year, resulting in spontaneous abortions, stillbirths, and congenital syphilis.[4] During 2010 it caused about 113,000 deaths down from 202,000 in 1990.[6] In sub-Saharan Africa, syphilis contributes to approximately 20% of perinatal deaths.[4] Rates are proportionally higher among intravenous drug users, those who are infected with HIV, and men who have sex with men.[8][9][10] In the United States, rates of syphilis as of 2007 were six times greater in men than women; they were nearly equal in 1997.[42] African Americans accounted for almost half of all cases in 2010.[43] As of 2014, syphilis infections continue to increase in the United States.[44]



Syphilis deaths per million persons in 2012

| | |
|---|---|
| 0–0 | 11–19 |
| 1–1 | 20–28 |
| 2–3 | 29–57 |
| 4–10 | 58–138 |

Syphilis was very common in Europe during the 18th and 19th centuries.[7] Flaubert found it universal among nineteenth-century Egyptian prostitutes.[45] In the developed world during the early 20th century, infections declined rapidly with the widespread use of antibiotics, until the 1980s and 1990s.[7] Since 2000, rates of syphilis have been increasing in the USA, Canada, the UK, Australia and Europe, primarily among men who have sex with men.[12] Rates of syphilis among American women have remained stable during this time, and rates among UK women have increased, but at a rate less than that of men.[46] Increased rates among heterosexuals have occurred in China and Russia since the 1990s.[12] This has been attributed to unsafe sexual practices, such as sexual promiscuity, prostitution, and decreasing use of barrier protection.[12][46][47]

Age-standardized disability adjusted life years from syphilis per 100,000 inhabitants in 2004[41]

| | |
|---|---|
| no data | 210–245 |
| <35 | 245–280 |
| 35–70 | 280–315 |
| 70–105 | 315–350 |
| 105–140 | 350–500 |
| 140–175 | >500 |
| 175–210 | |

Untreated, it has a mortality of 8% to 58%, with a greater death rate in males.[3] The symptoms of syphilis have become less severe over the 19th and 20th centuries, in part due to widespread availability of effective treatment and partly due to virulence of the spirochaete.[16] With early treatment, few complications result.[15] Syphilis increases the risk of HIV transmission by two to five times, and coinfection is common (30–60% in some urban centers).[3][12] In 2015 Cuba became the first country in the world to eradicate mother to child transmission of syphilis.[11]

# History

*Main article: History of syphilis*

The exact origin of syphilis is disputed.[3] Syphilis was definitely present in the Americas before European contact,[49] and it may have been carried from the Americas to Europe by the returning crewmen from Christopher Columbus's voyage to the Americas; or it may have existed in Europe previously, but

Portrait of Gerard de Lairesse by Rembrandt van Rijn, *circa* 1665–67, oil on canvas - De Lairesse, himself a painter and art theorist, had congenital syphilis that deformed his face and eventually blinded him.[48]

went unrecognized until shortly after Columbus returned.These are referred to as the *Columbian* and *pre-Columbian* hypotheses, respectively.[21]

The Columbian hypothesis is best supported by the available evidence.[50][51] The first written records of an outbreak of syphilis in Europe occurred in 1494 or 1495 in Naples, Italy, during a French invasion (Italian War of 1494–98).[7][21] As it was claimed to have been spread by French troops, it was initially known as the "French disease" by the people of Naples.[52] In 1530, the pastoral name "syphilis" (the name of a character) was first used by the Italian physician and poet Girolamo Fracastoro as the title of his Latin poem in dactylic hexameter describing the ravages of the disease in Italy.[53][54] It was also known historically as the "Great Pox".[55][56]

The causative organism, *Treponema pallidum*, was first identified by Fritz Schaudinn and Erich Hoffmann in 1905.[7] The first effective treatment for syphilis was Salvarsan, developed in 1910 by Paul Ehrlich. In 1943, trials of penicillin confirmed its effectiveness.[7][55] Before the discovery and use of antibiotics in the mid-twentieth century, mercury and isolation were commonly used, with treatments often worse than the disease.[55]

Many famous historical figures, including Franz Schubert, Arthur Schopenhauer, Édouard Manet,[7] Charles Baudelaire,[57] and Guy de Maupassant are believed to have had the disease.[58] Friedrich Nietzsche was long believed to have gone mad as a result of tertiary syphilis, but that diagnosis has recently come into question.[59]

## Arts and literature

*See also: List of syphilis cases*

An early medical illustration of people with syphilis, Vienna, 1498

The earliest known depiction of an individual with syphilis is Albrecht Dürer's *Syphilitic Man*, a woodcut believed to represent a Landsknecht, a Northern European mercenary.[60] The myth of the *femme fatale* or "poison women" of the 19th century is believed to be partly derived from the devastation of syphilis, with classic examples in literature including John Keats' *La Belle Dame sans Merci*.[61][62]

The artist Jan van der Straet painted a scene of a wealthy man receiving treatment for syphilis with the tropical wood guaiacum sometime around 1580.[63] The title of the work is "Preparation and Use of Guayaco for Treating Syphilis". That the artist chose to include this image in a series of works celebrating the New World indicates how important a treatment, however ineffective, for syphilis was to the European elite at that time. The richly colored and detailed work depicts four servants preparing the concoction while a physician looks on, hiding something behind his back while the hapless patient drinks.[64]

## Tuskegee and Guatemala studies

*See also: Tuskegee syphilis experiment and Guatemala syphilis experiment*

One of the most infamous United States cases of questionable medical ethics in the 20th century was the Tuskegee syphilis study.[65] The study took place in Tuskegee, Alabama, and was supported by the U.S. Public Health Service (PHS) in partnership with the Tuskegee Institute.[66] The study began in 1932, when syphilis was a widespread problem and there was no safe and effective treatment.[13] The study was designed to measure the progression

of untreated syphilis. By 1947, penicillin had been shown to be an effective cure for early syphilis and was becoming widely used to treat the disease.[66] Its use in later syphilis was still unclear.[13] Study directors continued the study and did not offer the participants treatment with penicillin.[66] This is debated, and some have found that penicillin was given to many of the subjects.[13]

A Work Projects Administration poster about syphilis circa 1940.

In the 1960s, Peter Buxtun sent a letter to the CDC, who controlled the study, expressing concern about the ethics of letting hundreds of black men die of a disease that could be cured. The CDC asserted that it needed to continue the study until all of the men had died. In 1972, Buxton went to the mainstream press, causing a public outcry. As a result, the program was terminated, a lawsuit brought those affected nine million dollars, and Congress created a commission empowered to write regulations to deter such abuses from occurring in the future.[66]

On 16 May 1997, thanks to the efforts of the Tuskegee Syphilis Study Legacy Committee formed in 1994, survivors of the study were invited to the White House to be present when President Bill Clinton apologized on behalf of the United States government for the study.[67]

Syphilis experiments were also carried out in Guatemala from 1946 to 1948. They were United States-sponsored human experiments, conducted during the government of Juan José Arévalo with the cooperation of some Guatemalan health ministries and officials. Doctors infected soldiers, prisoners, and mental patients with syphilis and other sexually transmitted diseases, without the informed consent of the subjects, and then treated them with antibiotics. In October 2010, the U.S. formally apologized to Guatemala for conducting these experiments.[68]

# Tuberculosis

From Wikipedia, the free encyclopedia

**Tuberculosis** (**TB**) is an infectious disease caused by the bacterium *Mycobacterium tuberculosis* (MTB).[1] Tuberculosis generally affects the lungs, but can also affect other parts of the body. Most infections do not have symptoms; in which case it is known as latent tuberculosis. About 10% of latent infections progress to active disease which, if left untreated, kills about half of those infected. The classic symptoms of active TB are a chronic cough with blood-containing sputum, fever, night sweats, and weight loss.[1] The historical term "**consumption**" came about due to the weight loss.[2] Infection of other organs can cause a wide range of symptoms.[3]

Tuberculosis is spread through the air when people who have active TB in their lungs cough, spit, speak, or sneeze.[1][4] People with latent TB do not spread the disease. Active infection occurs more often in people with HIV/AIDS and in those who smoke.[1] Diagnosis of active TB is based on chest X-rays, as well as microscopic examination and culture of body fluids. Diagnosis of latent TB relies on the tuberculin skin test (TST) or blood tests.[5]

Prevention of TB involves screening those at high risk, early detection and treatment of cases, and vaccination with the bacillus Calmette-Guérin vaccine.[6][7][8] Those at high risk include household, workplace, and social contacts of people with active TB.[8] Treatment requires the use of multiple antibiotics over a long period of time.[1] Antibiotic resistance is a growing problem with increasing rates of multiple drug-resistant tuberculosis (MDR-TB).[1]

One-third of the world's population is thought to be infected with TB.[1] New infections occur in about 1% of the population each year.[9] In 2014, there were 9.6 million cases of active TB which resulted in 1.5 million deaths. More than 95% of deaths occurred in developing countries. The number of new cases each year has decreased since 2000.[1] About 80% of people in many Asian and African countries test positive while 5–10% of people in the United States population tests positive by the tuberculin test.[10] Tuberculosis has been present in humans since ancient times.[11]

Video explanation

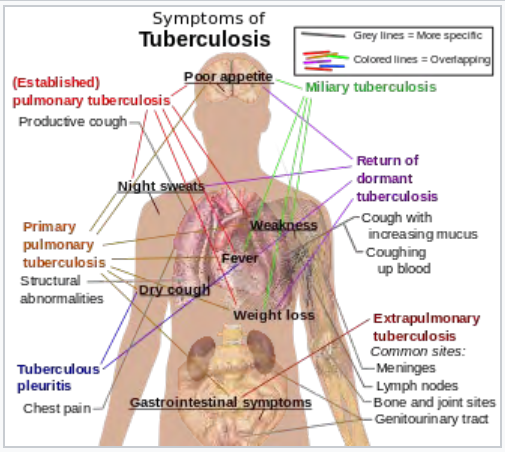
## Signs and symptoms

Tuberculosis may infect any part of the body, but most commonly occurs in the lungs (known as pulmonary tuberculosis).[3] Extrapulmonary TB occurs when tuberculosis develops outside of the lungs, although extrapulmonary TB may coexist with pulmonary TB.[3]

General signs and symptoms include fever, chills, night sweats, loss of appetite, weight loss, and fatigue.[3] Significant nail clubbing may also occur.[13]

### Pulmonary

If a tuberculosis infection does become active, it most commonly involves the lungs (in about 90% of cases).[11][14] Symptoms may include chest pain and a prolonged cough producing sputum. About 25% of people may not have any symptoms (i.e. they remain "asymptomatic").[11] Occasionally, people may cough up blood in small amounts, and in very rare cases, the infection may erode into the pulmonary artery or a Rasmussen's aneurysm, resulting in massive bleeding.[3][15] Tuberculosis may become a chronic illness and cause extensive scarring in the upper lobes of the lungs. The upper lung lobes are more frequently affected by tuberculosis than the lower ones.[3] The reason for this difference is not clear.[10] It may be due to either better air flow,[10] or poor lymph drainage within the upper lungs.[3]



The main symptoms of variants and stages of tuberculosis are given,[12] with many symptoms overlapping with other variants, while others are more (but not entirely) specific for certain variants. Multiple variants may be present simultaneously.

### Extrapulmonary

In 15–20% of active cases, the infection spreads outside the lungs, causing other kinds of TB.[16] These are collectively denoted as "extrapulmonary tuberculosis".[17] Extrapulmonary TB occurs more commonly in immunosuppressed persons and young children. In those with HIV, this occurs in more than 50% of cases.[17] Notable extrapulmonary infection sites include the pleura (in tuberculous pleurisy), the central nervous system (in tuberculous meningitis), the lymphatic system (in scrofula of the neck), the genitourinary system (in urogenital tuberculosis), and the bones and joints (in Pott disease of the spine), among others.

Spread to lymph nodes is the most common.[18] An ulcer originating from nearby infected lymph nodes may occur and is painless, slowly enlarging and has an appearance of "wash leather".[19]

When it spreads to the bones, it is known as "osseous tuberculosis",[20] a form of osteomyelitis.[10] A potentially more serious, widespread form of TB is called "disseminated tuberculosis", also known as miliary tuberculosis.[3] Miliary TB currently makes up about 10% of extrapulmonary cases.[21]

## Causes

### Mycobacteria

*Main article: Mycobacterium tuberculosis*

The main cause of TB is *Mycobacterium tuberculosis* (MTB), a small, aerobic, nonmotile bacillus.[3] The high lipid content of this pathogen accounts for many of its unique clinical characteristics.[22] It divides every 16 to 20 hours, which is an extremely slow rate compared with other bacteria, which usually divide in less than an hour.[23] Mycobacteria have an outer membrane lipid bilayer.[24] If a Gram stain is performed, MTB either stains very weakly "Gram-positive" or does not retain dye as a result of the high lipid and mycolic acid content of its cell wall.[25] MTB can withstand weak disinfectants and survive in a dry state for weeks. In nature, the bacterium can grow only within the cells of a host organism, but *M. tuberculosis* can be cultured in the laboratory.[26]

Scanning electron micrograph of *M. tuberculosis*

Using histological stains on expectorated samples from phlegm (also called "sputum"), scientists can identify MTB under a microscope. Since MTB retains certain stains even after being treated with acidic solution, it is classified as an acid-fast bacillus.[10][25] The most common acid-fast staining techniques are the Ziehl–Neelsen stain[27] and the Kinyoun stain, which dye acid-fast bacilli a bright red that stands out against a blue background.[28] Auramine-rhodamine staining[29] and fluorescence microscopy[30] are also used.

The *M. tuberculosis* complex (MTBC) includes four other TB-causing mycobacteria: *M. bovis*, *M. africanum*, *M. canetti*, and *M. microti*.[31] *M. africanum* is not widespread, but it is a significant cause of tuberculosis in parts of Africa.[32][33] *M. bovis* was once a common cause of tuberculosis, but the introduction of pasteurized milk has almost completely eliminated this as a public health problem in developed countries.[10][34] *M. canetti* is rare and seems to be limited to the Horn of Africa, although a few cases have been seen in African emigrants.[35][36] *M. microti* is also rare and is seen almost only in immunodeficient people, although its prevalence may be significantly underestimated.[37]

Other known pathogenic mycobacteria include *M. leprae*, *M. avium*, and *M. kansasii*. The latter two species are classified as "nontuberculous mycobacteria" (NTM). NTM cause neither TB nor leprosy, but they do cause pulmonary diseases that resemble TB.[38]

### Risk factors

*Main article: Risk factors for tuberculosis*

A number of factors make people more susceptible to TB infections. The most important risk factor globally is HIV; 13% of all people with TB

are infected by the virus.[39] This is a particular problem in sub-Saharan Africa, where rates of HIV are high.[40][41] Of people without HIV who are infected with tuberculosis, about 5–10% develop active disease during their lifetimes;[13] in contrast, 30% of those coinfected with HIV develop the active disease.[13]

Tuberculosis is closely linked to both overcrowding and malnutrition, making it one of the principal diseases of poverty.[11] Those at high risk thus include: people who inject illicit drugs, inhabitants and employees of locales where vulnerable people gather (e.g. prisons and homeless shelters), medically underprivileged and resource-poor communities, high-risk ethnic minorities, children in close contact with high-risk category patients, and health-care providers serving these patients.[42]

Chronic lung disease is another significant risk factor. Silicosis increases the risk about 30-fold.[43] Those who smoke cigarettes have nearly twice the risk of TB compared to nonsmokers.[44]

Other disease states can also increase the risk of developing tuberculosis. These include alcoholism[11] and diabetes mellitus (three-fold increase).[45]

Certain medications, such as corticosteroids and infliximab (an anti-αTNF monoclonal antibody), are becoming increasingly important risk factors, especially in the developed world.[11]

Genetic susceptibility also exists,[46] for which the overall importance remains undefined.[11]

# Mechanism

## Transmission

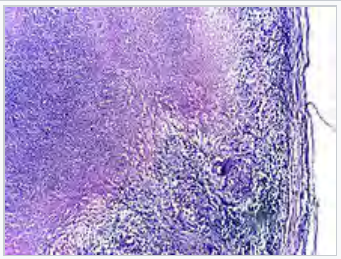
When people with active pulmonary TB cough, sneeze, speak, sing, or spit, they expel infectious aerosol droplets 0.5 to 5.0 μm in diameter. A single sneeze can release up to 40,000 droplets.[47] Each one of these droplets may transmit the disease, since the infectious dose of tuberculosis is very small (the inhalation of fewer than 10 bacteria may cause an infection).[48]

People with prolonged, frequent, or close contact with people with TB are at particularly high risk of becoming infected, with an estimated 22% infection rate.[49] A person with active but untreated tuberculosis may infect 10–15 (or more) other people per year.[50] Transmission should occur from only people with active TB – those with latent infection are not thought to be contagious.[10] The probability of transmission from one person to another depends upon several factors, including the number of infectious droplets expelled by the carrier, the effectiveness of ventilation, the duration of exposure, the virulence of the *M. tuberculosis* strain, the level of immunity in the uninfected person, and others.[51] The cascade of person-to-person spread can be circumvented by segregating those with active ("overt") TB and putting them on anti-TB drug regimens. After about two weeks of effective treatment, subjects with nonresistant active infections generally do not remain contagious to others.[49] If someone does become infected, it typically takes three to four weeks before the newly infected person becomes infectious enough to transmit the disease to others.[52]

Public health campaigns in the 1920s tried to halt the spread of TB.

## Pathogenesis

About 90% of those infected with *M. tuberculosis* have asymptomatic, latent TB infections (sometimes called LTBI),[53] with only a 10% lifetime chance that the latent infection will progress to overt, active tuberculous disease.[54] In those with HIV, the risk of developing active TB increases to nearly 10% a year.[54] If effective treatment is not given, the death rate for active TB cases is up to 66%.[50]



Microscopy of tuberculous epididymitis. H&E stain

TB infection begins when the mycobacteria reach the pulmonary alveoli, where they invade and replicate within endosomes of alveolar macrophages.[10][55] Macrophages identify the bacterium as foreign and attempt to eliminate it by phagocytosis. During this process, the bacterium is enveloped by the macrophage and stored temporarily in a membrane-bound vesicle called a phagosome. The phagosome then combines with a lysosome to create a phagolysosome. In the phagolysosome, the cell attempts to use reactive oxygen species and acid to kill the bacterium. However, *M. tuberculosis* has a thick, waxy mycolic acid capsule that protects it from these toxic substances. *M. tuberculosis* is able to reproduce inside the macrophage and will eventually kill the immune cell.

The primary site of infection in the lungs, known as the "Ghon focus", is generally located in either the upper part of the lower lobe, or the lower part of the upper lobe.[10] Tuberculosis of the lungs may also occur via infection from the blood stream. This is known as a Simon focus and is typically found in the top of the lung.[56] This hematogenous transmission can also spread infection to more distant sites, such as peripheral lymph nodes, the kidneys, the brain, and the bones.[10][57] All parts of the body can be affected by the disease, though for unknown reasons it rarely affects the heart, skeletal muscles, pancreas, or thyroid.[58]

Tuberculosis is classified as one of the granulomatous inflammatory diseases. Macrophages, T lymphocytes, B lymphocytes, and fibroblasts aggregate to form granulomas, with lymphocytes surrounding the infected macrophages. When other macrophages attack the infected macrophage, they fuse together to form a giant multinucleated cell in the alveolar lumen. The granuloma may prevent dissemination of the mycobacteria and provide a local environment for interaction of cells of the immune system.[60] However, more recent evidence suggests that the bacteria use the granulomas to avoid destruction by the host's immune system. Macrophages and dendritic cells in the granulomas are unable to present antigen to lymphocytes; thus the immune response is suppressed.[61] Bacteria inside the granuloma can become dormant, resulting in latent infection. Another feature of the granulomas is the development of abnormal cell death (necrosis) in the

Robert Carswell's illustration of tubercle[59]

center of tubercles. To the naked eye, this has the texture of soft, white cheese and is termed caseous necrosis.[60]

If TB bacteria gain entry to the blood stream from an area of damaged tissue, they can spread throughout the body and set up many foci of infection, all appearing as tiny, white tubercles in the tissues.[62] This severe form of TB disease, most common in young children and those with HIV, is called miliary tuberculosis.[63] People with this disseminated TB have a high fatality rate even with treatment (about 30%).[21][64]

In many people, the infection waxes and wanes. Tissue destruction and necrosis are often balanced by healing and fibrosis.[60] Affected tissue is replaced by scarring and cavities filled with caseous necrotic material. During active disease, some of these cavities are joined to the air passages bronchi and this material can be coughed up. It contains living bacteria, so can spread the infection. Treatment with appropriate antibiotics kills bacteria and allows healing to take place. Upon cure, affected areas are eventually replaced by scar tissue.[60]

## Diagnosis

*Main article: Tuberculosis diagnosis*

### Active tuberculosis

*M. tuberculosis* (stained red) in sputum

Diagnosing active tuberculosis based only on signs and symptoms is difficult,[65] as is diagnosing the disease in those who are immunosuppressed.[66] A diagnosis of TB should, however, be considered in those with signs of lung disease or constitutional symptoms lasting longer than two weeks.[66] A chest X-ray and multiple sputum cultures for acid-fast bacilli are typically part of the initial evaluation.[66] Interferon-γ release assays and tuberculin skin tests are of little use in the developing world.[67][68] IGRA have similar limitations in those with HIV.[68][69]

A definitive diagnosis of TB is made by identifying *M. tuberculosis* in a clinical sample (e.g., sputum, pus, or a tissue biopsy). However, the difficult culture process for this slow-growing organism can take two to six weeks for blood or sputum culture.[70] Thus, treatment is often begun before cultures are confirmed.[71]

Nucleic acid amplification tests and adenosine deaminase testing may allow rapid diagnosis of TB.[65] These tests, however, are not routinely recommended, as they rarely alter how a person is treated.[71] Blood tests to detect antibodies are not specific or sensitive, so they are not recommended.[72]

### Latent tuberculosis

*Main article: Latent tuberculosis*

Mantoux tuberculin skin test

The Mantoux tuberculin skin test is often used to screen people at high risk for TB.[66] Those who have been previously immunized may have a false-positive test result.[73] The test may be falsely negative in those with sarcoidosis, Hodgkin's lymphoma, malnutrition, and most notably, active tuberculosis.[10] Interferon gamma release assays (IGRAs), on a blood sample, are recommended in those who are positive to the Mantoux test.[71] These are not affected by immunization or most environmental mycobacteria, so they generate fewer false-positive results.[74] However, they are affected by *M. szulgai*, *M. marinum*, and *M. kansasii*.[75] IGRAs may increase sensitivity when used in addition to the skin test, but may be less sensitive than the skin test when used alone.[76]

## Prevention

Tuberculosis prevention and control efforts rely primarily on the vaccination of infants and the detection and appropriate treatment of active cases.[11] The World Health Organization has achieved some success with improved treatment regimens, and a small decrease in case numbers.[11] The US Preventive Services Task Force (USPSTF) recommends screening people who are at high risk for latent tuberculosis with either tuberculin skin tests or interferon-gamma release assays.[77]

### Vaccines

*Main articles: Tuberculosis vaccines and BCG vaccine*

The only available vaccine as of 2011 is Bacillus Calmette-Guérin (BCG).[78] In children it decreases the risk of getting the infection by 20% and the risk of infection turning into disease by nearly 60%.[79]

[11]

It is the most widely used vaccine worldwide, with more than 90% of all children being vaccinated. The immunity it induces decreases after about ten years.[11] As tuberculosis is uncommon in most of Canada, the United Kingdom, and the United States, BCG is administered to only those people at high risk.[80][81][82] Part of the reasoning against the use of the vaccine is that it makes the tuberculin skin test falsely positive, reducing the test's use in screening.[82] A number of new vaccines are currently in development.[11]

### Public health

The World Health Organization declared TB a "global health emergency" in 1993,[11] and in 2006, the Stop TB Partnership developed a Global Plan to Stop Tuberculosis that aimed to save 14 million lives between its launch and 2015.[83] A number of targets they set were not achieved by 2015, mostly due to the increase in HIV-associated tuberculosis and the emergence of multiple drug-resistant tuberculosis.[11] A tuberculosis classification system developed by the American Thoracic Society is used primarily in public health programs.[84]

## Management

*Main article: Tuberculosis management*

Treatment of TB uses antibiotics to kill the bacteria. Effective TB treatment is difficult, due to the unusual structure and chemical composition of the mycobacterial cell wall, which hinders the entry of drugs and makes many antibiotics ineffective.[85] The two antibiotics most commonly used are isoniazid and rifampicin, and treatments can be prolonged, taking several months.[51] Latent TB treatment usually employs a single antibiotic,[86] while active TB disease is best treated with combinations of several antibiotics to reduce the risk of the bacteria developing antibiotic resistance.[11] People with latent infections are also treated to prevent them from progressing to active TB disease later in life.[86] Directly observed therapy, i.e., having a health care provider watch the person take their medications, is recommended by the WHO in an effort to reduce the number of people not appropriately taking antibiotics.[87] The evidence to support this practice over people simply taking their medications independently is poor.[88][*needs update*] Methods to remind people of the importance of treatment do, however, appear effective.[89][*needs update*]

### New onset

The recommended treatment of new-onset pulmonary tuberculosis, as of 2010, is six months of a combination of antibiotics containing rifampicin, isoniazid, pyrazinamide, and ethambutol for the first two months, and only rifampicin and isoniazid for the last four months.[11] Where resistance to isoniazid is high, ethambutol may be added for the last four months as an alternative.[11]

### Recurrent disease

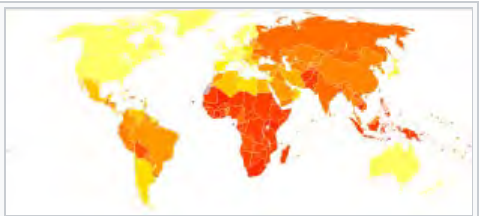
If tuberculosis recurs, testing to determine to which antibiotics it is sensitive is important before determining treatment.[11] If multiple drug-resistant TB is detected, treatment with at least four effective antibiotics for 18 to 24 months is recommended.[11]

### Medication resistance

Primary resistance occurs when a person becomes infected with a resistant strain of TB. A person with fully susceptible MTB may develop secondary (acquired) resistance during therapy because of inadequate treatment, not taking the prescribed regimen appropriately (lack of compliance), or using low-quality medication.[90] Drug-resistant TB is a serious public health issue in many developing countries, as its treatment is longer and requires more expensive drugs. MDR-TB is defined as resistance to the two most effective first-line TB drugs: rifampicin and isoniazid. Extensively drug-resistant TB is also resistant to three or more of the six classes of second-line drugs.[91] Totally drug-resistant TB is resistant to all currently used drugs.[92] It was first observed in 2003 in Italy,[93] but not widely reported until 2012,[92][94] and has also been found in Iran and India.[95][96] Bedaquiline is tentatively supported for use in multiple drug-resistant TB.[97]

XDR-TB is a term sometimes used to define *extensively resistant* TB, and constitutes one in ten cases of MDR-TB. Cases of XDR TB have been identified in more than 90% of countries.[95]

## Prognosis



Age-standardized disability-adjusted life years caused by tuberculosis per 100,000 inhabitants in 2004.[98]

| | |
|---|---|
| no data | 250–500 |
| ≤10 | 500–750 |
| 10–25 | 750–1000 |
| 25–50 | 1000–2000 |
| 50–75 | 2000–3000 |
| 75–100 | ≥ 3000 |

Progression from TB infection to overt TB disease occurs when the bacilli overcome the immune system defenses and begin to multiply. In primary TB disease (some 1–5% of cases), this occurs soon after the initial infection.[10] However, in the majority of cases, a latent infection occurs with no obvious symptoms.[10] These dormant bacilli produce active tuberculosis in 5–10% of these latent cases, often many years after infection.[13]

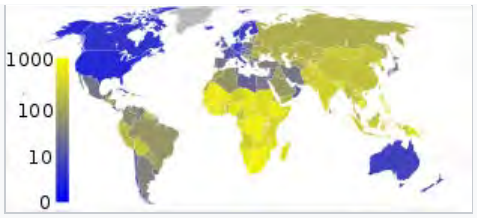
The risk of reactivation increases with immunosuppression, such as that caused by infection with HIV. In people coinfected with *M. tuberculosis* and HIV, the risk of reactivation increases to 10% per year.[10] Studies using DNA fingerprinting of *M. tuberculosis* strains have shown reinfection contributes more substantially to recurrent TB than previously thought,[99] with estimates that it might account for more than 50% of reactivated cases in areas where TB is common.[100] The chance of death from a case of tuberculosis is about 4% as of 2008, down from 8% in 1995.[11]

## Epidemiology

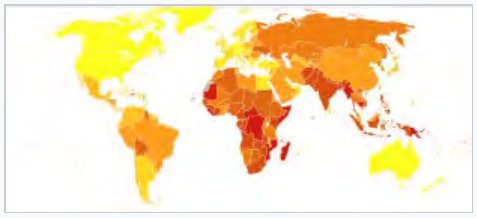
*Main article: Epidemiology of tuberculosis*

Roughly one-third of the world's population has

100–250



In 2007, the number of cases of TB per 100,000 people was highest in sub-Saharan Africa, and was also relatively high in Asia.[101]



Tuberculosis deaths per million persons in 2012

0-3
4-7
8-16
17-26

46-83
84-137
138-215
216-443
444-1,359

been infected with *M. tuberculosis*,[50] with new infections occurring in about 1% of the population each year.[9] However, most infections with *M. tuberculosis* do not cause TB disease,[102] and 90–95% of infections remain asymptomatic.[53] In 2012, an estimated 8.6 million chronic cases were active.[103] In 2010, 8.8 million new cases of TB were diagnosed, and 1.20–1.45 million deaths occurred, most of these occurring in developing countries.[39][104] Of these 1.45 million deaths, about 0.35 million occur in those also infected with HIV.[105]

Tuberculosis is the second-most common cause of death from infectious disease (after those due to HIV/AIDS).[3] The total number of tuberculosis cases has been decreasing since 2005, while new cases have decreased since 2002.[39] China has achieved particularly dramatic progress, with about an 80% reduction in its TB mortality rate between 1990 and 2010.[105] The number of new cases has declined by 17% between 2004–2014.[95] Tuberculosis is more common in developing countries; about 80% of the population in many Asian and African countries test positive in tuberculin tests, while only 5–10% of the US population test positive.[10] Hopes of totally controlling the disease have been dramatically dampened because of a number of factors, including the difficulty of developing an effective vaccine, the expensive and time-consuming diagnostic process, the necessity of many months of treatment, the increase in HIV-associated tuberculosis, and the emergence of drug-resistant cases in the 1980s.[11]

In 2007, the country with the highest estimated incidence rate of TB was Swaziland, with 1,200 cases per 100,000 people. India had the largest total incidence, with an estimated 2.0 million new cases.[106] In developed countries, tuberculosis is less common and is found mainly in urban areas. Rates per 100,000 people in different areas of the world were: globally 178, Africa 332, the Americas 36, Eastern Mediterranean 173, Europe 63, Southeast Asia 278, and Western Pacific 139 in 2010.[105] In Canada and Australia, tuberculosis is many times more common among the aboriginal peoples, especially in remote areas.[107][108] In the United States Native Americans have a fivefold greater mortality from TB,[109] and racial and ethnic minorities accounted for 84% of all reported TB cases.[110]

The rates of TB varies with age. In Africa, it primarily affects adolescents and young adults.[111] However, in countries where incidence rates have declined dramatically (such as the United States), TB is mainly a disease of older people and the immunocompromised (risk factors are listed above).[10][112] Worldwide, 22 "high-burden" states or countries together experience 80% of cases as well as 83% of deaths.[95]

## History

*Main articles: History of tuberculosis and Timeline of tuberculosis*

Tuberculosis has been present in humans since antiquity.[11] The earliest unambiguous detection of *M. tuberculosis* involves evidence of the disease in the remains of bison in Wyoming dated to around 17,000 years ago.[113] However, whether tuberculosis originated in bovines, then was transferred to humans, or whether it diverged from a common ancestor, is currently unclear.[114] A comparison of the genes of *M. tuberculosis* complex (MTBC) in humans to MTBC in animals suggests humans did not acquire MTBC from animals during animal domestication, as was previously believed. Both strains of the tuberculosis bacteria share a common ancestor, which could have infected humans even before the Neolithic Revolution.[115]

Egyptian mummy in the British Museum – tubercular decay has been found in the spine

Skeletal remains show prehistoric humans (4000 BC) had TB, and researchers have found tubercular decay in the spines of Egyptian mummies dating from 3000–2400 BC.[116] Genetic studies suggest TB was present in the Americas from about 100 AD.[117]

Before the Industrial Revolution, folklore often associated tuberculosis with vampires. When one member of a family died from it, the other infected members would lose their health slowly. People believed this was caused by the original person with TB draining the life from the other family members.[118]

Although the pulmonary form associated with tubercles was established as a pathology by Dr Richard Morton in 1689,[119][120] due to the variety of its symptoms, TB was not identified as a single disease until the 1820s. It was not named "tuberculosis" until 1839, by J. L. Schönlein.[121]

During 1838–1845, Dr. John Croghan, the owner of Mammoth Cave, brought a number of people with tuberculosis into the cave in the hope of curing the disease with the constant temperature and purity of the cave air; they died within a year.[122] Hermann Brehmer opened the first TB sanatorium in 1859 in Görbersdorf (now Sokołowsko), Silesia.[123]

The bacillus causing tuberculosis, *M. tuberculosis*, was identified and described on 24 March 1882 by Robert Koch. He received the Nobel Prize in physiology or medicine in 1905 for this discovery.[124] Koch did not believe the bovine (cattle) and human tuberculosis diseases were similar, which delayed the recognition of infected milk as a source of infection. Later, the risk of transmission from this source was dramatically reduced by the invention of the pasteurization process. Koch announced a glycerine extract of the tubercle bacilli as a "remedy" for tuberculosis in 1890, calling it "tuberculin". While it was not effective, it was later successfully adapted as a screening test for the presence of pre-symptomatic tuberculosis.[125] The World Tuberculosis Day was established on 24 March for this reason.

Albert Calmette and Camille Guérin achieved the first genuine success in immunization against tuberculosis in 1906, using attenuated bovine-strain tuberculosis. It was called bacille Calmette–Guérin (BCG). The BCG vaccine was first used on humans in 1921 in France,[126] but received widespread acceptance in the US, Great Britain, and Germany

Dr. Robert Koch discovered the tuberculosis bacillus.

only after World War II.[127]

Tuberculosis caused the most widespread public concern in the 19th and early 20th centuries as an endemic disease of the urban poor. In 1815, one in four deaths in England was due to "consumption". By 1918, one in six deaths in France was still caused by TB. After TB was determined to be contagious, in the 1880s, it was put on a notifiable disease list in Britain; campaigns were started to stop people from spitting in public places, and the infected poor were "encouraged" to enter sanatoria that resembled prisons (the sanatoria for the middle and upper classes offered excellent care and constant medical attention).[123] Whatever the (purported) benefits of the "fresh air" and labor in the sanatoria, even under the best conditions, 50% of those who entered died within five years (*circa* 1916).[123]

In Europe, rates of tuberculosis began to rise in the early 1600s to a peak level in the 1800s, when it caused nearly 25% of all deaths.[128] By the 1950s, mortality had decreased nearly 90%.[129] Improvements in public health began significantly reducing rates of tuberculosis even before the arrival of streptomycin and other antibiotics, although the disease remained a significant threat to public health such that when the Medical Research Council was formed in Britain in 1913, its initial focus was tuberculosis research.[130]

In 1946, the development of the antibiotic streptomycin made effective treatment and cure of TB a reality. Prior to the introduction of this drug, the only treatment (except sanatoria) was surgical intervention, including the "pneumothorax technique", which involved collapsing an infected lung to "rest" it and allow tuberculous lesions to heal.[131]

Because of the emergence of MDR-TB, surgery has been re-introduced as an option within the generally accepted standard of care in treating TB infections. Current surgical interventions involve removal of pathological chest cavities ("bullae") in the lungs to reduce the number of bacteria and to increase the exposure of the remaining bacteria to drugs in the bloodstream, thereby simultaneously reducing the total bacterial load and increasing the effectiveness of systemic antibiotic therapy.[132]

Hopes of completely eliminating TB (*cf.* smallpox) from the population were dashed after the rise of drug-resistant strains in the 1980s. The subsequent resurgence of tuberculosis resulted in the declaration of a global health emergency by the World Health Organization in 1993.[133]

## Names

*Phthisis* (Φθισις) is a Greek word for consumption, an old term for pulmonary tuberculosis;[2] around 460 BC, Hippocrates described phthisis as a disease of dry seasons.[134] The abbreviation "TB" is short for *tubercle bacillus*.

"Consumption" was the most common nineteenth century English word for the disease. The Latin root "con" meaning "completely" is linked to "sumere" meaning "to take up from under."[135] In The Life and Death of Mr. Badman by John Bunyan, the author calls consumption "the captain of all these men of death."[136]

## Public health efforts

The World Health Organization, Bill and Melinda Gates Foundation, and US government are subsidizing a fast-acting diagnostic tuberculosis test for use in low- and middle-income countries.[137][138][139] In addition to being fast-acting, the test can determine if there is resistance to the antibiotic rifampicin which may indicate multi-drug resistant tuberculosis and is accurate in those who are also infected with HIV.[137][140] Many resource-poor places as of 2011 have access to only sputum microscopy.[141]

India had the highest total number of TB cases worldwide in 2010, in part due to poor disease management within the private and public health care sector.[142] Programs such as the Revised National Tuberculosis Control Program are working to reduce TB levels amongst people receiving public health care.[143][144]

A 2014 the EIU-healthcare report that the need to address apathy and urging for increased funding. The report cites among others Lucica Ditui "[TB] is like an orphan. It has been neglected even in countries with a high burden and often forgotten by donors and those investing in health interventions."[95]

Slow progress has led to frustration, expressed by the executive director of the Global Fund to Fight AIDS, Tuberculosis and Malaria – Mark Dybul: "we have the tools to end TB as a pandemic and public health threat on the planet, but we are not doing it."[95] Several international organizations are pushing for more transparency in treatment, and more countries are implementing mandatory reporting of cases to the government, although adherence is often sketchy. Commercial treatment providers may at times overprescribe second-line drugs as well as supplementary treatment, promoting demands for further regulations.[95] The government of Brazil provides universal TB-care, which reduces this problem.[95] Conversely, falling rates of TB-infection may not relate to the number of programs directed at reducing infection rates but may be tied to increased level of education, income, and health of the population.[95] Costs of the disease, as calculated by the World Bank in 2009 may exceed 150 billion USD per year in "high burden" countries.[95] Lack of progress eradicating the disease may also be due to lack of patient follow-up – as among the 250M rural migrants in China.[95]

### Stigma

Slow progress in preventing the disease may in part be due to stigma associated with TB.[95] Stigma may be due to the fear of transmission from affected individuals. This stigma may additionally arise due to links between TB and poverty, and in Africa, AIDS.[95] Such stigmatization may be both real and perceived, for example; in Ghana individuals with TB are banned from attending public gatherings.[145]

Stigma towards TB may result in delays in seeking treatment,[95] lower treatment compliance, and family members keeping cause of death secret[145] – allowing the disease to spread further.[95] At odds is Russia, where stigma was associated with increased treatment compliance.[145] TB stigma also affects socially marginalized individuals to a greater degree and varies between regions.[145]

One way to decrease stigma may be through the promotion of "TB clubs", where those infected may share experiences and offer support, or through counseling.[145] Some studies have shown TB education programs to be effective in decreasing stigma, and may thus be effective in increasing treatment adherence.[145] Despite this, studies on the relationship between reduced stigma and mortality are lacking as of 2010, and similar efforts to decrease stigma surrounding AIDS have been minimally effective.[145] Some have claimed the stigma to be worse than the disease, and healthcare providers may unintentionally reinforce stigma, as those with TB are often perceived as difficult or otherwise undesirable.[95] A greater understanding of the social and cultural dimensions of tuberculosis may also help with stigma reduction.[146]

## Research

The BCG vaccine has limitations, and research to develop new TB vaccines is ongoing.[147] A number of potential candidates are currently in phase I and II clinical trials.[147] Two main approaches are being used to attempt to improve the efficacy of available vaccines. One approach involves adding a subunit vaccine to BCG, while the other strategy is attempting to create new and better live vaccines.[147] MVA85A, an example of a subunit vaccine, currently in trials in South Africa, is based on a genetically modified vaccinia virus.[148] Vaccines are hoped to play a significant role in treatment of both latent and active disease.[149]

To encourage further discovery, researchers and policymakers are promoting new economic models of vaccine development, including prizes, tax incentives, and advance market commitments.[150][151] A number of groups, including the Stop TB Partnership,[152] the South African Tuberculosis Vaccine Initiative, and the Aeras Global TB Vaccine Foundation, are involved with research.[153] Among these, the Aeras Global TB Vaccine Foundation received a gift of more than $280 million (US) from the Bill and Melinda Gates Foundation to develop and license an improved vaccine against tuberculosis for use in high burden countries.[154][155]

A number of medications are being studied for multi drug resistant tuberculosis including: bedaquiline and delamanid.[156] Bedaquiline received U.S. Food and Drug Administration (FDA) approval in late 2012.[157] The safety and effectiveness of these new agents are still uncertain, because they are based on the results of a relatively small studies.[156][158] However, existing data suggest that patients taking bedaquiline in addition to standard TB therapy are five times more likely to die than those without the new drug,[159] which has resulted in medical journal articles raising health policy questions about why the FDA approved the drug and whether financial ties to the company making bedaquiline influenced physicians' support for its use [158][160]

## Other animals

Mycobacteria infect many different animals, including birds,[161] rodents,[162] and reptiles.[163] The subspecies *Mycobacterium tuberculosis*, though, is rarely present in wild animals.[164] An effort to eradicate bovine tuberculosis caused by *Mycobacterium bovis* from the cattle and deer herds of New Zealand has been relatively successful.[165] Efforts in Great Britain have been less successful.[166][167]

As of 2015, tuberculosis appears to be widespread among captive elephants in the US. It is believed that the animals originally acquired the disease from humans, a process called reverse zoonosis. Because the disease can spread through the air to infect both humans and other animals, it is a public health concern affecting circuses and zoos.[168][169]

# Yellow fever

From Wikipedia, the free encyclopedia

*For other uses of "yellow fever", see Yellow fever (disambiguation).*
*"American Plague" redirects here. For the rock band, see The American Plague.*
*"Yellow plague" redirects here. For the Yellow Plague of Rhos in medieval Wales, see Maelgwn Gwynedd.*

**Yellow fever** is an acute viral disease.[3] In most cases, symptoms include fever, chills, loss of appetite, nausea, muscle pains particularly in the back, and headaches.[3] Symptoms typically improve within five days.[3] In some people within a day of improving, the fever comes back, abdominal pain occurs, and liver damage begins causing yellow skin.[5] If this occurs, the risk of bleeding and kidney problems is also increased.[3]

The disease is caused by the yellow fever virus and is spread by the bite of an infected female mosquito.[3] It infects only humans, other primates, and several species of mosquitoes.[3] In cities, it is spread primarily by mosquitoes of the *Aedes aegypti* type.[3] The virus is an RNA virus of the genus *Flavivirus*.[4] The disease may be difficult to tell apart from other illnesses, especially in the early stages.[3] To confirm a suspected case, blood sample testing with polymerase chain reaction is required.[5]

A safe and effective vaccine against yellow fever exists and some countries require vaccinations for travelers.[3] Other efforts to prevent infection include reducing the population of the transmitting mosquito.[3] In areas where yellow fever is common and vaccination is uncommon, early diagnosis of cases and immunization of large parts of the population is important to prevent outbreaks.[3] Once infected, management is symptomatic with no specific measures effective against the virus.[3] The second and more severe phase results in death in up to half of people without treatment.[3][6]

Yellow fever causes 200,000 infections and 30,000 deaths every year[3] with nearly 90% of these occurring in Africa.[5] Nearly a billion people live in an area of the world where the disease is common.[3] It is common in tropical areas of South America and Africa, but not in Asia.[3][7] Since the 1980s, the number of cases of yellow fever has been increasing.[3][8] This is believed to be due to fewer people being immune, more people living in cities, people moving frequently, and

changing climate.[3] The disease originated in Africa, from where it spread to South America through the slave trade in the 17th century.[1] Since the 17th century, several major outbreaks of the disease have occurred in the Americas, Africa, and Europe.[1] In the 18th and 19th centuries, yellow fever was seen as one of the most dangerous infectious diseases.[1] In 1927 yellow fever virus became the first human virus to be isolated.[4][9]

**Contents**

## Signs and symptoms [edit]

Yellow fever begins after an incubation period of three to six days.[10] Most cases only cause a mild infection with fever, headache, chills, back pain, fatigue, loss of appetite, muscle pain, nausea, and vomiting.[11] In these cases, the infection lasts only three to four days.

In 15 percent of cases, however, people enter a second, toxic phase of the disease with recurring fever, this time accompanied by jaundice due to liver damage, as well as abdominal pain.[12] Bleeding in the mouth, the eyes, and the gastrointestinal tract will cause vomit containing blood, hence the Spanish name for yellow fever, *vomito negro* ("black vomit").[13] There may also be kidney failure, hiccups, and delirium.[14][15]

The toxic phase is fatal in about 20 to 50 percent of cases, making the overall fatality rate for the disease about 3.0 to 7.5 percent.[16][17] However, the fatality rate of those with the toxic phase of the disease may exceed 50%.[18]

Surviving the infection provides lifelong immunity,[19] and normally there is no permanent organ damage.[20]

## Cause [edit]

Yellow fever is caused by the yellow fever virus, a 40- to 50-nm-wide enveloped RNA virus, the type species and namesake of the family Flaviviridae.[4] It was the first illness shown to be transmissible by filtered human serum and transmitted by mosquitoes, by Walter Reed around

1900.[21] The positive-sense, single-stranded RNA is around 11,000 nucleotides long and has a single open reading frame encoding a polyprotein. Host proteases cut this polyprotein into three structural (C, prM, E) and seven nonstructural proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B, NS5); the enumeration corresponds to the arrangement of the protein coding genes in the genome.[22] Minimal yellow fever virus (YFV) 3'UTR region is required for stalling of the host 5'-3' exonuclease XRN1. The UTR contains PKS3 pseudoknot structure which serves as a molecular signal to stall the exonuclease and is the only viral requirement for subgenomic flavivirus RNA (sfRNA) production. The sfRNAs are a result of incomplete degradation of the viral genome by the exonuclease and are important for viral pathogenicity.[23] Yellow fever belongs to the group of hemorrhagic fevers.

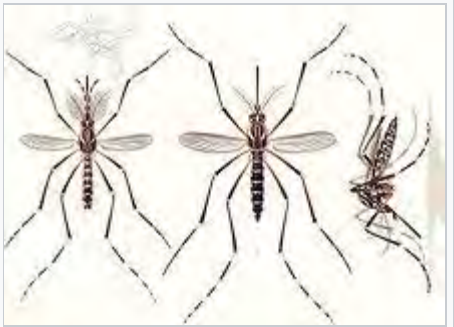
The viruses infect, amongst others, monocytes, macrophages, and dendritic cells. They attach to the cell surface via specific receptors and are taken up by an endosomal vesicle. Inside the endosome, the decreased pH induces the fusion of the endosomal membrane with the virus envelope. The capsid enters the cytosol, decays, and releases the genome. Receptor binding, as well as membrane fusion, are catalyzed by the protein E, which changes its conformation at low pH, causing a rearrangement of the 90 homodimers to 60 homotrimers.[22]

After entering the host cell, the viral genome is replicated in the rough endoplasmic reticulum (ER) and in the so-called vesicle packets. At first, an immature form of the virus particle is produced inside the ER, whose M-protein is not yet cleaved to its mature form and is therefore denoted as prM (precursor M) and forms a complex with protein E. The immature particles are processed in the Golgi apparatus by the host protein furin, which cleaves prM to M. This releases E from the complex which can now take its place in the mature, infectious virion.[22]

## Transmission [edit]

Yellow fever virus is mainly transmitted through the bite of the yellow fever mosquito *Aedes aegypti*, but other mostly Aedes mosquitoes such as the tiger mosquito (*Aedes albopictus*) can also serve as a vector for this virus. Like other arboviruses which are transmitted by mosquitoes, the yellow fever virus is taken up by a female mosquito when it ingests the blood of an infected human or other primate. Viruses reach the stomach of the mosquito, and if the virus concentration is high enough, the virions can infect epithelial cells and replicate there. From there, they reach the haemocoel (the blood system of mosquitoes) and from there the salivary glands. When the mosquito next sucks blood, it injects its saliva into the wound, and the virus reaches the bloodstream of the bitten person. Transovarial and transstadial transmission of the yellow fever virus within *A. aegypti*, that is, the transmission from a female mosquito to her eggs and then larvae, are indicated. This infection of vectors without a previous blood meal seems to play a role in single, sudden breakouts of the disease.[24]

*Aedes aegypti* feeding



Adults of the yellow fever mosquito *A. aegypti*: The male is on the left, females are on the right. Only the female mosquito bites humans to transmit the

Three epidemiologically different infectious cycles occur,[8] in which the virus is transmitted from mosquitoes to humans or other primates.[25] In the "urban cycle", only the yellow fever mosquito *A. aegypti* is involved. It is well adapted to urban areas and can also transmit other diseases, including Zika fever, dengue fever and chikungunya. The urban cycle is responsible for the major outbreaks of yellow fever that occur in Africa. Except in an outbreak in 1999 in Bolivia, this urban cycle no longer exists in South America.

Besides the urban cycle, both in Africa and South America, a sylvatic cycle (forest cycle or jungle cycle) is present, where *Aedes africanus* (in

disease.

Africa) or mosquitoes of the genus *Haemagogus* and *Sabethes* (in South America) serve as vectors. In the jungle, the mosquitoes infect mainly non-human primates; the disease is mostly asymptomatic in African primates. In South America, the sylvatic cycle is currently the only way humans can become infected, which explains the low incidence of yellow fever cases on the continent. People who become infected in the jungle can carry the virus to urban areas, where *A. aegypti* acts as a vector. Because of this sylvatic cycle, the yellow fever cannot be eradicated.[8]

In Africa, a third infectious cycle known as "savannah cycle" or intermediate cycle, occurs between the jungle and urban cycles. Different mosquitoes of the genus *Aedes* are involved. In recent years, this has been the most common form of transmission of yellow fever in Africa.[26]

There is concern about yellow fever spreading to southeast Asia, where its vector *Aedes aegypti* already occurs.[27]

## Pathogenesis [edit]

After transmission from a mosquito, the viruses replicate in the lymph nodes and infect dendritic cells in particular. From there, they reach the liver and infect hepatocytes (probably indirectly via Kupffer cells), which leads to eosinophilic degradation of these cells and to the release of cytokines. Apoptotic masses known as Councilman bodies appear in the cytoplasm of hepatocytes.[28][29]

Fatality may occur when cytokine storm, shock, and multiple organ failure follow.[16]

## Diagnosis [edit]

Yellow fever is most frequently a clinical diagnosis, made on the basis of symptoms and the diseased person's whereabouts prior to becoming ill. Mild courses of the disease can only be confirmed virologically. Since mild courses of yellow fever can also contribute significantly to regional outbreaks, every suspected case of yellow fever (involving symptoms of fever, pain, nausea and vomiting six to 10 days after leaving the affected area) is treated seriously.

If yellow fever is suspected, the virus cannot be confirmed until six to 10 days after the illness. A direct confirmation can be obtained by reverse transcription polymerase chain reaction where the genome of the virus is amplified.[5] Another direct approach is the isolation of the virus and its growth in cell culture using blood plasma; this can take one to four weeks.

Serologically, an enzyme linked immunosorbent assay during the acute phase of the disease using specific IgM against yellow fever or an increase in specific IgG-titer (compared to an earlier sample) can confirm yellow fever. Together with clinical symptoms, the detection of IgM or a fourfold increase in IgG-titer is considered sufficient indication for yellow fever. Since these tests can cross-react with other flaviviruses, like dengue virus, these indirect methods cannot conclusively prove yellow fever infection.

Liver biopsy can verify inflammation and necrosis of hepatocytes and detect viral antigens. Because of the bleeding tendency of yellow fever patients, a biopsy is only advisable *post mortem* to confirm the cause of death.

In a differential diagnosis, infections with yellow fever must be distinguished from other feverish illnesses like malaria. Other viral hemorrhagic fevers, such as Ebola virus, Lassa virus, Marburg virus, and Junin virus, must be excluded as cause.

## Prevention [edit]

Personal prevention of yellow fever includes vaccination, as well as avoidance of mosquito bites in areas where yellow fever is endemic. Institutional measures for prevention of yellow fever include vaccination programmes and measures of controlling mosquitoes. Programmes for distribution of mosquito nets for use in homes are providing reductions in cases of both malaria and yellow fever. Usage of EPA-registered insect

repellent is recommended when outdoors. A short duration of time is enough exposure for a potential mosquito bite. Long sleeved clothing, long pants, and socks are useful for prevention. The awareness of peak mosquito exposure is from dusk to dawn.The application of larvicides to water storage containers can help eliminate potential mosquito breeding sites. Adult mosquitos can be killed through insecticide spray usage, which decreases the transmission of yellow fever. [30]

- Use insect repellent when outdoors such as those containing DEET, picaridin, IR3535, or oil of lemon eucalyptus on exposed skin.
- Wear proper clothing to reduce mosquito bites. When weather permits, wear long-sleeves, long pants and socks when outdoors. Mosquitoes may bite through thin clothing, so spraying clothes with repellent containing permethrin or another EPA-registered repellent will give extra protection. Clothing pre-treated with permethrin is commercially available. Mosquito repellents containing permethrin are not approved for application directly to skin.
- The peak biting times for many mosquito species is dusk to dawn. However,& ;*Aedes aegypti*, one of the mosquitoes that transmits yellow fever virus, feeds during the daytime. Staying in accommodations with screened or air-conditioned rooms, particularly during peak biting times, will also reduce risk of mosquito bites.

## Vaccination [edit]

*Main article: Yellow fever vaccine*

Vaccination is recommended for those traveling to affected areas, because non-native people tend to suffer more severe illness when infected. Protection begins by the 10th day after vaccine administration in 95% of people,[31] and lasts for at least 10 years. About 81% of people are still immune after 30 years. The attenuated live vaccine stem 17D was developed in 1937 by Max Theiler.[31] The World Health Organization (WHO) recommends routine vaccinations for people living in affected areas between the ninth and 12th month after birth.[5] Up to one in four people experience fever, aches, and local soreness and redness at the site of injection.[32]

In rare cases (less than one in 200,000 to 300,000[31]), the vaccination can cause yellow fever vaccine–associated viscerotropic disease, which is fatal in 60% of cases. It is probably due to the genetic morphology of the immune system. Another possible side effect is an infection of the nervous system, which occurs in one in 200,000 to 300,000 cases, causing yellow fever vaccine-associated neurotropic disease, which can lead to meningoencephalitis and is fatal in less than 5%[31] of cases.[5][16]

In 2009, the largest mass vaccination against yellow fever began in West Africa, specifically Benin, Liberia, and Sierra Leone.[33][34] When it is completed in 2015, more than 12 million people will have been vaccinated against the disease.[33] According to the WHO, the mass vaccination cannot eliminate yellow fever because of the vast number of infected mosquitoes in urban areas of the target countries, but it will significantly reduce the number of people infected.[33] The WHO plans to continue the vaccination campaign in another five African countries — the Central African Republic, Ghana, Guinea, Ivory Coast, and Nigeria — and stated that about 160 million people in the continent could be at risk unless the organization acquires additional funding to support widespread vaccinations.[35]

In 2013, the WHO stated, "a single dose of vaccination is sufficient to confer life-long immunity against yellow fever disease."[36]

## Compulsory vaccination [edit]

Some countries in Asia are theoretically in danger of yellow fever epidemics (mosquitoes with the capability to transmit yellow fever and susceptible monkeys are present), although the disease does not yet occur there. To prevent introduction of the virus, some countries demand previous vaccination of foreign visitors if they have passed through yellow fever areas. Vaccination has to be proven in a vaccination certificate which is valid 10 days after the vaccination and lasts for 10 years. Although the WHO on 17 May 2013 advised that subsequent booster vaccinations are unnecessary, an older (than 10 years) certificate may not be acceptable at all border posts in all affected countries. A list of the countries that require yellow fever vaccination is published by the WHO.[37] If the vaccination cannot be conducted for some reasons, dispensation may be possible. In this case, an exemption certificate issued by a WHO-approved vaccination center is required. Although 32 of 44 countries where yellow fever occurs endemically do have vaccination programmes, in many of these countries, less than 50% of their population is vaccinated.[5]

## Vector control [edit]

Information campaign for prevention of dengue and yellow fever in Paraguay

Control of the yellow fever mosquito *A. aegypti* is of major importance, especially because the same mosquito can also transmit dengue fever and chikungunya disease. *A. aegypti* breeds preferentially in water, for example in installations by inhabitants of areas with precarious drinking water supply, or in domestic waste; especially tires, cans, and plastic bottles. These conditions are common in urban areas in developing countries.

Two main strategies are employed to reduce mosquito populations. One approach is to kill the developing larvae. Measures are taken to reduce the water accumulations in which the larva develops. Larvicides are used, as well as larvae-eating fish and copepods, which reduce the number of larvae. For many years, copepods of the genus *Mesocyclops* have been used in Vietnam for preventing dengue fever. It eradicated the mosquito vector in several areas. Similar efforts may be effective against yellow fever. Pyriproxyfen is recommended as a chemical larvicide, mainly because it is safe for humans and effective even in small doses.[5]

The second strategy is to reduce populations of the adult yellow fever mosquito. Lethal ovitraps can reduce *Aedes* populations, but with a decreased amount of pesticide because it targets the mosquitoes directly. Curtains and lids of water tanks can be sprayed with insecticides, but application inside houses is not recommended by the WHO. Insecticide-treated mosquito nets are effective, just as they are against the *Anopheles* mosquito that carries malaria.[5]

# Treatment [edit]

As for other flavivirus infections, no cure is known for yellow fever. Hospitalization is advisable and intensive care may be necessary because of rapid deterioration in some cases. Different methods for acute treatment of the disease have been shown to not be very successful; passive immunisation after emergence of symptoms is probably without effect. Ribavirin and other antiviral drugs, as well as treatment with interferons, do not have a positive effect in patients.[16] A symptomatic treatment includes rehydration and pain relief with drugs such as paracetamol (acetaminophen in the United States). Acetylsalicylic acid (aspirin) should not be given because of its anticoagulant effect, which can be devastating in the case of internal bleeding that can occur with yellow fever.

# Epidemiology [edit]

Yellow fever is common in tropical and subtropical areas of South America and Africa. Worldwide, about 600 million people live in endemic areas. The WHO estimates 200,000 cases of disease and 30,000 deaths a year occur; the number of officially reported cases is far lower.

## Africa [edit]

An estimated 90% of the infections occur on the African continent.[5] In 2008, the largest number of recorded cases were in Togo.

In March 2016, the Chinese government confirmed the first imported case in a 32-year-old man who had been in Angola, the site of an ongoing outbreak of yellow fever.[38] On 28 March 2016, ProMED-mail issued a warning that the yellow fever outbreak in Angola might spread further and that countries where dengue and the mosquito vector of dengue and yellow fever are present are at risk of a potential outbreak of yellow fever.[39] Authorities are warning that a spread to Asia could be serious since vaccine stockpiles are insufficient.[40]

Endemic range of yellow fever in Africa (2009)

Phylogenetic analysis identified seven genotypes of yellow fever viruses, and they are assumed to be differently adapted to humans and to the vector *A. aegypti*. Five genotypes (Angola, Central/East Africa, East Africa, West Africa I, and West Africa II) occur only in Africa. West Africa genotype I is found in Nigeria and the surrounding areas.[41] This appears to be especially virulent or infectious, as this type is often associated with major outbreaks. The three genotypes in East and Central Africa occur in areas where outbreaks are rare. Two recent outbreaks in Kenya (1992–1993) and Sudan (2003 and 2005) involved the East African genotype, which had remained unknown until these outbreaks occurred.[42]

## South America [edit]

In South America, two genotypes have been identified (South American genotypes I and II).[8] Based on phylogenetic analysis these two genotypes appear to have originated in West Africa[43] and were first introduced into Brazil.[44] The date of introduction into South America appears to be 1822 (95% confidence interval 1701 to 1911).[44] The historical record shows an outbreak of yellow fever occurred in Recife, Brazil, between 1685 and 1690. The disease seems to have disappeared, with the next outbreak occurring in 1849. It was likely introduced with the importation of slaves through the slave trade from Africa. Genotype I has been divided into five subclades, A through E.[45]

Endemic range of yellow fever in South America (2009)

## Asia [edit]

Though the main vector (*A. aegypti*) also occurs in tropical and subtropical regions of Asia, the Pacific and Australia, yellow fever does not occur in these parts of the globe. Proposed explanations include the idea that the strains of the mosquito in the East are less able to transmit the yellow fever virus, that immunity is present in the populations because of other diseases caused by related viruses (for example, dengue), and that the disease was never introduced because the shipping trade was insufficient, but none are considered satisfactory.[46][47] Another proposal is the absence of a slave trade to Asia on the scale of that to the Americas.[48] The trans-Atlantic slave trade was probably the means of introduction into the Western hemisphere from Africa.[49]

# History [edit]

*Main articles: History of yellow fever and Yellow fever epidemic of 1793*

Carlos Finlay

Walter Reed

The evolutionary origins of yellow fever most likely lie in Africa, with transmission of the disease from non-human primates to humans.[50][51] The virus is thought to have originated in East or Central Africa and spread from there to West Africa. As it was endemic in Africa, the natives had developed some immunity to it. When an outbreak of yellow fever would occur in an African village where colonists resided, most Europeans died, while the native population usually suffered nonlethal symptoms resembling influenza.[52] This phenomenon, in which certain populations develop immunity to yellow fever due to prolonged exposure in their childhood, is known as acquired immunity.[53] The virus, as well as the vector *A. aegypti,* were probably transferred to North and South America with the importation of slaves from Africa, part of the Columbian Exchange following European exploration and colonization.

The first definitive outbreak of yellow fever in the New World was in 1647 on the island of Barbados.[54] An outbreak was recorded by Spanish colonists in 1648 in the Yucatán Peninsula, where the indigenous Mayan people called the illness *xekik* ("blood vomit"). In 1685, Brazil suffered its first epidemic, in Recife. The first mention of the disease by the name "yellow fever" occurred in 1744.[55] McNeill argues that the environmental and ecological disruption caused by the introduction of sugar plantations created the conditions for mosquito and viral reproduction, and subsequent outbreaks of yellow fever.[56] Deforestation reduced insectivorous bird populations and other creatures that fed on mosquitoes and their eggs.

Although yellow fever is most prevalent in tropical-like climates, the northern United States were not exempted from the fever. The first outbreak in English-speaking North America occurred in New York in 1668, and a serious one afflicted Philadelphia in 1793.[57] English colonists in Philadelphia and the French in the Mississippi River Valley recorded major outbreaks in 1669, as well as those occurring later in the 18th and 19th centuries.

Sugar curing house, 1762. Sugar pots and jars on sugar plantations served as breeding place for larvae of *A. aegypti*, the vector of yellow fever.

The southern city of New Orleans was plagued with major epidemics during the 19th century, most notably in 1833 and 1853. At least 25 major outbreaks took place in the Americas during the 18th and 19th centuries, including particularly serious ones in Cartagena in 1741, Cuba in 1762 and 1900, Santo Domingo in 1803, and Memphis in 1878.[58] There has been considerable debate over whether the number of deaths caused by disease in the Haitian Revolution of the 1780s was exaggerated.[59]

Major outbreaks have also occurred in southern Europe. Gibraltar lost many to outbreaks in 1804, in 1814, and again in 1828.[60] Barcelona suffered the loss of several thousand citizens during an outbreak in 1821. Urban epidemics continued in the United States until 1905, with the last outbreak affecting New Orleans.[61]

In Colonial times and during the Napoleonic Wars, the West Indies were known as a particularly dangerous posting for soldiers due to the presence of yellow fever. The mortality rate in British garrisons in Jamaica was seven times that of garrisons in Canada, mostly because of yellow fever and other tropical disease like malaria.[62] Both English and French forces posted there were seriously affected by the "yellow jack." Wanting to regain control of the lucrative sugar trade in Saint-Domingue(Hispaniola), and with an eye on regaining France's New World empire, Napoleon sent an army under the command of his brother-in-law to Saint-Domingue to seize control after a slave revolt. The historian J. R. McNeill asserts that yellow fever accounted for about 35,000 to 45,000 casualties of these forces during the fighting.[63] Only one-third of

the French troops survived for withdrawal and return to France. Napoleon gave up on the island, and in 1804 Haiti proclaimed its independence as the second republic in the Western Hemisphere.

The yellow fever epidemic of 1793 in Philadelphia, which was then the capital of the United States, resulted in the deaths of several thousand people, more than 9% of the population. The national government fled the city, including President George Washington.[64] Additional yellow fever epidemics struck Philadelphia, Baltimore, and New York in the 18th and 19th centuries, and traveled along steamboat routes from New Orleans. They caused some 100,000–150,000 deaths in total.[65]

Yellow Fever Epidemic of 1878 can still be found in New Orleans' cemeteries.

In 1853, Cloutierville, Louisiana, had a late summer outbreak of yellow fever that quickly killed 68 of the 91 inhabitants. A local doctor concluded that some unspecified infectious agent had arrived in a package from New Orleans.[66][67] In 1858, St. Matthew's German Evangelical Lutheran Church in Charleston, South Carolina, suffered 308 yellow fever deaths, reducing the congregation by half.[68] A ship carrying persons infected with the virus arrived in Hampton Roads in southeastern Virginia in June 1855.[69] The disease spread quickly through the community, eventually killing over 3,000 people, mostly residents of Norfolk and Portsmouth. In 1873, Shreveport, Louisiana, lost almost a quarter of its population to yellow fever. In 1878, about 20,000 people died in a widespread epidemic in the Mississippi River Valley.[70] That year, Memphis had an unusually large amount of rain, which led to an increase in the mosquito population. The result was a huge epidemic of yellow fever.[71] The steamship *John D. Porter* took people fleeing Memphis northward in hopes of escaping the disease, but passengers were not allowed to disembark due to concerns of spreading yellow fever. The ship roamed the Mississippi River for the next two months before unloading her passengers.[72] The last major U.S. outbreak was in 1905 in New Orleans.[8][73]

Ezekiel Stone Wiggins, known as the Ottawa Prophet, proposed that the cause of a yellow fever epidemic in Jacksonville, Florida, in 1888, was astronomical.

> The planets were in the same line as the sun and earth and this produced, besides Cyclones, Earthquakes, etc., a denser atmosphere holding more carbon and creating microbes. Mars had an uncommonly dense atmosphere, but its inhabitants were probably protected from the fever by their newly discovered canals, which were perhaps made to absorb carbon and prevent the disease.[74]

In 1848 Josiah C. Nott suggested that yellow fever was spread by insects such as moths or mosquitoes, basing his ideas on the pattern of transmission of the disease.[75] Carlos Finlay, a Cuban doctor and scientist, proposed in 1881 that yellow fever might be transmitted by mosquitoes rather than direct human contact.[76][77] Since the losses from yellow fever in the Spanish–American War in the 1890s were extremely high, Army doctors began research experiments with a team led by Walter Reed, composed of doctors James Carroll, Aristides Agramonte, and Jesse William Lazear. They successfully proved Finlay's "mosquito hypothesis". Yellow fever was the first virus shown to be transmitted by mosquitoes. The physician William Gorgas applied these insights and eradicated yellow fever from Havana. He also campaigned against yellow fever during the construction of the Panama Canal, after a previous effort on the part of the French failed (in part due to mortality from the high incidence of yellow fever and malaria, which killed many workers).[8]

Yellow fever in Buenos Aires, 1871

Although Dr. Reed has received much of the credit in United States history books for "beating" yellow fever, he had fully credited Dr. Finlay with the discovery of the yellow fever vector, and how it might be controlled. Reed

often cited Finlay's papers in his own articles, and also gave him credit for the discovery in his personal correspondence.[78] The acceptance of Finlay's work was one of the most important and far-reaching effects of the Walter Reed Commission of 1900.[79] Applying methods first suggested by Finlay, the United States government and Army eradicated yellow fever in Cuba and later in Panama, allowing completion of the Panama Canal. While Reed built on the research of Carlos Finlay, historian François Delaporte notes that yellow fever research was a contentious issue. Scientists, including Finlay and Reed, became successful by building on the work of less prominent scientists, without always giving them the credit they were due.[80] Reed's research was essential in the fight against yellow fever. He should also receive full credit for his use of the first type of medical consent form during his experiments in Cuba, an attempt to ensure that participants knew they were taking a risk by being part of testing.[81]

Max Theiler

During 1920–23, the Rockefeller Foundation's International Health Board (IHB) undertook an expensive and successful yellow fever eradication campaign in Mexico. The IHB gained the respect of Mexico's federal government because of the success. The eradication of yellow fever strengthened the relationship between the US and Mexico, which had not been very good in the past. The eradication of yellow fever was also a major step toward better global health.[82]

In 1927, scientists isolated the yellow fever virus in West Africa.[83] Following this, two vaccines were developed in the 1930s. The vaccine 17D was developed by the South African microbiologist Max Theiler at the Rockefeller Institute in New York City. This vaccine was widely used by the U.S. Army during World War II.[54] Following the work of Ernest Goodpasture, Theiler used chicken eggs to culture the virus and won a Nobel Prize in 1951 for this achievement. A French team developed the French neurotropic vaccine (FNV), which was extracted from mouse brain tissue. Since this vaccine was associated with a higher incidence of encephalitis, FNV was not recommended after 1961. 17D is still in use and more than 400 million doses have been distributed. Little research has been done to develop new vaccines. Some researchers worry that the 60-year-old technology for vaccine production may be too slow to stop a major new yellow fever epidemic. Newer vaccines, based on vero cells, are in development and should replace 17D at some point.[5]

Using vector control and strict vaccination programs, the urban cycle of yellow fever was nearly eradicated from South America. Since 1943, only a single urban outbreak in Santa Cruz de la Sierra, Bolivia, has occurred. But, since the 1980s, the number of yellow fever cases has been increasing again, and *A. aegypti* has returned to the urban centers of South America. This is partly due to limitations on available insecticides, as well as habitat dislocations caused by climate change. It is also because the vector control program was abandoned. Although no new urban cycle has yet been established, scientists believe this could happen again at any point. An outbreak in Paraguay in 2008 was thought to be urban in nature, but this ultimately proved not to be the case.[5]

In Africa, virus eradication programs have mostly relied upon vaccination. These programs have largely been unsuccessful because they were unable to break the sylvatic cycle involving wild primates. With few countries establishing regular vaccination programs, measures to fight yellow fever have been neglected, making the future spread of the virus more likely.[5]

## Research [edit]

In the hamster model of yellow fever, early administration of the antiviral ribavirin is an effective early treatment of many pathological features of the disease.[84] Ribavirin treatment during the first five days after virus infection improved survival rates, reduced tissue damage in the liver and spleen, prevented hepatocellular steatosis, and normalised levels of alanine aminotransferase, a liver damage marker. The mechanism of action of ribavirin in reducing liver pathology in yellow fever virus infection may be similar to its activity in treatment of hepatitis C, a related virus.[84] Because ribavirin had failed to improve survival in a virulent rhesus model of yellow fever infection, it had been previously discounted as a possible

therapy.[85] Infection was reduced in mosquitoes with the wMel strain of Wolbachia.[86]

In the past, yellow fever has been researched by several countries as a potential biological weapon.[87]

55. ^ The earliest mention of "yellow fever" appears in a manuscript of 1744 by Dr. John Mitchell of Virginia; copies of the manuscript were sent to Mr. Cadwallader Colden, a physician in New York, and to Dr. Benjamin Rush of Philadelphia; the manuscript was eventually printed (in large part) in 1805 and reprinted in 1814. See:
    - (John Mitchell) (1805) (Mitchell's account of the Yellow Fever in Virginia in 1741–2), *The Philadelphia Medical Museum,* 1 (1) : 1–20.
    - (John Mitchell) (1814) "Account of the Yellow fever which prevailed in Virginia in the years 1737, 1741, and 1742, in a letter to the late Cadwallader Colden, Esq. of New York, from the late John Mitchell, M.D.F.R.S. of Virginia," *American Medical and Philosophical Register* … , **4** : 181–215. The term "yellow fever" appears on p. 186. On p. 188, Mitchell mentions "… the distemper was what is generally called the yellow fever in America." However, on pages 191–192, he states "… I shall consider the cause of the yellowness which is so remarkable in this distemper, as to have given it the name of the Yellow Fever."

    It should be noted, however, that Dr. Mitchell misdiagnosed the disease that he observed and treated, and that the disease was probably Weil's disease or hepatitis. See: Jarcho S (1957). "John Mitchell, Benjamin Rush, and yellow fever". *Bull Hist Med*. **31** (2): 132–6. PMID 13426674.

# Zika fever

From Wikipedia, the free encyclopedia

*"Zika" redirects here. For other uses, see Zika (disambiguation).*

**Zika fever** (also known as **Zika virus disease** and simply **Zika**) is an infectious disease caused by the Zika virus.[1] Most cases have no symptoms, but when present they are usually mild and can resemble dengue fever.[1][2] Symptoms may include fever, red eyes, joint pain, headache, and a maculopapular rash.[1][3][4] Symptoms generally last less than seven days.[3] It has not caused any reported deaths during the initial infection.[2] Mother-to-child transmission during pregnancy can cause microcephaly and other brain malformations in some babies.[5][6] Infections in adults have been linked to Guillain–Barré syndrome (GBS).[2]

Zika fever is mainly spread via the bite of mosquitoes of the *Aedes* type.[3] It can also be sexually transmitted and potentially spread by blood transfusions.[3][7] Infections in pregnant women can spread to the baby.[5][6][8] Diagnosis is by testing the blood, urine, or saliva for the presence of Zika virus RNA when the person is sick.[1][3]

Prevention involves decreasing mosquito bites in areas where the disease occurs and proper use of condoms.[3][7] Efforts to prevent bites include the use of insect repellent, covering much of the body with clothing, mosquito nets, and getting rid of standing water where mosquitoes reproduce.[1] There is no effective vaccine.[3] Health officials recommended that women in areas affected by the 2015–16 Zika outbreak consider putting off pregnancy and that pregnant women not travel to these areas.[3][9] While there is no specific treatment, paracetamol (acetaminophen) may help with the symptoms.[3] Admission to hospital is rarely necessary.[2]

The virus that causes the disease was first isolated in Africa in 1947.[10] The first documented outbreak among people occurred in 2007 in the Federated States of Micronesia.[3] As of January 2016, the disease was occurring in twenty regions of the Americas.[3] It is also known to occur in Africa, Asia, and the Pacific.[1] Due to an outbreak which started in Brazil in 2015, the World Health Organization declared it a Public Health Emergency of International Concern in February 2016.[11]

Video explanation of Zika virus and Zika fever

## Signs and symptoms [edit]

Most people who are infected have no or few symptoms.[12] Otherwise the most common signs and symptoms of Zika fever are fever, rash, conjunctivitis (red eyes), muscle and joint pain, and headache, which are similar to signs and symptoms of dengue and chikungunya fever.[13] The time from a mosquito bite to developing symptoms is not yet known, but is probably a few days to a week.[14] The disease lasts for several days to a week and is usually mild enough that people do not have to go to a hospital.[1][15]

Rash on an arm due to Zika fever

Due to being in the same family as dengue, there has been concern that it could cause similar bleeding disorders. However that has only been documented in one case, with blood seen in semen, also known as hematospermia.[16]

### Guillain–Barré syndrome [edit]

Zika virus infections have been strongly associated with GBS, which is a rapid onset of muscle weakness caused by the immune system damaging the peripheral nervous system, and which can progress to paralysis.[17] While both GBS and Zika infection can simultaneously occur in the same individual, it is difficult to definitively identify Zika virus as the cause of GBS.[18] Several countries affected by Zika outbreaks have reported increases in the rate of new cases of GBS. During the 2013–2014 outbreak in French Polynesia there were 42 reported cases of GBS over a 3-month period, compared to between 3 and

10 annually prior to the outbreak.[19]

### Pregnancy [edit]

The disease spreads from mother to child in the womb and can cause multiple problems, most notably microcephaly, in the baby. The full range of birth defects caused by infection during pregnancy is not known, but they appear to be common, with large scale abnormalities seen in up to 42% of live births.[20][21] The most common observed associations have been abnormalities with brain and eye development such as microcephaly and chorioretinal scarring.[22] Less commonly there have been systemic abnormalities such as hydrops fetalis, where there is abnormal accumulation of fluid in the fetus.[23][24] These abnormalities can lead to intellectual problems, seizures, vision problems, hearing problems, problems feeding and slow development.[25]

Microcephaly

Whether the stage of pregnancy at which the mother becomes infected affects the risk to the fetus is not well understood, nor is whether other risk factors affect outcomes.[5][6][8] One group has estimated the risk of a baby developing microcephaly at about 1% when the mother is infected during the first trimester, with the risk of developing microcephaly is uncertain beyond the first trimester.[26] Affected babies might appear normal but actually have brain abnormalities; infection in newborns could also lead to brain damage.[27]

## Cause [edit]

### Reservoir [edit]

Zika virus is a mosquito-borne flavivirus closely related to the dengue virus. While mosquitoes are the vector, the reservoir species remains unknown, though serological evidence has been found in West African monkeys and rodents.[28][29]

### Transmission [edit]

Transmission is via the bite of mosquitoes from the *Aedes* genus, primarily *Aedes aegypti* in tropical regions. It has also been isolated from *Ae. africanus*, *Ae. apicoargenteus*, *Ae. luteocephalus*,[30] *Ae. Albopictus*,[31][32] *Ae. vittatus* and *Ae. furcifer*.[28] During the 2007 outbreak on Yap Island in the South Pacific, *Aedes hensilli* was the vector, while *Aedes polynesiensis* spread the virus in French Polynesia in 2013.[33]

Zika virus can also spread by sexual transmission from infected men to their partners.[34][35][36] Zika virus has been isolated from semen samples, with one person having 100,000 times more virus in semen than blood or urine, two weeks after being infected.[37] It is unclear why levels in semen can be higher than other body fluids, and it is also unclear how long infectious virus can remain in semen. There have also been cases of men with no symptoms of Zika virus infection transmitting the disease.[38] The CDC has recommended that all men who have travelled to affected areas should wait at least 6 months before trying to attempt conception, regardless of if they were ill.[39] To date there have been no reported sexual transmissions from women to their sexual partners.[36] Oral, anal or vaginal sex can spread the disease.[40][41]

Cases of vertical perinatal transmission have been reported.[42] The CDC recommends that women with Zika fever should wait at least 8 weeks after they start having symptoms of disease before attempting to conceive.[43] There have been no reported cases of transmission from breastfeeding, but infectious virus has been found in breast milk.[44]

Like other flaviviruses it could potentially be transmitted by blood transfusion and several affected countries have developed strategies to screen blood donors.[15][45] The U.S. FDA has recommended universal screening of blood products for Zika.[46] The virus is detected in 3% of asymptomatic blood donors in French Polynesia.[47]

## Pathophysiology [edit]

While the pathophysiology of Zika-induced microcephaly is not yet fully known, it is reported to involve infection of the primary neural stem cells of the fetal brain, known as neural progenitor cells.[48][24] The main roles of brain stem cells are to proliferate until the correct number is achieved, and then to produce neurons through the process of neurogenesis.[49] Zika proteins NS4A and NS4B have also been shown to directly suppress neurogensis.[24] Infection of brain stem cells can cause cell death, which reduces the production of future neurons and leads to a smaller brain.[48] Zika also appears to have an equal tropism for cells of the developing eye, leading to high rates of eye abnormalities as well.[24]

## Diagnosis [edit]

It is difficult to diagnose Zika virus infection based on clinical signs and symptoms alone due to overlaps with other arboviruses that are endemic to similar areas.[15][50] The US Centers for Disease Control and Prevention (CDC) advises that "based on the typical clinical features, the differential diagnosis for Zika virus infection is broad. In addition to dengue, other considerations include leptospirosis, malaria, rickettsia, group A streptococcus, rubella, measles, and parvovirus, enterovirus, adenovirus, and alphavirus infections (e.g., chikungunya, Mayaro, Ross River, Barmah Forest, O'nyong'nyong, and Sindbis viruses)."[51]

In small case series, routine chemistry and complete blood counts have been normal in most patients. A few have been reported to have mild leukopenia, thrombocytopenia, and elevated liver transaminases.[52]

Zika virus can be identified by reverse transcriptase PCR (RT-PCR) in acutely ill patients. However, the period of viremia can be short[2] and the World Health Organization (WHO) recommends RT-PCR testing be done on serum collected within 1 to 3 days of symptom onset or on saliva samples collected during the first 3 to 5 days.[33] When evaluating paired samples, Zika virus was detected more frequently in saliva than serum.[52] Urine samples can be collected and tested up to 14 days after the onset of symptoms, as the virus has been seen to survive longer in the urine than either saliva or serum.[53] The longest period of detectable virus has been 11 days and Zika virus does not appear to establish latency.[28]

Later on, serology for the detection of specific IgM and IgG antibodies to Zika virus can be used. IgM antibodies can be detectable within 3 days of the onset of illness.[28] Serological cross-reactions with closely related flaviviruses such as dengue and West Nile virus as well as vaccines to flaviviruses are possible.[2][54][55] Commercial assays for Zika antibodies are now available but have not yet been FDA approved.[50][56]

### Screening in pregnancy [edit]

The CDC recommends screening some pregnant women even if they do not have symptoms of infection. Pregnant women who have traveled to affected areas should be tested between two and twelve weeks after their return from travel.[57] Due to the difficulties with ordering and interpreting tests for Zika virus, the CDC also recommends that healthcare providers contact their local health department for assistance.[57] For women living in affected areas, the CDC has recommended testing at the first prenatal visit with a doctor as well as in the mid-second trimester, though this may be adjusted based on local resources and the local burden of Zika virus.[57] Additional testing should be done if there are any signs of Zika virus disease. Women with positive test results for Zika virus infection should have their fetus monitored by ultrasound every three to four weeks to monitor fetal anatomy and growth.[57]

### Infant testing [edit]

For infants with suspected congenital Zika virus disease, the CDC recommends testing with both serologic and molecular assays such as RT-PCR, IgM ELISA and plaque reduction neutralization test (PRNT).[58] RT-PCR of the infants serum and urine should be performed in the first two days of life.[58] Newborns with a mother who was potentially exposed and who have positive blood tests, microcephaly or intracranial calcifications should have further testing including a thorough physical investigation for neurologic abnormalities, dysmorphic features, splenomegaly, hepatomegaly, and rash or other skin lesions.[58] Other recommended tests are cranial ultrasound, hearing evaluation,[59] and eye examination.[58] Testing should be done for any abnormalities encountered as well as for other congenital infections such as syphilis, toxoplasmosis, rubella, cytomegalovirus infection, lymphocytic choriomeningitis virus infection, and herpes simplex virus.[58] Some tests should be repeated up to 6 months later as there can be delayed effects, particularly with hearing.[58]

## Prevention [edit]

The virus is spread by mosquitoes, making mosquito avoidance an important element to disease control. The CDC recommends that individuals:[60]

- Cover exposed skin by wearing long-sleeved shirts and long pants treated with permethrin.[61]
- Use an insect repellent containing DEET,[62] picaridin, oil of lemon eucalyptus (OLE), or IR3535
- Always follow product directions and reapply as directed
- If you are also using sunscreen, apply sunscreen first, let it dry, then apply insect repellent
- Follow package directions when applying repellent on children. Avoid applying repellent to their hands, eyes, or mouth
- Stay and sleep in screened-in or air-conditioned rooms
- Use a bed net if the area where you are sleeping is exposed to the outdoors
- Cover cribs, strollers and carriers with mosquito netting for babies under 2 months old.

The CDC also recommends strategies for controlling mosquitoes such as eliminating standing water, repairing septic tanks and using screens on doors and windows.[63][64] Spraying insecticide is used to kill flying mosquitoes and larvicide can be used in water containers.[1]

Because Zika virus can be sexually transmitted, men who have gone to an area where Zika fever is occurring should be counseled to either abstain from sex or use condoms for 6 months after travel if their partner is pregnant or could potentially become pregnant.[15][34][43] Breastfeeding is still recommended by the WHO, even by women who have had Zika fever. There have been no recorded cases of Zika transmission to infants through breastfeeding, though the replicative virus has been detected in breast milk.[44][65]

When returning from travel, with or without symptoms, it is suggested that prevention of mosquito bites continue for 3 weeks in order reduce the risk of virus transmission to uninfected mosquitos.[60]

### CDC travel alert [edit]

Because of the "growing evidence of a link between Zika and microcephaly", in January 2016, the CDC issued a travel alert advising pregnant women to consider postponing travel to countries and territories with ongoing local transmission of Zika virus.[66] Later, the advice was updated to caution pregnant women to avoid these areas entirely if possible and, if travel is unavoidable, to protect themselves from mosquito bites.[67] Male partners of pregnant women and couples contemplating pregnancy who must travel to areas where Zika is active are advised to use condoms or abstain from sex entirely.[67] The agency also suggested that women thinking about becoming pregnant should consult with their physicians before traveling.[66][68]

As of September 2016, the CDC travel advisories include:[69]

- Cape Verde
- Many parts of the Caribbean: Anguilla, Antigua and Barbuda, Aruba, The Bahamas, Barbados, Bonaire, British Virgin Islands, Cayman Islands, Cuba, Curaçao, Dominica, Dominican Republic, Grenada, Guadeloupe, Haiti, Jamaica, Martinique, Puerto Rico, Saba, Saint Saint Barthélemy, Saint Lucia, Saint Martin, Saint Vincent and the Grenadines, Sint Eustatius, Sint Maarten, Trinidad and Tobago, and the U.S. Virgin Islands
- Central America: Belize, Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua, and Panama
- Mexico
- Most of South America: Argentina, Bolivia, Brazil, Colombia, Ecuador, French Guiana, Guyana, Paraguay, Peru, Suriname, and Venezuela
- Several Pacific Islands: American Samoa, Fiji, Marshall Islands, Micronesia, New Caledonia, Papua New Guinea, Samoa, and Tonga
- In Asia: Singapore, Malaysia, Brunei

### WHO response [edit]

Both the regional Pan American Health Organization (PAHO) as well as the WHO have issued statements of concern about the widespread public health impact of the Zika virus and its links to GBS and microcephaly.[70][71] The WHO Director-General, Margaret Chan, issued a statement in February 2016 "declaring that the recent cluster of microcephaly cases and other neurological disorders reported in Brazil, following a similar cluster in French Polynesia in 2014, constitutes a Public Health Emergency of International Concern."[11] The declaration allowed the WHO to coordinate international response to the virus as well as gave its guidance the force of international law under the International Health Regulations.[72][73] The declaration was ended in November 2016.[74]

### Vaccine [edit]

As of 2016 there was no available vaccine. Development was a priority of the US National Institutes of Health (NIH), but officials stated that development of a vaccine could take years.[2][15][50][75] To speed new drug development regulatory strategies were proposed by the WHO and NIH.[76][77] Animal and early human studies were underway as of September 2016.[78][79]

### Mosquito control [edit]

Disease control in the affected countries currently centres around mosquito control. Several approaches are available for the management of *Aedes aegypti* mosquito populations, including the destruction of larval breeding sites (the aquatic pools in which eggs are laid and larvae hatch prior to mosquito development into flying adults); and, insecticides targeting either the larval stages, adult mosquitoes or both. Additionally, a whole host of novel technologies are under current development for mosquito control and the World Health Organization has recently lent its support for the accelerated development of modern methods for mosquito control such as the use of *Wolbachia* bacteria to render mosquitoes resistant to the virus, and, the release of sterilized male mosquitoes that breed with wild female mosquitoes to give rise to non-viable offspring (offspring that do not survive to the biting, adult stage).[80]

Oxitec's genetically modified OX513A mosquito was approved by Brazil's National Biosecurity Technical Commission (CTNBio) in April 2014[81] and it was being used to try to combat mosquitoes carrying the Zika virus in the town of Piracicaba, São Paulo in 2016.[82]

## Treatment [edit]

There is currently no specific treatment for Zika virus infection. Care is supportive with treatment of pain, fever, and itching.[33] Some authorities have recommended against using aspirin and other NSAIDs as these have been associated with hemorrhagic syndrome when used for other flaviviruses.[2][15] Additionally, aspirin use is generally avoided in children when possible due to the risk of Reye syndrome.[83]

Zika virus had been relatively little studied until the major outbreak in 2015, and no specific antiviral treatments are available as yet.[15] Advice to pregnant women is to avoid any risk of infection so far as possible, as once infected there is little that can be done beyond supportive treatment.[84]

## Outcomes [edit]

Most of the time, Zika fever resolves on its own in 2 to 7 days, but rarely, some people develop Guillain–Barré syndrome.[2][85] The fetus of a pregnant woman who has Zika fever may die or be born with congenital central nervous system malformations, like microcephaly.[2]

## Epidemiology [edit]

Countries with active Zika virus transmission as of September 2016. From http://www.cdc.gov/zika/geo/active-countries.html

In April 1947, as part of studies sponsored by the Rockefeller Foundation into yellow fever, 6 caged rhesus monkeys were placed in the canopy of the Zika Forest of Uganda.[86] On April 18 one of the monkeys (no. 776) developed a fever and blood samples revealed the first known case of Zika fever.[28][86] Population surveys at the time in Uganda found a 6.1% prevalence.[42] The first human cases were reported in Nigeria in 1954.[87] A few outbreaks have been reported in tropical Africa and in some areas in Southeast Asia.[88] There have been no documented cases of Zika virus in the Indian subcontinent. Surveys have found antibodies to Zika in healthy people in India which could indicate past exposure, though it could also be due to cross-reaction with other flaviviruses.[89]

By using phylogenetic analysis of Asian strains, it was estimated that Zika virus had moved to Southeast Asia by 1945.[42] In 1977–1978, Zika virus infection was described as a cause of fever in Indonesia.[90] Before 2007, there were only 13 reported natural infections with Zika virus, all with a mild, self-limited febrile illness.[28][91]

### Yap Islands [edit]

*Main article: 2007 Yap Islands Zika virus outbreak*

The first major outbreak, with 185 confirmed cases, was reported in 2007 in the Yap Islands of the Federated States of Micronesia.[92] A total of 108 cases were confirmed by PCR or serology and 72 additional cases were suspected. The most common symptoms were rash, fever, arthralgia, and conjunctivitis, and no deaths were reported. The mosquito *Aedes hensilli*, which was the predominant species identified in Yap during the outbreak, was probably the main vector of transmission. While the way of introduction of the virus on Yap Island remains uncertain, it is likely to have happened through introduction of infected mosquitoes or a human infected with a strain related to those in Southeast Asia.[42][92] This was also the first time Zika fever had been reported outside Africa and Asia.[4] Before the Yap Island outbreak, only 14 human cases had ever been reported.[93]

### Oceania [edit]

*Main article: 2013–2014 Zika virus outbreaks in Oceania*

In 2013–2014, several outbreaks of Zika were reported in French Polynesia, New Caledonia, Easter Island and the Cook Islands. The source of the virus was thought to be an independent introduction of the virus from Southeast Asia, unrelated to the Yap Islands outbreak.[42]

### Americas [edit]

*Further information: 2015–16 Zika virus epidemic*

Genetic analyses of Zika virus strains suggest that Zika first entered the Americas between May and December 2013.[94] It was first detected in the Western Hemisphere in February 2014, and rapidly spread throughout South and Central America, reaching Mexico in November 2015.[15][42][95] In 2016 it established local transmission in Florida and Texas.[96][97] The first death in the United States due to Zika occurred in February 2016.[98]

Areas of active Zika Virus transmission, April 2016

In May 2015, Brazil officially reported its first 16 cases of the illness.[99] According to the Brazilian Health Ministry, as of November 2015 there was no official count of the number of people infected with the virus in Brazil, since the disease is not subject to compulsory notification. Even so, cases were reported in 14 states of the country. Mosquito-borne Zika virus is suspected to be the cause of 2,400 possible cases of microcephaly and 29 infant deaths in Brazil in 2015 (of the 2400 or so notified cases in 2015, 2165 were under investigation in December 2015, 134 were confirmed and 102 were ruled out for microcephaly).[100]

The Brazilian Health Ministry has reported at least 2,400 suspected cases of microcephaly in the country in 2015 as of 12 December, and 29 fatalities.[100][101][102][103] Before the Zika outbreak, only an average of 150 to 200 cases per year were reported in Brazil.[104] In the state of Pernambuco the reported rates of microcephaly in 2015 are 77 times higher than in the previous 5 years.[104] A model using data from a Zika outbreak in French Polynesia estimated the risk of microcephaly in children born to mothers who acquired Zika virus in the first trimester to be 1%.[105]

On 24 January 2016, the WHO warned that the virus is likely to spread to nearly all countries of the Americas, since its vector, the mosquito *Aedes aegypti*, is found in all countries in the region, except for Canada and continental Chile.[106][107] The mosquito and dengue fever have been detected in Chile's Easter Island, some 3,500 km (2,200 mi) away from its closest point in mainland Chile, since 2002.[108]

In February 2016, WHO declared the outbreak a Public Health Emergency of International Concern as evidence grew that Zika is a cause of birth defects and neurological problems.[15][109][110][111] In April 2016, WHO stated there is a scientific consensus, based on preliminary evidence, that Zika is a cause of microcephaly in infants and Guillain–Barré syndrome in adults.[8] Studies of this and prior outbreaks have found Zika infection during pregnancy to be associated with early pregnancy loss and other pregnancy problems.[112][113]

### Asia [edit]

In 2016 imported or locally transmitted Zika was reported in all the countries of Asia except Brunei, Hong Kong, Myanmar and Nepal.[114] Serological surveys have indicated that Zika virus is endemic in most areas of Asia, though at a low level.[114] While there was a sharp rise in the amount of cases of Zika detected in Singapore after the 2016 Summer Olympics in Brazil, genetic analysis revealed that the strains were more closely related to strains from Thailand than from those causing the epidemic in the Americas.[115][116][117]

## History [edit]

### Microcephaly and other infant disorders [edit]

Following the initial Zika outbreak in Northeastern Brazil, physicians observed a very large surge of reports of infants born with microcephaly, with 20 times the number of expected cases.[118][119] Many of these

cases have since been confirmed, leading WHO officials to project that approximately 2,500 infants will be found to have born in Brazil with Zika-related microcephaly.[120][121] On 10 March 2016, a research group from the Faculty of Medicine, University of Ljubljana (Slovenia), led by young researcher Jernej Mlakar, M.D., published an article in The New England Journal of Medicine, connecting the Zika virus to microcephaly.[122]

Proving that Zika causes these effects is difficult and complex for several reasons.[123][124] For example, the effects on an infant might not be seen until months after the mother's initial infection, long after the time when Zika is easily detected in the body.[123] In addition, research is also needed to determine the mechanism by which Zika produces these effects.[125]

Since the initial outbreak, studies that use several different methods found evidence of a link, leading public health officials to conclude that it appears increasingly likely the virus is linked to microcephaly and miscarriage.[125][126] On 1 February 2016, the World Health Organization declared recently reported clusters of microcephaly and other neurological disorders a Public Health Emergency of International Concern (PHEIC).[127] On 8 March 2016, the WHO Committee reconfirmed that the association between Zika and neurological disorders is of global concern.[125]

The Zika virus was first linked with newborn microcephaly during the Brazil Zika virus outbreak. In 2015, there were 2,782 suspected cases of microcephaly compared with 147 in 2014 and 167 in 2013.[118] Confirmation of many of the recent cases is pending,[128] and it is difficult to estimate how many cases went unreported before the recent awareness of the risk of virus infections.[129]

Brazilian President Dilma Rousseff in a videoconference about the Zika virus at the National Center for Disaster Management.

In March 2016, researchers published a prospective cohort study that found profound impacts in 29 percent of infants of mothers infected with Zika, some of whom were infected late in pregnancy.[20] This study did not suffer from some of the difficulties of studying Zika: the study followed women who presented to a Rio de Janeiro clinic with fever and rash within the last five days. The women were then tested for Zika using PCR, then the progress of the pregnancies were followed using ultrasound.[20][130]

In November 2015, the Zika virus was isolated in a newborn baby from the northeastern state of Ceará, Brazil, with microcephaly and other congenital disorders. *The Lancet* medical journal reported in January 2016 that the Brazilian Ministry of Health had confirmed 134 cases of microcephaly "believed to be associated with Zika virus infection" with an additional 2,165 cases in 549 counties in 20 states remaining under investigation.[15][131] An analysis of 574 cases of microcephaly in Brazil during 2015 and the first week of 2016, reported in March 2016, found an association with maternal illness involving rash and fever during the first trimester of pregnancy.[132] During this period, 12 Brazilian states reported increases of at least 3 standard deviations (SDs) in cases of microcephaly compared with 2000–14, with the northeastern states of Bahia, Paraíba and Pernambuco reporting increases of more than 20 SDs.[132]

In January 2016, a baby in Oahu, Hawaii, was born with microcephaly, the first case in the United States of brain damage linked to the virus. The baby and mother tested positive for a past Zika virus infection. The mother, who had probably acquired the virus while traveling in Brazil in May 2015 during the early stages of her pregnancy, had reported her bout of Zika. She recovered before relocating to Hawaii. Her pregnancy had progressed normally, and the baby's condition was not known until birth.[133]

In March 2016, first solid evidence was reported on how the virus affects the development of the brain. It appears to preferentially kill developing brain cells.[134] The first cases of birth defects linked to Zika in Colombia[135] and in Panama were reported in March 2016.[136]

Ocular disorders in newborns have also been linked to Zika virus infection.[137] In one study in Pernambuco state in Brazil, about 40 percent of babies with Zika-related microcephaly also had scarring of the retina [138]

with spots, or pigment alteration.

On 20 February 2016, Brazilian scientists announced that they had successfully sequenced the Zika virus genome, and expressed hope that this would help in both developing a vaccine and in determining the nature of any link to birth defects.[139]

In February 2016, rumors that microcephaly is caused by the use of the larvicide pyriproxyfen in drinking water were refuted by scientists.[140][141][142] "It's important to state that some localities that do not use pyriproxyfen also had reported cases of microcephaly", read a Brazilian government statement.[143] The Brazilian government also refuted conspiracy theories that chickenpox and rubella vaccinations or genetically modified mosquitoes were causing increases in microcephaly.[142]

Researchers also suspected that Zika virus could be transmitted by a pregnant woman to her babies ("vertical transmission"). This remained unproven until February 2016, when a paper by Calvet et al. was published, showing not only was the Zika virus genome found in the amniotic fluid but also IgM antibodies against the virus.[144] This means that not only can the virus cross the placental barrier, but also the antibodies produced by the mother can reach the fetus, which suggests that vertical transmission is plausible in these cases. One other study published in March 2016 by Mlakar and colleagues analyzed autopsy tissues from a fetus with microcephaly that was probably related to Zika virus; researchers found ZIKV in the brain tissue and suggested that the brain injuries were probably associated with the virus, which also shed a light on the vertical transmission theory.[122]

### Guillain–Barré syndrome [edit]

A high rate of the autoimmune disease Guillain–Barré syndrome (GBS), noted in the French Polynesia outbreak, has also been found in the outbreak that began in Brazil.[131] Laboratory analysis found Zika infections in some patients with GBS in Brazil, El Salvador, Suriname and Venezuela,[145] and the WHO declared on 22 March 2016 that Zika appeared to be "implicated" in GBS infection and that if the pattern was confirmed it would represent a global public health crisis.[146]

## Research [edit]

Some experimental methods of prevention include breeding and releasing mosquitoes that have been genetically modified to prevent them from transmitting pathogens, or have been infected with the *Wolbachia* bacterium, believed to inhibit the spread of viruses.[15][147] A strain of *Wolbachia* helped to reduce the vector competence of the Zika virus in infected *Aedes aegypti* released in Medellin, Colombia.[148] Gene drive is a technique for changing wild populations, for instance to combat insects so they cannot transmit diseases (in particular mosquitoes in the cases of malaria and Zika).[149] Another method which been researched aims to render male mosquitoes infertile by nuclear radiation in the hope to reduce populations; this is done with a cobalt-60 gamma cell irradiator.[150] In 2016 the World Health Organisation encouraged field trials of transgenic male *Aedes aegypti* mosquitoes developed by Oxitec to try to halt the spread of the Zika virus.[151]

# Birth control

From Wikipedia, the free encyclopedia

*For other uses, see Birth control (disambiguation).*

**Birth control**, also known as **contraception** and **fertility control**, is a method or device used to prevent pregnancy.[1] Birth control has been used since ancient times, but effective and safe methods of birth control only became available in the 20th century.[2] Planning, making available, and using birth control is called family planning.[3][4] Some cultures limit or discourage access to birth control because they consider it to be morally, religiously, or politically undesirable.[2]

The most effective methods of birth control are sterilization by means of vasectomy in males and tubal ligation in females, intrauterine devices (IUDs), and implantable birth control. This is followed by a number of hormone based methods including oral pills, patches, vaginal rings, and injections. Less effective methods include physical barriers such as condoms, diaphragms and birth control sponges and fertility awareness methods. The least effective methods are spermicides and withdrawal by the male before ejaculation. Sterilization, while highly effective, is not usually reversible; all other methods are reversible, most immediately upon stopping them.[5] Safe sex practices, such as with the use of male or female condoms, can also help prevent sexually transmitted infections.[6] Other methods of birth control do not protect against sexually transmitted diseases.[7] Emergency birth control can prevent pregnancy if taken within the 72 to 120 hours after unprotected sex.[8][9] Some argue not having sex as a form of birth control, but abstinence-only sex education may increase teenage pregnancies if offered without birth control education, due to non-compliance.[10][11]

A package of birth control pills

MeSH D003267

[edit on Wikidata]

In teenagers, pregnancies are at greater risk of poor outcomes. Comprehensive sex education and access to birth control decreases the rate of unwanted pregnancies in this age group.[12][13] While all forms of birth control can generally be used by young people,[14] long-acting reversible birth control such as implants, IUDs, or vaginal rings are more successful in reducing rates of teenage pregnancy.[13] After the delivery of a child, a woman who is not exclusively breastfeeding may become pregnant again after as few as four to six weeks. Some methods of birth control can be started immediately following the birth, while others require a delay of up to six months. In women who are breastfeeding, progestin-only methods are preferred over combined oral birth control pills. In women who have reached menopause, it is recommended that birth control be continued for one year after the last period.[14]

About 222 million women who want to avoid pregnancy in developing countries are not using a modern birth control method.[15][16] Birth control use in developing countries has decreased the number of deaths during or around the time of pregnancy by 40% (about 270,000 deaths prevented in 2008) and could prevent 70% if the full demand for birth control were met.[17][18] By lengthening the time between pregnancies, birth control can improve adult women's delivery outcomes and the survival of their children.[17] In the developing world women's earnings, assets, weight, and their children's schooling and health all improve with greater access to birth control.[19] Birth control increases economic growth because of fewer dependent children, more women participating in the workforce, and less use of scarce resources.[19][20]

## Methods [edit]

*See also: Comparison of birth control methods*

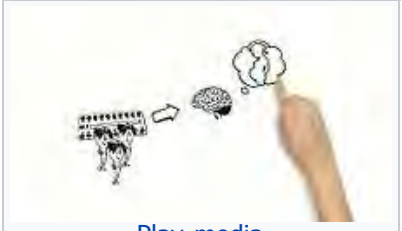
Birth control methods include barrier methods, hormonal birth control, intrauterine devices (IUDs), sterilization, and behavioral methods. They are used before or during sex while emergency contraceptives are effective for up to a few days after sex. Effectiveness is generally expressed as the percentage of women who become pregnant using a given method during the first year,[25] and sometimes as a lifetime failure rate among methods with high effectiveness, such as tubal ligation.[26] The most effective methods are those that are long acting and do not require ongoing health care visits.[27] Surgical sterilization, implantable hormones, and intrauterine devices all have first-year failure rates of less than 1%.[21] Hormonal contraceptive pills, patches or vaginal rings, and the lactational amenorrhea method (LAM), if used strictly, can also have first-year (or for LAM, first-6-month) failure rates of less than 1%.[27] With typical use first-year failure rates are considerably high, at 9%, due to incorrect usage.[21] Other methods such as condoms, diaphragms, and spermicides have higher first-year failure rates even with perfect usage.[27] The American Academy of Pediatrics recommends long acting reversible birth control as first line for young people.[28]

**Chance of pregnancy during first year of use**[21][22]

| Method | Typical use | Perfect use |
|---|---|---|
| No birth control | 85% | 85% |
| Combination pill | 9% | 0.3% |
| Progestin-only pill | 13% | 1.1% |
| Sterilization (female) | 0.5% | 0.5% |
| Sterilization (male) | 0.15% | 0.1% |
| Condom (female) | 21% | 5% |
| Condom (male) | 18% | 2% |
| Copper IUD | 0.8% | 0.6% |
| Hormonal IUD | 0.2% | 0.2% |
| Patch | 9% | 0.3% |
| Vaginal ring | 9% | 0.3% |
| Depo-Provera | 6% | 0.2% |
| Implant | 0.05% | 0.05% |
| Diaphragm and spermicide | 12% | 6% |
| Fertility awareness | 24% | 0.4–5% |
| Withdrawal | 22% | 4% |
| Lactational amenorrhea method (6 months failure rate) | 0-7.5%[23] | <2%[24] |

While all methods of birth control have some potential adverse effects, the risk is less than that of pregnancy.[27] After stopping or removing many methods of birth control, including oral contraceptives, IUDs, implants and injections, the rate of pregnancy during the subsequent year is the same as for those who used no birth control.[29]

In those with specific health problems, certain forms of birth control may require further investigations.[30] For women who are otherwise healthy, many methods of birth control should not require a medical exam—including birth control pills, injectable or implantable birth control, and condoms.[31] Specifically, a pelvic



Play media

exam, breast exam, or blood test before starting birth control pills do not appear to affect outcomes and, therefore, are not required.[32][33] In 2009, the World Health Organization (WHO) published a detailed list of medical eligibility criteria for each type of birth control.[30]

Contraception – How to prevent unwanted pregnancy

## Hormonal [edit]

Hormonal contraception is available in a number of different forms, including oral pills, implants under the skin, injections, patches, IUDs and a vaginal ring. They are currently available only for women, although hormonal contraceptives for men have and are being clinically tested.[34] There are two types of oral birth control pills, the combined oral contraceptive pills (which contain both estrogen and a progestogen) and the progestogen-only pills (sometimes called minipills).[35] If either is taken during pregnancy, they do not increase the risk of miscarriage nor cause birth defects.[33] Both types of birth control pills prevent fertilization mainly by inhibiting ovulation and thickening cervical mucous.[36][37] Their effectiveness depends on the user remembering to take the pills.[33] They may also change the lining of the uterus and thus decrease implantation.[37]

Combined hormonal contraceptives are associated with a slightly increased risk of venous and arterial blood clots.[38] Venous clots, on average, increase from 2.8 to 9.8 per 10,000 women years[39] which is still less than that associated with pregnancy.[38] Due to this risk, they are not recommended in women over 35 years of age who continue to smoke.[40] Due to the increased risk they are included in decision tools such as the DASH score and PERC rule used to predict the risk of blood clots.[41]

The effect on sexual desire is varied, with increase or decrease in some but with no effect in most.[42] Combined oral contraceptives reduce the risk of ovarian cancer and endometrial cancer and do not change the risk of breast cancer.[43][44] They often reduce menstrual bleeding and painful menstruation cramps.[33] The lower doses of estrogen released from the vaginal ring may reduce the risk of breast tenderness, nausea, and headache associated with higher dose estrogen products.[43]

Progestin-only pills, injections and intrauterine devices are not associated with an increased risk of blood clots and may be used by women with previous blood clots in their veins.[38][45] In those with a history of arterial blood clots, non-hormonal birth control or a progestin-only method other than the injectable version should be used.[38] Progestin-only pills may improve menstrual symptoms and can be used by breastfeeding women as they do not affect milk production. Irregular bleeding may occur with progestin-only methods, with some users reporting no periods.[46] The progestins drospirenone and desogestrel minimize the androgenic side effects but increase the risks of blood clots and are thus not first line.[47] The perfect use first-year failure rate of the injectable progestin, Depo-Provera, is 0.2%; the typical use first failure rate is 6%.[21]

## Barrier [edit]

Barrier contraceptives are devices that attempt to prevent pregnancy by physically preventing sperm from entering the uterus.[48] They include male condoms, female condoms, cervical caps, diaphragms, and contraceptive sponges with spermicide.[48]

Globally, condoms are the most common method of birth control.[49] Male condoms are put on a man's erect penis and physically block ejaculated sperm from entering the body of a sexual partner.[50] Modern condoms are most often made from latex, but some are made from other materials such as polyurethane, or lamb's intestine.[50] Female condoms are also available, most often made of nitrile, latex or polyurethane.[51] Male condoms have the advantage of being inexpensive, easy to use, and have few adverse effects.[52] Making condoms available to teenagers does not [53]

appear to affect the age of onset of sexual activity or its frequency. In Japan about 80% of couples who are using birth control use condoms, while in Germany this number is about 25%,[54] and in the United States it is 18%.[55]

Male condoms and the diaphragm with spermicide have typical use first-year failure rates of 18% and 12%, respectively.[21] With perfect use condoms are more effective with a 2% first-year failure rate versus a 6% first-year rate with the diaphragm.[21] Condoms have the additional benefit of helping to prevent the spread of some sexually transmitted infections such as HIV/AIDS.[5]

Contraceptive sponges combine a barrier with a spermicide.[27] Like diaphragms, they are inserted vaginally before intercourse and must be placed over the cervix to be effective.[27] Typical failure rates during the first year depend on whether or not a woman has previously given birth, being 24% in those who have and 12% in those who have not.[21] The sponge can be inserted up to 24 hours before intercourse and must be left in place for at least six hours afterward.[27] Allergic reactions[56] and more severe adverse effects such as toxic shock syndrome have been reported.[57]

## Intrauterine devices [edit]

The current intrauterine devices (IUD) are small devices, often 'T'-shaped, often containing either copper or levonorgestrel, which are inserted into the uterus. They are one form of long-acting reversible contraception which are the most effective types of reversible birth control.[58] Failure rates with the copper IUD is about 0.8% while the levonorgestrel IUD has a failure rates of 0.2% in the first year of use.[59] Among types of birth control, they along with birth control implants result in the greatest satisfaction among users.[60] As of 2007, IUDs are the most widely used form of reversible contraception, with more than 180 million users worldwide.[61]

Copper T shaped IUD with removal strings

Evidence supports effectiveness and safety in adolescents[60] and those who have and have not previously had children.[62] IUDs do not affect breastfeeding and can be inserted immediately after delivery.[63] They may also be used immediately after an abortion.[64] Once removed, even after long term use, fertility returns to normal immediately.[65]

While copper IUDs may increase menstrual bleeding and result in more painful cramps[66] hormonal IUDs may reduce menstrual bleeding or stop menstruation altogether.[63] Cramping can be treated with NSAIDs.[67] Other potential complications include expulsion (2–5%) and rarely perforation of the uterus (less than 0.7%).[63][67] A previous model of the intrauterine device (the Dalkon shield) was associated with an increased risk of pelvic inflammatory disease, however the risk is not affected with current models in those without sexually transmitted infections around the time of insertion.[68]

## Sterilization [edit]

Surgical sterilization is available in the form of tubal ligation for women and vasectomy for men.[2] There are no significant long-term side effects, and tubal ligation decreases the risk of ovarian cancer.[2] Short term complications are twenty times less likely from a vasectomy than a tubal ligation.[2][69] After a vasectomy, there may be swelling and pain of the scrotum which usually resolves in a week or two.[70] With tubal ligation, complications occur in 1 to 2 percent of procedures with serious complications usually due to the anesthesia.[71] Neither method offers protection from sexually transmitted infections.[2]

This decision may cause regret in some men and women. Of women aged over 30 who have undergone tubal

ligation, about 5% regret their decision, as compared with 20% of women aged under 30.[2] By contrast, less than 5% of men are likely to regret sterilization. Men more likely to regret sterilization are younger, have young or no children, or have an unstable marriage.[72] In a survey of biological parents, 9% stated they would not have had children if they were able to do it over again.[73]

Although sterilization is considered a permanent procedure,[74] it is possible to attempt a tubal reversal to reconnect the fallopian tubes or a vasectomy reversal to reconnect the vasa deferentia. In women the desire for a reversal is often associated with a change in spouse.[74] Pregnancy success rates after tubal reversal are between 31 and 88 percent, with complications including an increased risk of ectopic pregnancy.[74] The number of males who request reversal is between 2 and 6 percent.[75] Rates of success in fathering another child after reversal are between 38 and 84 percent; with success being lower the longer the time period between the original procedure and the reversal.[75] Sperm extraction followed by in vitro fertilization may also be an option in men.[76]

## Behavioral [edit]

Behavioral methods involve regulating the timing or method of intercourse to prevent introduction of sperm into the female reproductive tract, either altogether or when an egg may be present.[77] If used perfectly the first-year failure rate may be around 3.4%, however if used poorly first-year failure rates may approach 85%.[78]

## Fertility awareness [edit]

Fertility awareness methods involve determining the most fertile days of the menstrual cycle and avoiding unprotected intercourse.[77] Techniques for determining fertility include monitoring basal body temperature, cervical secretions, or the day of the cycle.[77] They have typical first-year failure rates of 24%; perfect use first-year failure rates depend on which method is used and range from 0.4% to 5%.[21] The evidence on which these estimates are based, however, is poor as the majority of people in trials stop their use early.[77] Globally, they are used by about 3.6% of couples.[79] If based on both basal body temperature and another primary sign, the method is referred to as symptothermal. Overall first-year failure rates of <2% to 20% have been reported in clinical studies of the symptothermal method.[80][81]

A CycleBeads, used for estimating fertility based on days since last menstruation

## Withdrawal [edit]

The withdrawal method (also known as coitus interruptus) is the practice of ending intercourse ("pulling out") before ejaculation.[82] The main risk of the withdrawal method is that the man may not perform the maneuver correctly or in a timely manner.[82] First-year failure rates vary from 4% with perfect usage to 22% with typical usage.[21] It is not considered birth control by some medical professionals.[27]

There is little data regarding the sperm content of pre-ejaculatory fluid.[83] While some tentative research did not find sperm,[83] one trial found sperm present in 10 out of 27 volunteers.[84] The withdrawal method is used as birth control by about 3% of couples.[79]

## Abstinence [edit]

Though some groups advocate total sexual abstinence, by which they mean the avoidance of all sexual activity, in the context of birth control the term usually means abstinence from vaginal intercourse.[85][86] Abstinence is 100% effective in preventing pregnancy; however, not everyone who intends to be abstinent refrains from all sexual activity, and in many populations there is a significant risk of pregnancy from nonconsensual sex.[87][88]

Abstinence-only sex education does not reduce teenage pregnancy.[7][89] Teen pregnancy rates are higher in students given abstinence-only education, as compared with comprehensive sex education.[89][90] Some authorities recommend that those using abstinence as a primary method have backup method(s) available (such as condoms or emergency contraceptive pills).[91] Deliberate non-penetrative sex without vaginal sex or deliberate oral sex without vaginal sex are also sometimes considered birth control.[92] While this generally avoids pregnancy, pregnancy can still occur with intercrural sex and other forms of penis-near-vagina sex (genital rubbing, and the penis exiting from anal intercourse) where sperm can be deposited near the entrance to the vagina and can travel along the vagina's lubricating fluids.[93][94]

## Lactation [edit]

The lactational amenorrhea method involves the use of a woman's natural postpartum infertility which occurs after delivery and may be extended by breastfeeding.[95] This usually requires the presence of no periods, exclusively breastfeeding the infant, and a child younger than six months.[24] The World Health Organization states that if breastfeeding is the infant's only source of nutrition, the failure rate is 2% in the six months following delivery.[96] Six uncontrolled studies of lactational amenorrhea method users found failure rates at 6 months postpartum between 0% and 7.5%.[97] Failure rates increase to 4–7% at one year and 13% at two years.[98] Feeding formula, pumping instead of nursing, the use of a pacifier, and feeding solids all increase its failure rate.[99] In those who are exclusively breastfeeding, about 10% begin having periods before three months and 20% before six months.[98] In those who are not breastfeeding, fertility may return four weeks after delivery.[98]

### Emergency [edit]

A split dose of two emergency contraceptive pills

Emergency contraceptive methods are medications (sometimes misleadingly referred to as "morning-after pills")[100] or devices used after unprotected sexual intercourse with the hope of preventing pregnancy.[8] They work primarily by preventing ovulation or fertilization.[2][101] They are unlikely to affect implantation, but this has not been completely exclude.[101] A number of options exist, including high dose birth control pills, levonorgestrel, mifepristone, ulipristal and IUDs.[102] Levonorgestrel pills, when used within 3 days, decrease the chance of pregnancy after a single episode of unprotected sex or condom failure by 70% (resulting in a pregnancy rate of 2.2%).[8] Ulipristal, when used within 5 days, decreases the chance of pregnancy by about 85% (pregnancy rate 1.4%) and might be a little more effective than levonorgestrel.[8][102][103] Mifepristone is also more effective than levonorgestrel while copper IUDs are the most effective method.[102] IUDs can be inserted up to five days after intercourse and prevent about 99% of pregnancies after an episode of unprotected sex (pregnancy rate of 0.1 to 0.2%).[2][104] This makes them the most effective form of emergency contraceptive.[105] In those who are overweight or obese levonorgestrel is less effective and an IUD or ulipristal is recommended.[106]

Providing emergency contraceptive pills to women in advance does not affect rates of sexually transmitted infections, condom use, pregnancy rates, or sexual risk-taking behavior.[107][108] All methods have minimal side effects.[102]

### Dual protection [edit]

Dual protection is the use of methods that prevent both sexually transmitted infections and pregnancy.[109] This can be with condoms either alone or along with another birth control method or by the avoidance of penetrative sex.[110][111] If pregnancy is a high concern using two methods at the same time is reasonable,[110] and two forms of birth control is recommended in those taking the anti-acne drug isotretinoin, due to the high risk of birth defects if taken during pregnancy.[112]

## Effects [edit]

### Health [edit]

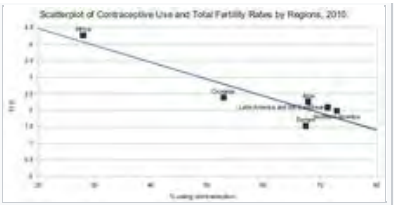
*See also: Maternal health*

Maternal mortality rate as of 2010.[113]

Contraceptive use in developing countries is estimated to have decreased the number of maternal deaths by 40% (about 270,000 deaths prevented in 2008) and could prevent 70% of deaths if the full demand for birth control were met.[17][18] These benefits are achieved by reducing the number of unplanned pregnancies that subsequently result in unsafe abortions and by preventing pregnancies in those at high risk.[17]

Birth control also improves child survival in the developing world by lengthening the time between pregnancies.[17] In this population, outcomes are worse when a mother gets pregnant within eighteen months of a previous delivery.[17][114] Delaying another pregnancy after a miscarriage however does not appear to alter risk and women are advised to attempt pregnancy in this situation whenever they are ready.[114]

Teenage pregnancies, especially among younger teens, are at greater risk of adverse outcomes including early birth, low birth weight, and death of the

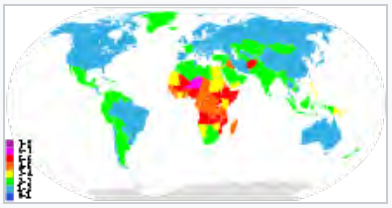


Contraceptive use and total fertility rate by region.

infant.[12] In the United States 82% of pregnancies in those between 15 and 19 are unplanned.[67] Comprehensive sex education and access to birth control are effective in decreasing pregnancy rates in this age group.[115]

## Finances [edit]

*See also: Family economics and Cost of raising a child*



Countries by fertility rate as of 2015

| | |
|---|---|
| 7–8 Children | 3–4 Children |
| 6–7 Children | 2–3 Children |
| 5–6 Children | 1–2 Children |
| 4–5 Children | 0–1 Children |

In the developing world, birth control increases economic growth due to there being fewer dependent children and thus more women participating in the workforce.[19] Women's earnings, assets, body mass index, and their children's schooling and body mass index all improve with greater access to birth control.[19] Family planning via the use of modern birth control is one of the most cost-effective health interventions.[116] For every dollar spent, the United Nations estimates that two to six dollars are saved.[16] These cost savings are related to preventing unplanned pregnancies and decreasing the spread of sexually transmitted illnesses.[116] While all methods are beneficial financially, the use of copper IUDs resulted in the greatest savings.[116]

The total medical cost for a pregnancy, delivery and care of a newborn in the United States is on average $21,000 for a vaginal delivery and $31,000 for a Caesarean section as of 2012.[117] In most other countries the cost is less than half.[117] For a child born in 2011, an average US family will spend $235,000 over 17 years to raise them.[118]

# Prevalence [edit]

*Main article: Prevalence of birth control*

Percentage of women using modern birth control as of 2010

| | | |
|---|---|---|
| 6% | 42% | 78% |
| 12% | 48% | 84% |
| 18% | 54% | 86% |
| 24% | 60% | No data |
| 30% | 66% | |
| 36% | 72% | |

Globally, as of 2009, approximately 60% of those who are married and able to have children use birth control.[119] How frequently different methods are used varies widely between countries.[119] The most common method in the developed world is condoms and oral contraceptives, while in Africa it is oral contraceptives and in Latin America and Asia it is sterilization.[119] In the developing world overall, 35% of birth control is via female sterilization, 30% is via IUDs, 12% is via oral contraceptives, 11% is via condoms, and 4% is via male sterilization.[119]

While less used in the developed countries than the developing world, the number of women using IUDs as of 2007 was more than 180 million.[61] Avoiding sex when fertile is used by about 3.6% of women of childbearing age, with usage as high as 20% in areas of South America.[120] As of 2005, 12% of couples are using a male form of birth control (either condoms or a vasectomy) with higher rates in the developed world.[121] Usage of male forms of birth control has decreased between 1985 and 2009.[119] Contraceptive use among women in Sub-Saharan Africa has risen from about 5% in 1991 to about 30% in 2006.[122]

As of 2012, 57% of women of childbearing age want to avoid pregnancy (867 of 1520 million).[123] About 222 million women however were not able to access birth control, 53 million of whom were in sub-Saharan Africa and 97 million of whom were in Asia.[123] This results in 54 million unplanned pregnancies and nearly 80,000 maternal deaths a year.[119] Part of the reason that many women are without birth control is that many countries limit access due to religious or political reasons,[2] while another contributor is poverty.[124] Due to restrictive abortion laws in Sub-Saharan Africa, many women turn to unlicensed abortion providers for unintended pregnancy, resulting in about 2–4% obtaining unsafe abortions each year.[124]

# History [edit]

*Main article: History of birth control*

## Early history [edit]

The Egyptian Ebers Papyrus from 1550 BCE and the Kahun Papyrus from 1850 BCE have within them some of the earliest documented descriptions of birth control: the use of honey, acacia leaves and lint to be placed in the vagina to block sperm.[125][126] It is believed that in Ancient Greece silphium was used as birth control which, due to its effectiveness and thus desirability, was harvested into extinction.[127]

Ancient silver coin from Cyrene depicting a stalk of silphium

In medieval Europe, any effort to halt pregnancy was deemed immoral by the Catholic Church,[125] although it is believed that women of the time still used a number of birth control measures, such as coitus interruptus and inserting lily root and rue into the vagina.[128] Women in the Middle Ages were also encouraged to tie weasel testicles around their thighs during sex to prevent pregnancy.[129] The oldest condoms discovered to date were recovered in the ruins of Dudley Castle in England, and are dated back to 1640.[129] They were made of animal gut, and were most likely used to prevent the spread of sexually transmitted diseases during the English Civil War.[129] Casanova, living in 18th century Italy, described the use of a lambskin covering to prevent pregnancy; however, condoms only became widely available in the 20th century.[125]

## Birth control movement [edit]

"And the villain still pursues her", a satirical Victorian era postcard

The birth control movement developed during the 19th and early 20th centuries.[130] The Malthusian League, based on the ideas of Thomas Malthus, was established in 1877 in the United Kingdom to educate the public about the importance of family planning and to advocate for getting rid of penalties for promoting birth control.[131] It was founded during the "Knowlton trial" of Annie Besant and Charles Bradlaugh, who were prosecuted for publishing on various methods of birth control.[132]

In the United States, Margaret Sanger and Otto Bobsein popularized the phrase "birth control" in 1914.[133][134] Sanger was mainly active in the United States but had gained an international reputation by the 1930s. At the time, under the Comstock Law, distribution of birth control information was illegal. She jumped bail in 1914 after her arrest for distributing birth control information and left the United States for the United Kingdom to return in 1915.[135] Sanger established a short-lived birth-control clinic based in the Brownville section of Brooklyn, New York [136] in 1916, which was shut down after eleven days and resulted in her arrest.[137] The publicity surrounding the arrest, trial, and appeal sparked birth control activism across the United States.[138]

The first permanent birth-control clinic was established in Britain in 1921 by Marie Stopes working with the Malthusian League.[139] The clinic, run by midwives and supported by visiting doctors,[140] offered women's birth-control advice and taught them the use of a cervical cap. Her clinic made contraception acceptable during the 1920s by presenting it in scientific terms. In 1921, Sanger founded the American Birth Control League, which later became the Planned Parenthood Federation of America.[141] In 1924 the Society for the Provision of Birth Control Clinics was founded to campaign for municipal clinics; this led to the opening of a second clinic in Greengate, Salford in 1926.[142] Throughout the 1920s, Stopes and other feminist pioneers, including Dora Russell and Stella Browne, played a major role in breaking down taboos about sex. In April 1930 the Birth Control Conference assembled 700 delegates and was successful in bringing birth control and abortion into the political sphere – three months later, the Ministry of Health, in the United Kingdom, allowed local authorities to give birth-control advice in welfare centres.[143]

In 1936 the U.S. court ruled in U.S. v. One Package that medically prescribing contraception to save a persons life or well being was not illegal under the Comstock Law; following this decision, the American Medical Association Committee on Contraception revoked its 1936 statement condemning birth control. A national survey in 1937 showed 71 percent of the adult population supported the use of contraception. By 1938 347 birth control clinics were running in the United States despite their advertisement still being illegal. First Lady Eleanor Roosevelt publicly supported birth control and family planning.[144] In 1966, President Lyndon B. Johnson started endorsing public funding for family planning services, and the Federal Government began subsidizing birth control services for low-income families.[145] The Affordable Care Act, passed into law on March 23, 2010 under President Barack Obama, requires all plans in the Health Insurance Marketplace to cover contraceptive methods. These include barrier methods, hormonal methods, implanted devices, emergency contraceptives, and sterilization procedures.[146]

## Modern methods [edit]

In 1909, Richard Richter developed the first intrauterine device made from silkworm gut, which was further developed and marketed in Germany by Ernst Gräfenberg in the late 1920s.[147] In 1951, a chemist, named Carl Djerassi from Mexico City made the hormones in progesterone pill using Mexican yams.[148] Djerassi had chemically created the pill but was not equipped to distribute them to patients. Meanwhile, Gregory Pincus and John Rock with help from the Planned Parenthood Federation of America developed the first birth control pills in the 1950s, such as mestranol/noretynodrel, which became publicly available in the 1960s through the Food and Drug Administration under the name *Enovid*.[141][149] Medical abortion became an alternative to surgical abortion with the availability of prostaglandin analogs in the 1970s and mifepristone in the 1980s.[150]

# Society and culture [edit]

## Legal positions [edit]

*Further information: Timeline of reproductive rights legislation*

Human rights agreements require most governments to provide family planning and contraceptive information and services. These include the requirement to create a national plan for family planning services, remove laws that limit access to family planning, ensure that a wide variety of safe and effective birth control methods are available including emergency contraceptives, make sure there are appropriately trained healthcare providers and facilities at an affordable price, and create a process to review the programs implemented. If governments fail to do the above it may put them in breach of binding international treaty obligations.[151]

In America, Griswold v. Connecticut overturned a state law prohibiting dissemination of contraception information based on a constitutional right to privacy for marital relationships. In 1971, Eisenstadt v. Baird extended this right to privacy to single people.[152]

In 2010, the United Nations launched the *Every Woman Every Child* movement to assess the progress toward meeting women's contraceptive needs. The initiative has set a goal of increasing the number of users of modern birth control by 120 million women in the world's 69 poorest countries by the year 2020. Additionally, they aim to eradicate discrimination against girls and young women who seek contraceptives.[153] The American Congress of Obstetricians and Gynecologists (ACOG) recommended in 2014 that oral birth control pills should be over the counter medications.[154]

Since at least the 1870s, American religious, medical, legislative, and legal commentators have debated contraception laws. Ana Garner and Angela Michel have found that in these discussions men often attach reproductive rights to moral and political matters, as part of an ongoing attempt to regulate human bodies. In press coverage between 1873-2013 they found a divide between institutional ideology and real-life experiences of women.[155]

## Religious views [edit]

*Main article: Religion and birth control*

Religions vary widely in their views of the ethics of birth control.[156] The Roman Catholic Church officially only accepts natural family planning,[157] although large numbers of Catholics in developed countries accept and use modern methods of birth control.[158][159][160] Among Protestants there is a wide range of views from supporting none to allowing all methods of birth control.[161] Views in Judaism range from the stricter Orthodox sect to the more relaxed Reform sect.[162] Hindus may use both natural and artificial contraceptives.[163] A common Buddhist view is that preventing conception is acceptable, while intervening after conception has occurred is not.[164] In Islam, contraceptives are allowed if they do not threaten health, although their use is discouraged by some.[165]

## World Contraception Day [edit]

September 26 is World Contraception Day, devoted to raising awareness and improving education about sexual and reproductive health, with a vision of *a world where every pregnancy is wanted.*[166] It is supported by a group of governments and international NGOs, including the Office of Population Affairs, the Asian Pacific Council on Contraception, Centro Latinamericano Salud y Mujer, the European Society of Contraception and Reproductive Health, the German Foundation for World Population, the International Federation of Pediatric and Adolescent Gynecology, International Planned Parenthood Federation, the Marie Stopes International, Population Services International, the Population Council, the United States Agency for International Development (USAID), and Women Deliver.[166]

## Misconceptions [edit]

There are a number of common misconceptions regarding sex and pregnancy.[167] Douching after sexual intercourse [168]

is not an effective form of birth control. Additionally, it is associated with a number of health problems and thus is not recommended.[169] Women can become pregnant the first time they have sexual intercourse[170] and in any sexual position.[171] It is possible, although not very likely, to become pregnant during menstruation.[172]

## Research directions [edit]

### Females [edit]

Improvements of existing birth control methods are needed, as around half of those who get pregnant unintentionally are using birth control at the time.[27] A number of alterations of existing contraceptive methods are being studied, including a better female condom, an improved diaphragm, a patch containing only progestin, and a vaginal ring containing long-acting progesterone.[173] This vaginal ring appears to be effective for three or four months and is currently available in some areas of the world.[173] For women who rarely have sex, the taking of the hormonal birth control levonorgestrel around the time of sex looks promising.[174]

A number of methods to perform sterilization via the cervix are being studied. One involves putting quinacrine in the uterus which causes scarring and infertility. While the procedure is inexpensive and does not require surgical skills, there are concerns regarding long-term side effects.[175] Another substance, polidocanol, which functions in the same manner is being looked at.[173] A device called Essure, which expands when placed in the fallopian tubes and blocks them, was approved in the United States in 2002.[175]

### Males [edit]

*Main article: Male contraceptive*

Methods of male birth control include condoms, vasectomies and withdrawal.[176][177] Between 25 and 75% of males who are sexually active would use hormonal birth control if it was available for them.[121][176] A number of hormonal and non-hormonal methods are in trials,[121] and there is some research looking at the possibility of contraceptive vaccines.[178]

A reversible surgical method under investigation is reversible inhibition of sperm under guidance (RISUG) which consists of injecting a polymer gel, styrene maleic anhydride in dimethyl sulfoxide, into the vas deferens. An injection with sodium bicarbonate washes out the substance and restores fertility. Another is an intravas device which involves putting a urethane plug into the vas deferens to block it. A combination of an androgen and a progestin seems promising, as do selective androgen receptor modulators.[121] Ultrasound and methods to heat the testicles have undergone preliminary studies.[179]

## Other animals [edit]

Neutering or spaying, which involves removing some of the reproductive organs, is often carried out as a method of birth control in household pets. Many animal shelters require these procedures as part of adoption agreements.[180] In large animals the surgery is known as castration.[181]

Birth control is also being considered as an alternative to hunting as a means of controlling overpopulation in wild animals.[182] Contraceptive vaccines have been found to be effective in a number of different animal populations.[183][184] Kenyan goat herders fix a skirt, called and olor, to male goats to prevent them from impregnating female goats.[185]

# Carbamazepine

From Wikipedia, the free encyclopedia
(Redirected from Carbamazepine)

**Carbamazepine** (**CBZ**), sold under the tradename **Tegretol** among others, is a medication used primarily in the treatment of epilepsy and neuropathic pain.[2] It is not effective for absence seizures or myoclonic seizures. It is used in schizophrenia along with other medications and as a second line agent in bipolar disorder.[2] Carbamazepine appears to work as well as phenytoin and valproate.[3][4]

Common side effects include nausea and drowsiness. Serious side effects may include skin rashes, decreased bone marrow function, suicidal thoughts, or confusion. It should not be used in those with a history of bone marrow problems. Use during pregnancy may cause harm to the baby; however stopping it in pregnant women with seizures is not recommended. Its use during breastfeeding is not recommended. Care should be taken in those with either kidney or liver problems.[2]

Carbamazepine was discovered in 1953 by Swiss chemist Walter Schindler.[5] It was first marketed in 1962.[6] It is available as a generic medication and is not very expensive.[7] It is on the WHO Model List of Essential Medicines, the most important medications needed in a basic health system.[8] The wholesale cost in the developing world is between 0.01 and 0.07 USD per dose as of 2014.[9]

## Medical uses [edit]

Carbamazepine is typically used for the treatment of seizure

disorders and neuropathic pain.[2] It is used off-label as a second-line treatment for bipolar disorder and in combination with an antipsychotic in some cases of schizophrenia when treatment with a conventional antipsychotic alone has failed.[2][10] It is not effective for absence seizures or myoclonic seizures.[2]

In the United States, the FDA-approved medical uses are epilepsy (including partial seizures, generalized tonic-clonic seizures and mixed seizures), trigeminal neuralgia, and manic and mixed episodes of bipolar I disorder.[11]

As of 2014 a controlled release formulation was available for which there is tentative evidence showing fewer side effects and unclear evidence with regard to whether there is a difference in efficacy.[12]

## Adverse effects [edit]

In the US, the label for carbamazepine contains warnings concerning:

- effects on the body's production of red blood cells, white blood cells, and platelets: rarely, there are major effects of aplastic anemia and agranulocytosis reported and more commonly, there are minor changes such as decreased white blood cell or platelet counts, that do not progress to more serious problems.[1]
- increased risks of suicide[1]
- increased risks of hyponatraemia and SIADH[1][13]
- risk of seizures, if the person stops taking the drug abruptly[1]
- risks to the fetus in women who are pregnant, specifically congenital malformations like spina bifida, and developmental disorders.[1][14]

Common adverse effects may include drowsiness, dizziness, headaches and migraines, motor coordination impairment, nausea, vomiting, and/or constipation. Alcohol use while taking carbamazepine may lead to enhanced depression of the central nervous system.[1] Less common side effects may include increased risk of seizures in people with mixed seizure disorders,[15] abnormal heart rhythms, blurry or double vision.[1] Also, rare case reports of an auditory side effect have been made, whereby patients perceive sounds about a semitone lower than previously; this unusual side effect is usually not noticed by most people, and disappears after the person stops taking carbamazepine.[16]

## Interactions [edit]

Carbamazepine has a potential for drug interactions; caution should be used in combining other medicines with it, including other antiepileptics and mood stabilizers.[11] Lower levels of carbamazepine are seen when administrated with phenobarbital, phenytoin, or primidone, which can

result in breakthrough seizure activity. Carbamazepine, as a CYP450 inducer, may increase clearance of many drugs, decreasing their concentration in the blood to subtherapeutic levels and reducing their desired effects.[17] Drugs that are more rapidly metabolized with carbamazepine include warfarin, lamotrigine, phenytoin, theophylline, and valproic acid.[11] Drugs that decrease the metabolism of carbamazepine or otherwise increase its levels include erythromycin,[18] cimetidine, propoxyphene, and calcium channel blockers.[11] Carbamazepine also increases the metabolism of the hormones in birth control pills and can reduce their effectiveness, potentially leading to unexpected pregnancies.[11] As a drug that induces cytochrome P450 enzymes, it accelerates elimination of many benzodiazepines and decreases their action.[19]

Valproic acid and valnoctamide both inhibit microsomal epoxide hydrolase (MEH), the enzyme responsible for the breakdown of carbamazepine-10,11 epoxide into inactive metabolites.[20] By inhibiting MEH, valproic acid and valnoctamide cause a build-up of the active metabolite, prolonging the effects of carbamazepine and delaying its excretion.

Grapefruit juice raises the bioavailability of carbamazepine by inhibiting CYP3A4 enzymes in the gut wall and in the liver.[1] Carbamazepine increases the processing of methadone resulting in lower blood levels.[21]

### Pharmacogenetics [edit]

Dangerous and potentially fatal skin reactions, including Stevens–Johnson syndrome and toxic epidermal necrolysis, caused by carbamazepine therapy are significantly more common in patients with a particular human leukocyte antigen allele, HLA-B*1502.[22] Odds ratios for the development of Stevens-Johnson syndrome or toxic epidermal necrolysis in patients who carry the allele can be in the double, triple or even quadruple digits, depending on the population studied.[23][24] HLA-B*1502 occurs almost exclusively in patients with ancestry across broad areas of Asia, but has a very low or absent frequency in European, Japanese, Korean and African populations.[22][25] However, the HLA-A*31:01 allele has been shown to be a strong predictor of both mild and severe adverse reactions to carbamazepine among Japanese and Europeans.[24]

## Pharmacokinetics [edit]

Carbamazepine is relatively slowly but well absorbed after oral administration. Its plasma half-life is about 30 hours when it is given as single dose, but it is a strong inducer of hepatic enzymes and the plasma half-life shortens to about 15 hours when it is given repeatedly.[*medical citation needed*]

## Mechanism of action [edit]

The mechanism of action of carbamazepine and its derivatives is relatively well understood. Carbamazepine is a use-dependant blocker of voltage-gated sodium channels. It is ionised within intracellular fluid, and is then able to bind to activated voltage-gated sodium channels, preventing repetitive and sustained firing of an action potential.This leaves the affected cells less excitable until the drug dissociates. Carbamazepine is

also a GABA receptor agonist, as it has also been shown to potentiate GABA receptors made up of alpha1, beta2, and gamma2 subunits.[26] This mechanism may contribute to its efficacy in neuropathic pain and bipolar disorder. Laboratory research has further demonstrated that carbamazepine is a serotonin releasing agent and possibly even a serotonin reuptake inhibitor.[27][28][29]

## History [edit]

Carbamazepine was discovered by chemist Walter Schindler at J.R. Geigy AG (now part of Novartis) in Basel, Switzerland, in 1953.[30][31] It was first marketed as a drug to treat epilepsy in Switzerland in 1963 under the brand name "Tegretol"; its use for trigeminal neuralgia (formerly known as tic douloureux) was introduced at the same time.[30] It has been used as an anticonvulsant and antiepileptic in the UK since 1965, and has been approved in the US since 1968.[2]

In 1971, Drs. Takezaki and Hanaoka first used carbamazepine to control mania in patients refractory to antipsychotics (lithium was not available in Japan at that time). Dr. Okuma, working independently, did the same thing with success. As they were also epileptologists, they had some familiarity with the antiaggression effects of this drug. Carbamazepine was studied for bipolar disorder throughout the 1970s.[32]

## Environmental fate [edit]

*Main article: Environmental impact of pharmaceuticals and personal care products*

Carbamazepine has been detected in wastewater effluent.[33]:224 Field and laboratory studies have been conducted to understand the accumulation of carbamazepine in food plants grown in soil treated with sludge, which vary with respect to the concentrations of carbamazepine present in sludge and in the concentrations of sludge in the soil; taking into account only studies that used concentrations normally found, a 2014 review found that "the accumulation of carbamazepine into plants grown in soil amended with biosolids poses a *de minimis* risk to human health according to the approach."[33]:227

## Brand names [edit]

Carbamazepine is available worldwide under many brand names.[34]

# Cefalexin

From Wikipedia, the free encyclopedia

(Redirected from Cephalexin)

**Cefalexin**, also spelled **cephalexin**, is an antibiotic that can treat a number of bacterial infections. It kills gram-positive and some gram-negative bacteria by disrupting the growth of the bacterial cell wall. Cefalexin is a beta-lactam antibiotic within the class of first-generation cephalosporins.[3] It works similarly to other agents within this class, including intravenous cefazolin, but can be taken by mouth.[4]

Cefalexin can treat certain bacterial infections, including those of the middle ear, bone and joint, skin, and urinary tract. It may also be used for certain types of pneumonia, strep throat, and to prevent bacterial endocarditis. Cefalexin is not effective against infections caused by methicillin-resistant *Staphylococcus aureus* (MRSA), *Enterococcus*, or *Pseudomonas*. Like other antibiotics, cefalexin cannot treat viral infections, such as the flu, common cold or acute bronchitis. Cefalexin can be used in those who have mild or moderate allergies to penicillin. However, it is not recommended in those with severe penicillin allergies.[3]

Common side effects include stomach upset and diarrhea.[3] An allergic reaction and infection with *Clostridium difficile*, a type of diarrhea, is also possible.[3] To date, no evidence of harm to the baby has been found when used during pregnancy[3][5] or breast feeding.[6] It can be used in children and those over 65 years of age. Those with kidney problems may require a decrease in dose.[3]

In 2012, cefalexin was one of the top 100 most prescribed medications in the United States.[7] In Canada, it was the 5th most common antibiotic used in 2013.[8] In Australia, it is one of the top 15 most prescribed medications.[9] Cefalexin was developed in 1967.[10] It was first marketed in 1969 and 1970 under the names **Keflex** and **Ceporex**, among others.[1][11] Generic drug versions are available under several other trade names and are inexpensive.[3][12] Cefalexin is on the World Health Organization's List of Essential Medicines, the most important medications needed in a health system.[13]

**Contents**

## Medical uses [edit]

A course of cefalexin capsules, commonly prescribed for infections

Cefalexin can treat a number of bacterial infections including: otitis media, streptococcal pharyngitis, bone and joint infections, pneumonia, cellulitis, and urinary tract infections.[3] It may be used to prevent bacterial endocarditis.[3] It can also be used for the prevention of recurrent urinary-tract infections.[14]

Cefalexin does not treat methicillin-resistant *Staphylococcus aureus* infections.[14]

Cefalexin is a useful alternative to penicillins in patients with penicillin intolerance. For example, penicillin is the treatment of choice for respiratory tract infections caused by *Streptococcus*, but cefalexin may be used as an alternative in penicillin-intolerant patients.[15] Caution must be exercised when administering cephalosporin antibiotics to penicillin-sensitive patients, because cross sensitivity with beta-lactam antibiotics has been documented in up to 10% of patients with a documented penicillin allergy.[16]

## Pregnancy and breastfeeding [edit]

It is pregnancy category B in the United States and category A in Australia, meaning that no evidence of harm has been found after being taken by many pregnant women.[3][5] Use during breast feeding is generally safe.[6]

## Adverse effects [edit]

The most common adverse effects of cefalexin, like other oral cephalosporins, are gastrointestinal (stomach area) disturbances and hypersensitivity reactions. Gastrointestinal disturbances include nausea, vomiting, and diarrhea, diarrhea being most common.[17] Hypersensitivity reactions include skin rashes, urticaria, fever, and anaphylaxis.[18] Pseudomembranous colitis and *Clostridium difficile* have been reported with use of cefalexin.[18]

Signs and symptoms of an allergic reaction include rash, itching, swelling, trouble breathing, or red, blistered, swollen, or peeling skin. Overall, cefalexin allergy occurs in less than 0.1% of patients, but it is seen in 1% to 10% of patients with a penicillin allergy.[19]

## Interactions [edit]

Like other β-lactam antibiotics, renal excretion of cefalexin is delayed by probenecid.[20] Alcohol consumption does not have a negative interaction with cefalexin,[21] but reduces the rate at which it is absorbed.[22] Cefalexin also interacts with metformin, an antidiabetic drug,[18] and this can lead to higher concentrations of metformin in the body.[18][23]

## Mechanism of action [edit]

Cefalexin is a beta-lactam antibiotic of the cephalosporin family.[24] It is bactericidal and acts by inhibiting synthesis of the peptidoglycan layer of the bacterial cell wall.[25] As cefalexin closely resembles d-alanyl-d-alanine, an amino acid ending on the peptidoglycan layer of the cell wall, it is able to irreversibly bind to the active site of PBP, which is essential for the synthesis of the cell wall.[25] It is most active against gram-positive cocci, and has moderate activity against some gram-negative bacilli.[26] However, some bacterial cells have the enzyme β-lactamase, which hydrolyzes the beta-lactam ring, rendering the drug inactive. This contributes to antibacterial resistance towards cephalexin.[27]

## Society and culture [edit]

Cefalexin is on the World Health Organization's List of Essential Medicines, the most important medications needed in a health system.[13] The World Health Organization classifies cephalexin as a highly important antimicrobial in their list of Critically Important Antimicrobials for Human Medicine.[28]

### Names [edit]

Cefalexin is the INN and BAN while cephalexin is the USAN and AAN.

Common brand names for cefalexin include Keflex, Cepol, Ceporexine, Ceporex, Cefadal, Derantel, Mecilex, Medoxine, Sporibest (Bionova), Xahl, and Tokiolexin.[29]

# Cholera vaccine

From Wikipedia, the free encyclopedia

**Cholera vaccines** are vaccines that are effective at preventing cholera.[1] They are about 85% effective during the first six months and 50–60% effective during the first year.[1][2][3] The effectiveness decreases to less than 50% after two years. When a significant portion of the population is immunized benefits from herd immunity may occur among those not immunized. The World Health Organization recommends their use in combination with other measures among those at high risk. Two doses or three doses of the oral form are typically recommended.[1] An injectable form is available in some, but not all, areas of the world.[1][2]

Both of the available types of oral vaccine are generally safe. Mild abdominal pain or diarrhea may occur. They are safe in pregnancy and in those with poor immune function. They are licensed for use in more than 60 countries. In countries where the disease is common, the vaccine appears to be cost effective.[1]

The first vaccines used against cholera were developed in the late 1800s. They were the first widely used vaccine that was made in a laboratory.[4] Oral vaccines were first introduced in the 1990s.[1] It is on the World Health Organization's List of Essential Medicines, the most important medication needed in a basic health system.[5] The cost to immunize against cholera is between 0.1 and 4.0 USD.[6]

Contents

## Medical use [edit]

Oral cholera vaccines are increasingly used as an additional tool to control cholera outbreaks in combination with the traditional interventions to improve safe water supply, sanitation, handwashing and other means to improve hygiene. Since licensure of Dukoral and Shanchol, over a million doses of these vaccines have been deployed in various mass oral cholera campaigns around the world.[7] In addition, Vietnam incorporates oral cholera vaccination in its public health programme and over 9 million doses have been administered through targeted mass vaccination or immunization of school-aged children in cholera endemic regions.

(what is this?) (verify)

The cholera vaccine is largely used by backpackers and persons visiting locations where there is a high risk of cholera infection. However, since it does not provide 100% immunity from the disease, food hygiene precautions should also be taken into consideration when visiting an area where there is a high risk of becoming infected with cholera. Although the protection observed has been described as "moderate", herd immunity can multiply the effectiveness of vaccination. Dukoral has been licensed for children 2 years of age and older, Shanchol for children 1 year of age and older. The administration of the vaccine to adults confers additional indirect protection (herd immunity) to children.

The World Health Organization (WHO) recommends both preventive and reactive use of the vaccine, making the following key statements:[8]

> WHO recommends that current available cholera vaccines be used as complements to traditional control and preventive measures in areas where the disease is endemic and should be considered in areas at risk for outbreaks. Vaccination should not disrupt the provision of other high priority health interventions to control or prevent cholera outbreaks.... Reactive vaccination might be considered in view of limiting the extent of large prolonged outbreaks, provided the local infrastructure allows it, and an in-depth analysis of past cholera data and identification of a defined target area have been performed.

The WHO as of late 2013 established a revolving stockpile of 2 million OCV doses.[9] The supply is increasing to 6 million as a South Korean companies has gone into production (2016), the old production not being able to handle WHO demand in Haiti and Sudan for 2015, nor prior years. GAVI Alliance donated $115 million to help pay for expansions.[10][11]

## Oral [edit]

Oral vaccines provide protection in 52% of cases the first year following vaccination and in 62% of cases the second year.[3] There are two variants of the oral vaccine currently in use: WC-rBS and BivWC. WC-rBS (marketed as "Dukoral") is a monovalent inactivated vaccine containing killed whole cells of *V. cholerae* O1 plus additional recombinant cholera toxin B subunit. BivWC (marketed as "Shanchol" and "mORCVAX") is a bivalent inactivated vaccine containing killed whole cells of *V. cholerae* O1 and *V. cholerae* O139. mORCVAX is only available in Vietnam.

Dukoral: vial of inactivated vaccine with packet of sodium bicarbonate buffer.

Bacterial strains of both Inaba and Ogawa serotypes and of El Tor and Classical biotypes are included in the vaccine. Dukoral is taken orally with bicarbonate buffer, which protects the antigens from the gastric acid. The vaccine acts by inducing antibodies against both the bacterial components and CTB. The antibacterial intestinal antibodies prevent the bacteria from attaching to the intestinal wall, thereby impeding colonisation of V. cholerae O1. The anti-toxin intestinal antibodies prevent the cholera toxin from binding to the intestinal mucosal surface, thereby preventing the toxin-mediated diarrhoeal symptoms.[12]

## Injectable [edit]

Although rarely in use, the injected cholera vaccines are effective for people living where cholera is common. They offer some degree of protection for up to two years after a single shot, and for three to four years with annual booster. They reduce the risk of death from cholera by 50% in the first year after vaccination.[2]

# Side effects [edit]

Both of the available types of oral vaccine are generally safe. Mild abdominal pain or diarrhea may occur.

They are safe in pregnancy and in those with poor immune function. They are licensed for use in more than 60 countries. In countries where the disease is common, the vaccine appears to be cost effective.[1]

## Society and culture [edit]

The first vaccines used against cholera were developed in the late 19th century. They were the first widely used vaccine that was made in a laboratory.[4] There were several pioneers in the development of the vaccine. In 1884, Catalan physician Jaume Ferran i Clua developed a live vaccine he had isolated from cholera patients in Marseilles, and used it that on over 30,000 individuals in Valencia during that year's epidemic. Waldemar Haffkine then developed a vaccine with less severe side effects, testing it on more than 40,000 people in the Calcutta area from 1893 to 1896. Finally, in 1896, Wilhelm Kolle introduced a heat-killed vaccine that was significantly easier to prepare than Haffkine's, using it on a large scale in Japan in 1902.[13]

Oral vaccines were first introduced in the 1990s.[1] It is on the World Health Organization's List of Essential Medicines, the most important medication needed in a basic health system.[5] The cost to immunize against cholera is between 0.1 and 4.0 USD.[14]

In 2016 the US Food and Drug Administration approved Vaxchora to prevent cholera for travelers. Vaxchora is the only FDA-approved vaccine for the prevention of cholera.[15]

# Cocaine

From Wikipedia, the free encyclopedia

*For other uses, see Cocaine (disambiguation).*

**Cocaine**, also known as **coke**, is a strong stimulant mostly used as a recreational drug.[9] It is commonly snorted, inhaled, or injected into the veins. Mental effects may include loss of contact with reality, an intense feeling of happiness, or agitation. Physical symptoms may include a fast heart rate, sweating, and large pupils.[8] High doses can result in very high blood pressure or body temperature.[10] Effects begin within seconds to minutes of use and last between five and ninety minutes.[8] Cocaine has a small number of accepted medical uses such as numbing and decreasing bleeding during nasal surgery.[11]

Cocaine is addictive due to its effect on the reward pathway in the brain. After a short period of use, there is a high risk that dependence will occur.[9] Its use also increases the risk of stroke, myocardial infarction, lung problems in those who smoke it, blood infections, and sudden cardiac death.[9][12] Cocaine sold on the street is commonly mixed with local anesthetics, cornstarch, quinine, or sugar which can result in additional toxicity.[13] Following repeated doses a person may have decreased ability to feel pleasure and be very physically tired.[9]

Cocaine acts by inhibiting the reuptake of serotonin, norepinephrine, and dopamine. This results in greater concentrations of these three neurotransmitters in the brain.[9] It can easily cross the blood–brain barrier and may lead to the breakdown of the barrier.[14][15] Cocaine is made from the leaves of the *coca* plant which are mostly grown in South America.[8] In 2013, 419 kilograms were produced legally.[16] It is estimated that the illegal market for cocaine is 100 to 500 billion USD each year. With further processing crack cocaine can be produced from cocaine.[9]

After cannabis, cocaine is the most frequently used illegal drug globally.[17] Between 14 and 21 million people use the drug each year. Use is highest in North America followed by Europe and South America. Between one and three percent of people in the developed world have used cocaine at some point in their life.[9] In 2013 cocaine use directly resulted in 4,300 deaths, up from 2,400 in 1990.[18] The leaves of the *coca*

## Medical

Topical cocaine can be used as a local numbing agent to help with painful procedures in the mouth or nose.[20] TAC is one such formulation used for pediatrics.

Cocaine was historically useful as a topical anesthetic in eye and nasal surgery, although it is now predominantly used for nasal and lacrimal duct surgery. The major disadvantages of this use are cocaine's intense vasoconstrictor activity and the potential for cardiovascular toxicity. Cocaine has since been largely replaced in Western medicine by synthetic local anesthetics such as benzocaine, proparacaine, lidocaine, and tetracaine, though it remains available for use if specified. If vasoconstriction is desired for a procedure (as it reduces bleeding), the anesthetic is combined with a vasoconstrictor such as phenylephrine or epinephrine. In Australia it is currently[*when?*] prescribed for use as a local anesthetic for conditions such as mouth and lung ulcers.[*citation needed*] Some ENT specialists occasionally use cocaine within the practice when performing procedures such as nasal cauterization. In this scenario dissolved cocaine is soaked into a ball of cotton wool, which is placed in the nostril for the 10–15 minutes immediately before the procedure, thus performing the dual role of both numbing the area to be cauterized, and vasoconstriction. Even when used this way, some of the used cocaine may be absorbed through oral or nasal mucosa and give systemic effects.[*citation needed*] An alternative method of administration for ENT surgery is mixed with adrenaline and sodium bicarbonate, as Moffett's Solution.

## Recreational

Cocaine is a powerful nervous system stimulant.[21] Its effects can last from fifteen or thirty minutes to an hour. The duration of cocaine's effects depends on the amount taken and the route of administration.[22] Cocaine can be in the form of fine white powder, bitter to the taste. When inhaled or injected, it causes a numbing effect. Crack cocaine is a smokeable form of cocaine made into small "rocks" by processing cocaine with sodium bicarbonate (baking soda) and water.[*citation needed*]

Cocaine increases alertness, feelings of well-being and euphoria, energy and motor activity, feelings of competence and sexuality. Cocaine's stimulant effects are similar to that of amphetamine, however, these effects tend to be much shorter lasting and more prominent.[*citation needed*]

## Oral

Many users rub the powder along the gum line, or onto a cigarette filter which is then smoked, which numbs the gums and teeth – hence the colloquial names of "numbies", "gummers", or "cocoa puffs" for this type of administration. This is mostly done with the small amounts of cocaine remaining on a surface after insufflation (snorting). Another oral method is to wrap up some cocaine in rolling paper and swallow (parachute) it. This is sometimes called a "snow bomb."[*citation needed*]

A spoon containing baking soda, cocaine, and a small amount of water. Used in a "poor-man's" crack-cocaine production

### Coca leaf

Coca leaves are typically mixed with an alkaline substance (such as lime) and chewed into a wad that is retained in the mouth between gum and cheek (much in the same as chewing tobacco is chewed) and sucked of its juices. The juices are absorbed slowly by the mucous membrane of the inner cheek and by the gastrointestinal tract when

swallowed. Alternatively, coca leaves can be infused in liquid and consumed like tea. Ingesting coca leaves generally is an inefficient means of administering cocaine. Advocates of the consumption of the coca leaf state that coca leaf consumption should not be criminalized as it is not actual cocaine, and consequently it is not properly the illicit drug.[*citation needed*]

Because cocaine is hydrolyzed and rendered inactive in the acidic stomach, it is not readily absorbed when ingested alone. Only when mixed with a highly alkaline substance (such as lime) can it be absorbed into the bloodstream through the stomach. The efficiency of absorption of orally administered cocaine is limited by two additional factors. First, the drug is partly catabolized by the liver. Second, capillaries in the mouth and esophagus constrict after contact with the drug, reducing the surface area over which the drug can be absorbed. Nevertheless, cocaine metabolites can be detected in the urine of subjects that have sipped even one cup of coca leaf infusion. Therefore, this is an actual additional form of administration of cocaine, albeit an inefficient one.[*citation needed*]

Orally administered cocaine takes approximately 30 minutes to enter the bloodstream. Typically, only a third of an oral dose is absorbed, although absorption has been shown to reach 60% in controlled settings. Given the slow rate of absorption, maximum physiological and psychotropic effects are attained approximately 60 minutes after cocaine is administered by ingestion. While the onset of these effects is slow, the effects are sustained for approximately 60 minutes after their peak is attained.[*citation needed*]

Contrary to popular belief, both ingestion and insufflation result in approximately the same proportion of the drug being absorbed: 30 to 60%. Compared to ingestion, the faster absorption of insufflated cocaine results in quicker attainment of maximum drug effects. Snorting cocaine produces maximum physiological effects within 40 minutes and maximum psychotropic effects within 20 minutes, however, a more realistic activation period is closer to 5 to 10 minutes, which is similar to ingestion of cocaine. Physiological and psychotropic effects from nasally insufflated cocaine are sustained for approximately 40–60 minutes after the peak effects are attained.[23]

Coca tea, an infusion of coca leaves, is also a traditional method of consumption. The tea has often been recommended for travelers in the Andes to prevent altitude sickness.[24] However, its actual effectiveness has never been systematically studied.[24] This method of consumption has been practised for many centuries by the indigenous tribes of South America. One specific purpose of ancient coca leaf consumption was to increase energy and reduce fatigue in messengers who made multi-day quests to other settlements.[*citation needed*]

In 1986 an article in the *Journal of the American Medical Association* revealed that U.S. health food stores were selling dried coca leaves to be prepared as an infusion as "Health Inca Tea."[25] While the packaging claimed it had been "decocainized," no such process had actually taken place. The article stated that drinking two cups of the tea per day gave a mild stimulation, increased heart rate, and mood elevation, and the tea was essentially harmless. Despite this, the DEA seized several shipments in Hawaii, Chicago, Georgia, and several locations on the East Coast of the United States, and the product was removed from the shelves.

## Insufflation

Nasal insufflation (known colloquially as "snorting," "sniffing," or "blowing") is a common method of ingestion of recreational powdered cocaine.[26] The drug coats and is absorbed through the mucous membranes lining the nasal passages. When insufflating cocaine, absorption through the nasal membranes is approximately 30–60%, with higher doses leading to increased absorption efficiency. Any material not directly absorbed through the mucous membranes is collected in mucus and swallowed (this "drip" is considered pleasant by some and unpleasant by others). In a study[27] of cocaine users, the average time taken to reach peak subjective effects was 14.6 minutes. Any damage to the inside of the nose is because cocaine highly constricts blood vessels – and therefore blood and oxygen/nutrient flow – to that area.

Lines of cocaine prepared for insufflation

Nosebleeds after cocaine insufflation are due to irritation and damage of mucus membranes by foreign particles and adulterants and not the cocaine itself;[*citation needed*] as a vasoconstrictor, cocaine acts to reduce bleeding.

Rolled up banknotes, hollowed-out pens, cut straws, pointed ends of keys, specialized spoons, long fingernails, and (clean) tampon applicators are often used to insufflate cocaine. Such devices are often called "tooters" by users. The cocaine typically is poured onto a flat, hard surface (such as a mirror, CD case or book) and divided into "bumps", "lines" or "rails", and then insufflated.[28] The amount of cocaine in a line varies widely from person to person and occasion to occasion (the purity of the cocaine is also a factor), but one line is generally considered to be a single dose and is typically 35 mg (a "bump") to 100 mg (a "rail")[*dubious – discuss*]. As tolerance builds rapidly in the short-term (hours), many lines are often snorted to produce greater effects.[*citation needed*]

A 2001 study reported that the sharing of straws used to "snort" cocaine can spread blood diseases such as hepatitis C.[29]

## Injection

Drug injection provides the highest blood levels of drug in the shortest amount of time. Subjective effects not commonly shared with other methods of administration include a ringing in the ears moments after injection (usually when in excess of 120 milligrams) lasting 2 to 5 minutes including tinnitus and audio distortion. This is colloquially referred to as a "bell ringer". In a study of cocaine users, the average time taken to reach peak subjective effects was 3.1 minutes.[27] The euphoria passes quickly. Aside from the toxic effects of cocaine, there is also danger of circulatory emboli from the insoluble substances that may be used to cut the drug. As with all injected illicit substances, there is a risk of the user contracting blood-borne infections if sterile injecting equipment is not available or used. Additionally, because cocaine is a vasoconstrictor, and usage often entails multiple injections within several hours or less, subsequent injections are progressively more difficult to administer, which in turn may lead to more injection attempts and more consequences from improperly performed injection.[*citation needed*]

An injected mixture of cocaine and heroin, known as "speedball" is a particularly dangerous combination, as the converse effects of the drugs actually complement each other, but may also mask the symptoms of an overdose. It has been responsible for numerous deaths, including celebrities such as John Belushi, Chris Farley, Mitch Hedberg, River Phoenix, Layne Staley and Philip Seymour Hoffman.

Experimentally, cocaine injections can be delivered to animals such as fruit flies to study the mechanisms of cocaine addiction.[30]

## Inhalation

*See also: Crack cocaine*

Inhalation or smoking is one of the several means cocaine is administered. Cocaine is smoked by inhaling the vapor by sublimating solid cocaine by heating.[31] In a 2000 Brookhaven National Laboratory medical department study, based on self reports of 32 abusers who participated in the study,"peak high" was found [27]

at mean of 1.4min +/- 0.5 minutes. Pyrolysis products of cocaine that occur only when heated/smoked have been shown to change the effect profile, *i.e.* anhydroecgonine methyl ester when co-administered with cocaine increases the dopamine in CPu and NAc brain regions, and has $M_1$- and $M_3$- receptor affinity.[32]

Smoking freebase or crack cocaine is most often accomplished using a pipe made from a small glass tube, often taken from "love roses," small glass tubes with a paper rose that are promoted as romantic gifts.[33] These are sometimes called "stems", "horns", "blasters" and "straight shooters". A small piece of clean heavy copper or occasionally stainless steel scouring pad – often called a "brillo" (actual Brillo Pads contain soap, and are not used) or "chore" (named for Chore Boy brand copper scouring pads) – serves as a reduction base and flow modulator in which the "rock" can be melted and boiled to vapor. Crack smokers also sometimes smoke through a soda can with small holes in the bottom.[*citation needed*]

Crack is smoked by placing it at the end of the pipe; a flame held close to it produces vapor, which is then inhaled by the smoker. The effects, felt almost immediately after smoking, are very intense and do not last long – usually 5 to 15 minutes.[*citation needed*]

When smoked, cocaine is sometimes combined with other drugs, such as cannabis, often rolled into a joint or blunt. Powdered cocaine is also sometimes smoked, though heat destroys much of the chemical; smokers often sprinkle it on cannabis.[*citation needed*]

The language referring to paraphernalia and practices of smoking cocaine vary, as do the packaging methods in the street level sale.[*citation needed*]

### Suppository

Little research has been focused on the suppository (anal or vaginal insertion) method of administration, also known as "plugging". This method of administration is commonly administered using an oral syringe. Cocaine can be dissolved in water and withdrawn into an oral syringe which may then be lubricated and inserted into the anus or vagina before the plunger is pushed. Anecdotal evidence of its effects is infrequently discussed, possibly due to social taboos in many cultures. The rectum and the vaginal canal is where the majority of the drug would be taken up through the membranes lining its walls.[*citation needed*]

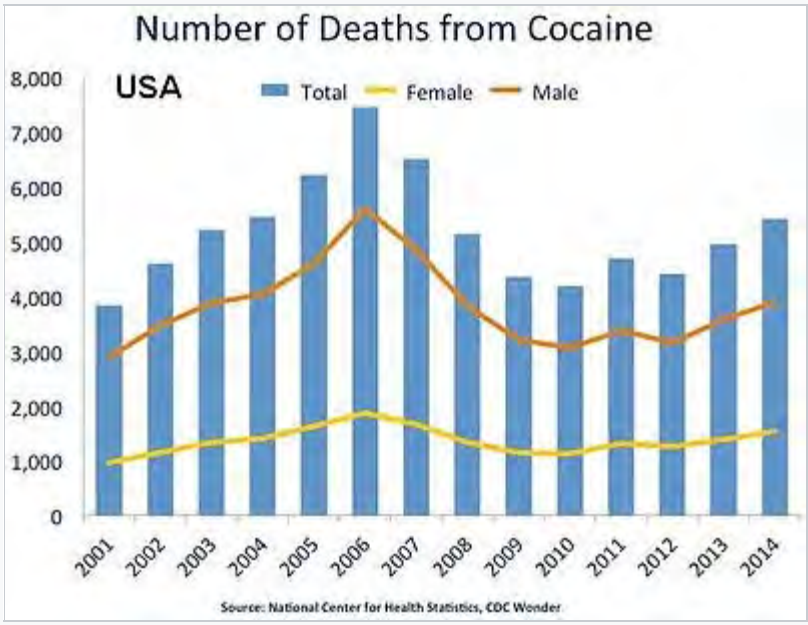
## Adverse effects

### Acute

*Main article: Cocaine intoxication*

With excessive or prolonged use, the drug can cause itching, fast heart rate, hallucinations, and paranoid delusions.[36] Overdoses cause hyperthermia and a marked elevation of blood pressure, which can be life-threatening,[36] arrhythmias,[37] and death.[37]

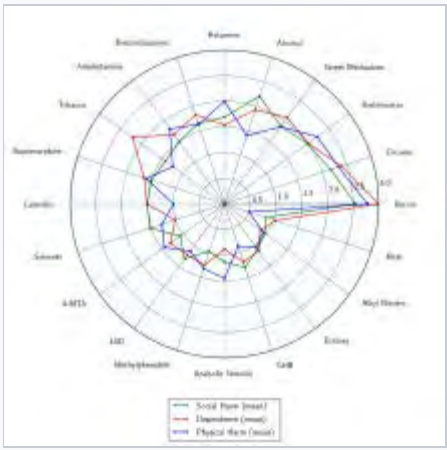
Anxiety, paranoia, and restlessness can also occur, especially during the comedown. With excessive dosage, tremors, convulsions and increased body temperature are observed.[21] Severe cardiac adverse events, particularly sudden cardiac death, become a serious risk at high doses due to cocaine's blocking effect on cardiac sodium channels.[37]



Timeline of number of yearly U.S. overdose deaths involving cocaine.[34]

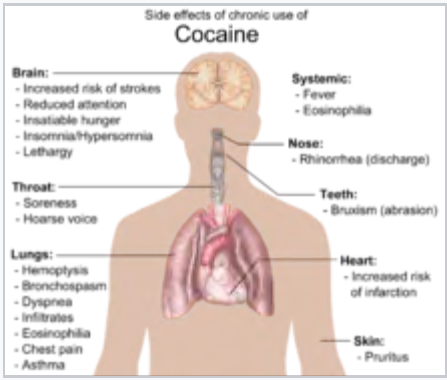
### Chronic

Chronic cocaine intake causes strong imbalances of transmitter levels in order to compensate extremes. Thus, receptors disappear from the cell surface or reappear on it, resulting more or less in an "off" or "working mode" respectively, or they change their susceptibility for binding partners (ligands) – mechanisms called downregulation and upregulation. However, studies suggest cocaine abusers do not show normal age-related loss of striatal dopamine transporter (DAT) sites, suggesting cocaine has neuroprotective properties for dopamine neurons.[38] Possible side effects include insatiable hunger, aches, insomnia/oversleeping, lethargy, and persistent runny nose. Depression with suicidal ideation may develop in very heavy users. Finally, a loss of vesicular monoamine transporters, neurofilament proteins, and other morphological changes appear to indicate a long term damage of dopamine neurons. All these effects contribute a rise in tolerance thus requiring a larger dosage to achieve the same effect. [39] The lack of normal amounts of serotonin and dopamine in the brain is the cause of the dysphoria and depression felt after the initial high. Physical withdrawal is not dangerous. Physiological changes caused by cocaine withdrawal include vivid and unpleasant dreams, insomnia or hypersomnia, increased appetite and psychomotor retardation or agitation.[39]



Addiction experts in psychiatry, chemistry, pharmacology, forensic science, epidemiology, and the police and legal services engaged in delphic analysis regarding 20 popular recreational drugs. Cocaine was ranked the 2nd in dependence and physical harm and 3rd in social harm.[35]

Physical side effects from chronic smoking of cocaine include coughing up blood, bronchospasm, itching, fever, diffuse alveolar infiltrates without effusions, pulmonary and systemic eosinophilia, chest pain, lung trauma, sore throat, asthma, hoarse voice, dyspnea (shortness of breath), and an aching, flu-like syndrome. Cocaine constricts blood vessels, dilates pupils, and increases body temperature, heart rate, and blood pressure. It can also cause headaches and gastrointestinal complications such as abdominal pain and nausea. A common but untrue belief is that the smoking of cocaine chemically breaks down tooth enamel and causes tooth decay. However, cocaine does often cause involuntary tooth grinding, known as bruxism, which can deteriorate tooth enamel and lead to gingivitis.[40] Additionally, stimulants like cocaine, methamphetamine, and even caffeine cause dehydration and dry mouth. Since saliva is an important mechanism in maintaining one's oral pH level, chronic stimulant abusers who do not hydrate sufficiently may experience demineralization of their teeth due to the pH of the tooth surface dropping too low (below 5.5).



Side effects of chronic cocaine use

Chronic intranasal usage can degrade the cartilage separating the nostrils (the septum nasi), leading eventually to its complete disappearance. Due to the absorption of the cocaine from cocaine hydrochloride, the remaining hydrochloride forms a dilute hydrochloric acid.[41]

Cocaine may also greatly increase this risk of developing rare autoimmune or connective tissue diseases such as lupus, Goodpasture syndrome, vasculitis, glomerulonephritis, Stevens–Johnson syndrome, and other diseases.[42][43][44][45] It can also cause a wide array of kidney diseases and kidney failure.[46][47]

Cocaine misuse doubles both the risks of hemorrhagic and ischemic strokes,[48] as well as increases the risk of other infarctions, such as myocardial infarction.[49]

## Addiction

Cocaine hydrochloride

Cocaine addiction occurs through accumbal ΔFosB overexpression, which arises through transcriptional regulation and epigenetic remodeling of the nucleus accumbens.

## Dependence and withdrawal

Cocaine dependence is a form of psychological dependence that develops from regular cocaine use and produces a withdrawal state with emotional-motivational deficits upon cessation of cocaine use.

# Pharmacology

## Pharmacodynamics

The pharmacodynamics of cocaine involve the complex relationships of neurotransmitters (inhibiting monoamine uptake in rats with ratios of about: serotonin:dopamine = 2:3, serotonin:norepinephrine = 2:5[50]) The most extensively studied effect of cocaine on the central nervous system is the blockade of the dopamine transporter protein. Dopamine transmitter released during neural signaling is normally recycled via the transporter; i.e., the transporter binds the transmitter and pumps it out of the synaptic cleft back into the presynaptic neuron, where it is taken up into storage vesicles. Cocaine binds tightly at the dopamine transporter forming a complex that blocks the transporter's function. The dopamine transporter can no longer perform its reuptake function, and thus dopamine accumulates in the synaptic cleft.

Cocaine's affects certain serotonin (5-HT) receptors; in particular, it has been shown to antagonize the 5-HT3 receptor, which is a ligand-gated ion channel. The overabundance of 5-HT3 receptors in cocaine conditioned rats display this trait, however the exact effect of 5-HT3 in this process is unclear.[51] The 5-HT2 receptor (particularly the subtypes 5-HT2AR, 5-HT2BR and 5-HT2CR) are involved in the locomotor-activating effects of cocaine.[52]

Cocaine has been demonstrated to bind as to directly stabilize the DAT transporter on the open outward-facing conformation. Further, cocaine binds in such a way as to inhibit a hydrogen bond innate to DAT. Cocaine's binding properties are such that it attaches so this hydrogen bond will not form and is blocked from formation due to the tightly locked orientation of the cocaine molecule. Research studies have suggested that the affinity for the transporter is not what is involved in habituation of the substance so much as the conformation and binding properties to where and how on the transporter the molecule binds.[53]

Sigma receptors are affected by cocaine, as cocaine functions as a sigma ligand agonist.[54] Further specific receptors it has been demonstrated to function on are NMDA and the D1 dopamine receptor.[55]

Cocaine also blocks sodium channels, thereby interfering with the propagation of action potentials;[37] thus, like lignocaine and novocaine, it acts as a local anesthetic. It also functions on the binding sites to the dopamine and serotonin sodium dependent transport area as targets as separate mechanisms from its

reuptake of those transporters; unique to its local anesthetic value which makes it in a class of functionality different from both its own derived phenyltropanes analogues which have that removed. In addition to this cocaine has some target binding to the site of the Kappa-opioid receptor as well.[56] Cocaine also causes vasoconstriction, thus reducing bleeding during minor surgical procedures. The locomotor enhancing properties of cocaine may be attributable to its enhancement of dopaminergic transmission from the substantia nigra. Recent research points to an important role of circadian mechanisms[57] and clock genes[58] in behavioral actions of cocaine.

Cocaine can often cause reduced food intake, many chronic users lose their appetite and can experience severe malnutrition and significant weight loss. Cocaine effects, further, are shown to be potentiated for the user when used in conjunction with new surroundings and stimuli, and otherwise novel environs.[59]

### Pharmacokinetics

Cocaine is extensively metabolized, primarily in the liver, with only about 1% excreted unchanged in the urine. The metabolism is dominated by hydrolytic ester cleavage, so the eliminated metabolites consist mostly of benzoylecgonine (BE), the major metabolite, and other significant metabolites in lesser amounts such as ecgonine methyl ester (EME) and ecgonine. Further minor metabolites of cocaine include norcocaine, p-hydroxycocaine, m-hydroxycocaine, p-hydroxybenzoylecgonine (pOHBE), and m-hydroxybenzoylecgonine.[60] If consumed with alcohol, cocaine combines with alcohol in the liver to form cocaethylene. Studies have suggested cocaethylene is both more euphoric, and has a higher cardiovascular toxicity than cocaine by itself.[61][62][63]

Depending on liver and kidney function, cocaine metabolites are detectable in urine. Benzoylecgonine can be detected in urine within four hours after cocaine intake and remains detectable in concentrations greater than 150 ng/mL typically for up to eight days after cocaine is used. Detection of accumulation of cocaine metabolites in hair is possible in regular users until the sections of hair grown during use are cut or fall out.

## Chemistry

### Appearance

Cocaine in its purest form is a white, pearly product. Cocaine appearing in powder form is a salt, typically cocaine hydrochloride. Street cocaine is often adulterated or "cut" with talc, lactose, sucrose, glucose, mannitol, inositol, caffeine, procaine, phencyclidine, phenytoin, lignocaine, strychnine, amphetamine, or heroin.[64]

The color of "crack" cocaine depends upon several factors including the origin of the cocaine used, the method of preparation – with ammonia or baking soda – and the presence of impurities, but will generally range from white to a yellowish cream to a light brown. Its texture will also depend on the adulterants, origin and processing of the powdered cocaine, and the method of converting the base. It ranges from a crumbly texture, sometimes extremely oily, to a hard, almost crystalline nature.

A pile of cocaine hydrochloride

### Forms

#### Salt

Cocaine - a tropane alkaloid - is a weakly alkaline compound, and can therefore combine with acidic compounds to form various salts. The hydrochloride (HCl) salt of cocaine is by far the most commonly encountered, although the sulfate ($-SO_4$) and the nitrate ($-NO_3$) are

A piece of compressed cocaine powder

occasionally seen. Different salts dissolve to a greater or lesser extent in various solvents – the hydrochloride salt is polar in character and is quite soluble in water.

## Base

*Main article: Freebase (chemistry)*

As the name implies, "freebase" is the base form of cocaine, as opposed to the salt form. It is practically insoluble in water whereas hydrochloride salt is water-soluble.

Smoking freebase cocaine has the additional effect of releasing methylecgonidine into the user's system due to the pyrolysis of the substance (a side effect which insufflating or injecting powder cocaine does not create). Some research suggests that smoking freebase cocaine can be even more cardiotoxic than other routes of administration[65] because of methylecgonidine's effects on lung tissue[66] and liver tissue.[67]

Pure cocaine is prepared by neutralizing its compounding salt with an alkaline solution which will precipitate to non-polar basic cocaine. It is further refined through aqueous-solvent liquid-liquid extraction.

## Crack cocaine

*Main article: Crack cocaine*

A woman smoking crack cocaine

Crack is a lower purity form of free-base cocaine that is usually produced by neutralization of cocaine hydrochloride with a solution of baking soda (sodium bicarbonate, $NaHCO_3$) and water, producing a very hard/brittle, off-white-to-brown colored, amorphous material that contains sodium carbonate, entrapped water, and other by-products as the main impurities.

The "freebase" and "crack" forms of cocaine are usually administered by vaporization of the powdered substance into smoke, which is then inhaled.[68]

The origin of the name "crack" comes from the "crackling" sound (and hence the onomatopoeic moniker "crack") that is produced when the cocaine and its impurities (i.e. water, sodium bicarbonate) are heated past the point of vaporization.[69]

"Rocks" of crack cocaine

Pure cocaine base/crack can be smoked because it vaporizes smoothly, with little or no decomposition at 98 °C (208 °F),[70] which is below the boiling point of water.

In contrast, cocaine hydrochloride does not vaporize until heated to a much higher temperature (about 197 °C), and considerable decomposition/burning occurs at these high temperatures. This effectively destroys some of the cocaine and yields a sharp, acrid, and foul-tasting smoke.

Smoking or vaporizing cocaine and inhaling it into the lungs produces an almost immediate "high" that can be very powerful (and addicting) quite rapidly – this initial crescendo of stimulation is known as a "rush". While the stimulating effects may last for hours, the euphoric sensation is very brief, prompting the user to smoke more immediately.

## Coca leaf infusions

This article **needs additional citations for verification**. Please help improve this article by adding citations to reliable sources. Unsourced material may be challenged and removed. *(April 2014) (Learn how and when to remove this template message)*

Coca herbal infusion (also referred to as coca tea) is used in coca-leaf producing countries much as any herbal medicinal infusion would elsewhere in the world. The free and legal commercialization of dried coca leaves under the form of filtration bags to be used as "coca tea" has been actively promoted by the governments of Peru and Bolivia for many years as a drink having medicinal powers. Visitors to the city of Cuzco in Peru, and La Paz in Bolivia are greeted with the offering of coca leaf infusions (prepared in teapots with whole coca leaves) purportedly to help the newly arrived traveler overcome the malaise of high altitude sickness. The effects of drinking coca tea are a mild stimulation and mood lift. It does not produce any significant numbing of the mouth nor does it give a rush like snorting cocaine. In order to prevent the demonization of this product, its promoters publicize the unproven concept that much of the effect of the ingestion of coca leaf infusion would come from the secondary alkaloids, as being not only quantitatively different from pure cocaine but also qualitatively different.

It has been promoted as an adjuvant for the treatment of cocaine dependence. In one controversial study, coca leaf infusion was used—in addition to counseling—to treat 23 addicted coca-paste smokers in Lima, Peru. Relapses fell from an average of four times per month before treatment with coca tea to one during the treatment. The duration of abstinence increased from an average of 32 days prior to treatment to 217 days during treatment. These results suggest that the administration of coca leaf infusion plus counseling would be an effective method for preventing relapse during treatment for cocaine addiction. Importantly, these results also suggest strongly that the primary pharmacologically active metabolite in coca leaf infusions is actually cocaine and not the secondary alkaloids.[*improper synthesis?*]

The cocaine metabolite benzoylecgonine can be detected in the urine of people a few hours after drinking one cup of coca leaf infusion.[71]

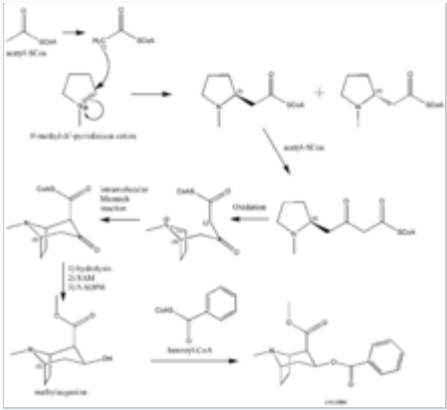
## Biosynthesis

*Main article: Biosynthesis of cocaine*

The first synthesis and elucidation of the cocaine molecule was by Richard Willstätter in 1898.[72] Willstätter's synthesis derived cocaine from tropinone. Since then, Robert Robinson and Edward Leete have made significant contributions to the mechanism of the synthesis. (-$NO_3$)

Biosynthesis of *N*-methyl-pyrrolinium cation

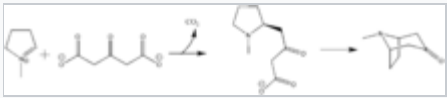
The additional carbon atoms required for the synthesis of cocaine are derived from acetyl-CoA, by addition of two acetyl-CoA units to the *N*-methyl-$\Delta^1$-pyrrolinium cation.[73] The first addition is a Mannich-like reaction with the enolate anion from acetyl-CoA acting as a nucleophile towards the pyrrolinium cation. The second addition occurs through a Claisen condensation. This produces a racemic mixture of the 2-substituted pyrrolidine, with the retention of the thioester from the Claisen condensation. In formation of tropinone from racemic ethyl [2,3-$^{13}C_2$]$_4$(Nmethyl-2-pyrrolidinyl)-3-oxobutanoate there is no preference for either stereoisomer.[74] In the biosynthesis of cocaine, however, only the (S)-enantiomer can cyclize to form the tropane ring system of cocaine. The stereoselectivity of this reaction was further investigated through study of prochiral methylene hydrogen discrimination.[75] This is due to the extra chiral center at C-2.[76] This process occurs through an oxidation, which regenerates the pyrrolinium cation and formation of an enolate anion, and an intramolecular Mannich reaction. The tropane ring



Biosynthesis of cocaine

system undergoes hydrolysis, SAM-dependent methylation, and reduction via NADPH for the formation of methylecgonine. The benzoyl moiety required for the formation of the cocaine diester is synthesized from phenylalanine via cinnamic acid.[77] Benzoyl-CoA then combines the two units to form cocaine.

## *N*-methyl-pyrrolinium cation



Robinson biosynthesis of tropane

The biosynthesis begins with L-Glutamine, which is derived to L-ornithine in plants. The major contribution of L-ornithine and L-arginine as a precursor to the tropane ring was confirmed by Edward Leete.[78] Ornithine then undergoes a pyridoxal phosphate-dependent decarboxylation to form putrescine. In animals, however, the urea cycle derives putrescine from ornithine. L-ornithine is converted to L-arginine,[79] which is then decarboxylated via PLP to form agmatine. Hydrolysis of the imine derives *N*-carbamoylputrescine followed with hydrolysis of the urea to form putrescine. The separate pathways of converting ornithine to putrescine in plants and animals have converged. A SAM-dependent *N*-methylation of putrescine gives the *N*-methylputrescine product, which then undergoes oxidative deamination by the action of diamine oxidase to yield the aminoaldehyde. Schiff base formation confirms the biosynthesis of the *N*-methyl-$\Delta^1$-pyrrolinium cation.

Reduction of tropinone

## Robert Robinson's acetonedicarboxylate

The biosynthesis of the tropane alkaloid, however, is still uncertain. Hemscheidt proposes that Robinson's acetonedicarboxylate emerges as a potential intermediate for this reaction.[80] Condensation of *N*-methylpyrrolinium and acetonedicarboxylate would generate the oxobutyrate. Decarboxylation leads to tropane alkaloid formation.

## Reduction of tropinone

The reduction of tropinone is mediated by NADPH-dependent reductase enzymes, which have been characterized in multiple plant species.[81] These plant species all contain two types of the reductase enzymes, tropinone reductase I and tropinone reductase II. TRI produces tropine and TRII produces pseudotropine. Due to differing kinetic and pH/activity characteristics of the enzymes and by the 25-fold higher activity of TRI over TRII, the majority of the tropinone reduction is from TRI to form tropine.[82]

# Detection in body fluids

Cocaine and its major metabolites may be quantified in blood, plasma, or urine to monitor for abuse, confirm a diagnosis of poisoning, or assist in the forensic investigation of a traffic or other criminal violation or a sudden death. Most commercial cocaine immunoassay screening tests cross-react appreciably with the major cocaine metabolites, but chromatographic techniques can easily distinguish and separately measure each of these substances. When interpreting the results of a test, it is important to consider the cocaine usage history of the individual, since a chronic user can develop tolerance to doses that would incapacitate a cocaine-naive individual, and the chronic user often has high baseline values of the metabolites in his system. Cautious interpretation of testing results may allow a distinction between passive or active usage,

and between smoking versus other routes of administration.[83] In 2011, researchers at John Jay College of Criminal Justice reported that dietary zinc supplements can mask the presence of cocaine and other drugs in urine. Similar claims have been made in web forums on that topic.[84]

# Usage

According to a 2007 United Nations report, Spain is the country with the highest rate of cocaine usage (3.0% of adults in the previous year).[86] Other countries where the usage rate meets or exceeds 1.5% are the United States (2.8%), England and Wales (2.4%), Canada (2.3%), Italy (2.1%), Bolivia (1.9%), Chile (1.8%), and Scotland (1.5%).[86]

**Global estimates of illegal drug users in 2014 (in millions of users)**[85]

| Substance | Best estimate | Low estimate | High estimate |
|---|---|---|---|
| Amphetamine-type stimulants | 35.65 | 15.34 | 55.90 |
| Cannabis | 182.50 | 127.54 | 233.65 |
| **Cocaine** | 18.26 | 14.88 | 22.08 |
| Ecstasy | 19.40 | 9.89 | 29.01 |
| Opiates | 17.44 | 13.74 | 21.59 |
| Opioids | 33.12 | 28.57 | 38.52 |

## Europe

Cocaine is the second most popular illegal recreational drug in Europe (behind cannabis). Since the mid-1990s, overall cocaine usage in Europe has been on the rise, but usage rates and attitudes tend to vary between countries. European countries with the highest usage rates are the United Kingdom, Spain, Italy, and the Republic of Ireland.

Approximately 12 million Europeans (3.6%) have used cocaine at least once, 4 million (1.2%) in the last year, and 2 million in the last month (0.5%).

About 3.5 million or 87.5% of those who have used the drug in the last year[*when?*] are young adults (15–34 years old). Usage is particularly prevalent among this demographic: 4% to 7% of males have used cocaine in the last year in Spain, Denmark, Republic of Ireland, Italy, and the United Kingdom. The ratio of male to female users is approximately 3.8:1, but this statistic varies from 1:1 to 13:1 depending on country.[87]

In 2014 London had the highest amount of cocaine in their sewage out of 50 European cities.[88]

## United States

*Main article: Cocaine in the United States*

Cocaine is the second most popular illegal recreational drug in the United States (behind cannabis)[89] and the U.S. is the world's largest consumer of cocaine.[90] Cocaine is commonly used in middle to upper-class communities and is known as a "rich man's drug". It is also popular amongst college students, as a party drug. A study throughout the entire United States has reported that around 48 percent of people who graduated high school in 1979 have used Cocaine recreationally during some point in their lifetime, compared to approximately 20 percent of students who graduated between the years of 1980 and 1995.[91] Its users span over different ages, races, and professions. In the 1970s and 1980s, the drug became particularly popular in the disco culture as cocaine usage was very common and popular in many discos such as Studio 54.

# History

## Discovery

For over a thousand years South American indigenous peoples have chewed the leaves of *Erythroxylon coca*, a plant that contains vital

Coca leaf in Bolivia

nutrients as well as numerous alkaloids, including cocaine. The coca leaf was, and still is, chewed almost universally by some indigenous communities. The remains of coca leaves have been found with ancient Peruvian mummies, and pottery from the time period depicts humans with bulged cheeks, indicating the presence of something on which they are chewing.[92] There is also evidence that these cultures used a mixture of coca leaves and saliva as an anesthetic for the performance of trepanation.[93]

When the Spanish arrived in South America, most at first ignored aboriginal claims that the leaf gave them strength and energy, and declared the practice of chewing it the work of the Devil.[*citation needed*] But after discovering that these claims were true, they legalized and taxed the leaf, taking 10% off the value of each crop.[94] In 1569, Nicolás Monardes described the indigenous peoples' practice of chewing a mixture of tobacco and coca leaves to induce "great contentment":[95]

> When they wished to make themselves drunk and out of judgment they chewed a mixture of tobacco and coca leaves which make them go as they were out of their wittes.

In 1609, Padre Blas Valera wrote:

> Coca protects the body from many ailments, and our doctors use it in powdered form to reduce the swelling of wounds, to strengthen broken bones, to expel cold from the body or prevent it from entering, and to cure rotten wounds or sores that are full of maggots. And if it does so much for outward ailments, will not its singular virtue have even greater effect in the entrails of those who eat it?[*citation needed*]

## Isolation and naming

Although the stimulant and hunger-suppressant properties of coca had been known for many centuries, the isolation of the cocaine alkaloid was not achieved until 1855. Various European scientists had attempted to isolate cocaine, but none had been successful for two reasons: the knowledge of chemistry required was insufficient at the time,[*citation needed*] and contemporary conditions of sea-shipping from South America could degrade the cocaine in the plant samples available to European chemists.[*citation needed*]

The cocaine alkaloid was first isolated by the German chemist Friedrich Gaedcke in 1855. Gaedcke named the alkaloid "erythroxyline", and published a description in the journal *Archiv der Pharmazie*.[96]

In 1856, Friedrich Wöhler asked Dr. Carl Scherzer, a scientist aboard the *Novara* (an Austrian frigate sent by Emperor Franz Joseph to circle the globe), to bring him a large amount of coca leaves from South America. In 1859, the ship finished its travels and Wöhler received a trunk full of coca. Wöhler passed on the leaves to Albert Niemann, a Ph.D. student at the University of Göttingen in Germany, who then developed an improved purification process.[97]

Niemann described every step he took to isolate cocaine in his dissertation titled *Über eine neue organische Base in den Cocablättern* (*On a New Organic Base in the Coca Leaves*), which was published in 1860—it earned him his Ph.D. and is now in the British Library. He wrote of the alkaloid's "colourless transparent prisms" and said that "Its solutions have an alkaline reaction, a bitter taste, promote the flow of saliva and leave a peculiar numbness, followed by a sense of cold when applied to the tongue." Niemann named the alkaloid "cocaine" from "coca" (from Quechua "cuca") + suffix "ine".[97][98] Because of its use as a local anesthetic, a suffix "-caine" was later extracted and used to form names of synthetic local anesthetics.

The first synthesis and elucidation of the structure of the cocaine molecule was by Richard Willstätter in 1898.[72] It was the first biomimetic synthesis of an organic structure recorded in academic chemical

literature.[99][100] The synthesis started from tropinone, a related natural product and took five steps. The name comes from "coca" and the alkaloid suffix "-ine", forming "cocaine".

## Medicalization

With the discovery of this new alkaloid, Western medicine was quick to exploit the possible uses of this plant.

In 1879, Vassili von Anrep, of the University of Würzburg, devised an experiment to demonstrate the analgesic properties of the newly discovered alkaloid. He prepared two separate jars, one containing a cocaine-salt solution, with the other containing merely salt water. He then submerged a frog's legs into the two jars, one leg in the treatment and one in the control solution, and proceeded to stimulate the legs in several different ways. The leg that had been immersed in the cocaine solution reacted very differently from the leg that had been immersed in salt water.[101]
