Karl Koller (a close associate of Sigmund Freud, who would write about cocaine later) experimented with cocaine for ophthalmic usage. In an infamous experiment in 1884, he experimented upon himself by applying a cocaine solution to his own eye and then pricking it with pins. His findings were presented to the Heidelberg Ophthalmological Society. Also in 1884, Jellinek demonstrated the effects of cocaine as a respiratory system anesthetic. In 1885, William Halsted demonstrated nerve-block anesthesia,[102] and James Leonard Corning demonstrated peridural anesthesia.[103] 1898 saw Heinrich Quincke use cocaine for spinal anesthesia.

Today, cocaine has a very limited medical use.

"Cocaine toothache drops", 1885 advertisement of cocaine for dental pain in children

## Popularization

In 1859, an Italian doctor, Paolo Mantegazza, returned from Peru, where he had witnessed first-hand the use of coca by the local indigenous peoples. He proceeded to experiment on himself and upon his return to Milan he wrote a paper in which he described the effects. In this paper he declared coca and cocaine (at the time they were assumed to be the same) as being useful medicinally, in the treatment of "a furred tongue in the morning, flatulence, and whitening of the teeth."

A chemist named Angelo Mariani who read Mantegazza's paper became immediately intrigued with coca and its economic potential. In 1863, Mariani started marketing a wine called Vin Mariani, which had been treated with coca leaves, to become cocawine. The ethanol in wine acted as a solvent and extracted the cocaine from the coca leaves, altering the drink's effect. It contained 6 mg cocaine per ounce of wine, but Vin Mariani which was to be exported contained 7.2 mg per ounce, to compete with the higher cocaine content of similar drinks in the United States. A "pinch of coca leaves" was included in John Styth Pemberton's original 1886 recipe for Coca-Cola, though the company began using decocainized leaves in 1906 when the Pure Food and Drug Act was passed.

In 1879 cocaine began to be used to treat morphine addiction. Cocaine was introduced into clinical use as a local anesthetic in Germany in 1884, about the same time as Sigmund Freud published his work *Über Coca*, in which he wrote that cocaine causes:[*citation needed*]

Pope Leo XIII purportedly carried a hip flask of the coca-treated Vin Mariani with him, and awarded a Vatican gold medal to Angelo Mariani.[104]

> Exhilaration and lasting euphoria, which in no way differs from the normal euphoria of the healthy person. You perceive an increase of self-control and possess more vitality and capacity for work. In other words, you are simply normal, and it is soon hard to believe you are under the influence of any drug. Long intensive physical work is performed without any fatigue. This result is enjoyed without any of the unpleasant after-effects that follow exhilaration brought about by alcoholic beverages. No craving for the further use of cocaine appears after the first, or even after repeated taking of the drug.

In 1885 the U.S. manufacturer Parke-Davis sold cocaine in various forms, including cigarettes, powder, and even a cocaine mixture that could be injected directly into the user's veins with the included needle. The company promised that its cocaine products would "supply the place of food, make the coward brave, the silent eloquent and render the sufferer insensitive to pain."

By the late Victorian era, cocaine use had appeared as a vice in literature. For example, it was injected by Arthur Conan Doyle's fictional Sherlock Holmes, generally to offset the boredom he felt when he was not working on a case.

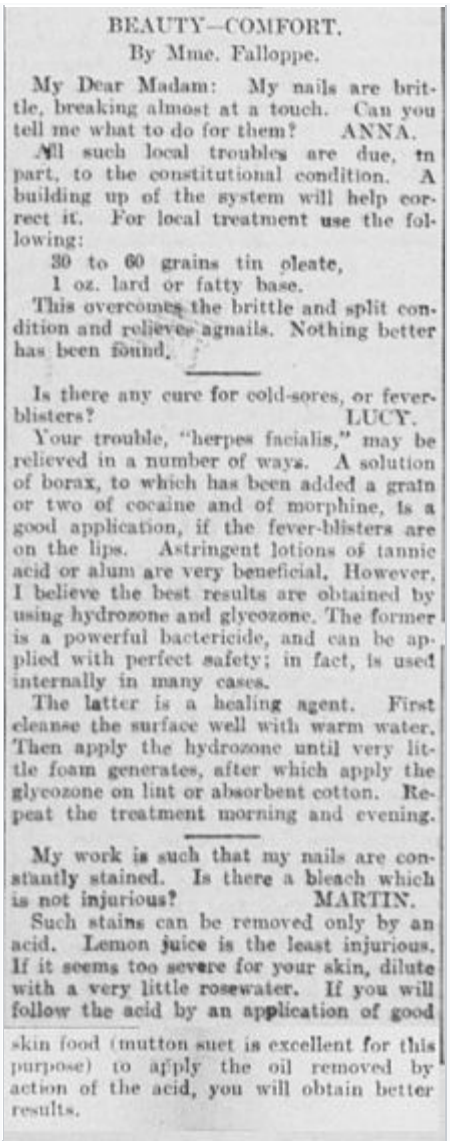
In early 20th-century Memphis, Tennessee, cocaine was sold in neighborhood drugstores on Beale Street, costing five or ten cents for a small boxful. Stevedores along the Mississippi River used the drug as a stimulant, and white employers encouraged its use by black laborers.[105]

In 1909, Ernest Shackleton took "Forced March" brand cocaine tablets to Antarctica, as did Captain Scott a year later on his ill-fated journey to the South Pole.[106]

During the mid-1940s, amidst WWII, cocaine was considered for inclusion as an ingredient of a future generation of 'pep pills' for the German military code named D-IX.[107]

## Modern usage

In many countries, cocaine is a popular recreational drug. In the United States, the development of "crack" cocaine introduced the substance to a generally poorer inner-city market. Use of the powder form has stayed relatively constant, experiencing a new height of use



BEAUTY—COMFORT.
By Mme. Falloppe.

My Dear Madam: My nails are brittle, breaking almost at a touch. Can you tell me what to do for them? ANNA.

All such local troubles are due, in part, to the constitutional condition. A building up of the system will help correct it. For local treatment use the following:

30 to 60 grains tin oleate,
1 oz. lard or fatty base.

This overcomes the brittle and split condition and relieves agnails. Nothing better has been found.

Is there any cure for cold-sores, or fever-blisters? LUCY.

Your trouble, "herpes facialis," may be relieved in a number of ways. A solution of borax, to which has been added a grain or two of cocaine and of morphine, is a good application, if the fever-blisters are on the lips. Astringent lotions of tannic acid or alum are very beneficial. However, I believe the best results are obtained by using hydrozone and glycozone. The former is a powerful bactericide, and can be applied with perfect safety; in fact, is used internally in many cases.

The latter is a healing agent. First cleanse the surface well with warm water. Then apply the hydrozone until very little foam generates, after which apply the glycozone on lint or absorbent cotton. Repeat the treatment morning and evening.

My work is such that my nails are constantly stained. Is there a bleach which is not injurious? MARTIN.

Such stains can be removed only by an acid. Lemon juice is the least injurious. If it seems too severe for your skin, dilute with a very little rosewater. If you will follow the acid by an application of good skin food (mutton suet is excellent for this purpose) to apply the oil removed by action of the acid, you will obtain better results.

In this 1904 advice column from *the Tacoma Times*, "Madame Falloppe" recommended that cold sores be treated with a solution of borax, cocaine, and morphine.

Women purchase cocaine capsules in Berlin, 1924

during the late 1990s and early 2000s in the U.S., and has become much more popular in the last few years in the UK.[*citation needed*][*when?*]

Cocaine use is prevalent across all socioeconomic strata, including age, demographics, economic, social, political, religious, and livelihood.[*citation needed*]

The estimated U.S. cocaine market exceeded US$70 billion in street value for the year 2005, exceeding revenues by corporations such as Starbucks.[108][109] There is a tremendous demand for cocaine in the U.S. market, particularly among those who are making incomes affording luxury spending, such as single adults and professionals with discretionary income. Cocaine's status as a club drug shows its immense popularity among the "party crowd".

D.C. Mayor Marion Barry captured on a surveillance camera smoking crack cocaine during a sting operation by the FBI and D.C. Police.

In 1995 the World Health Organization (WHO) and the United Nations Interregional Crime and Justice Research Institute (UNICRI) announced in a press release the publication of the results of the largest global study on cocaine use ever undertaken. However, a decision by an American representative in the World Health Assembly banned the publication of the study, because it seemed to make a case for the positive uses of cocaine. An excerpt of the report strongly conflicted with accepted paradigms, for example "that occasional cocaine use does not typically lead to severe or even minor physical or social problems." In the sixth meeting of the B committee, the US representative threatened that "If World Health Organization activities relating to drugs failed to reinforce proven drug control approaches, funds for the relevant programs should be curtailed". This led to the decision to discontinue publication. A part of the study was recuperated and published in 2010, including profiles of cocaine use in 20 countries,

but are unavailable as of 2015.[110]

In October 2010 it was reported that the use of cocaine in Australia has doubled since monitoring began in 2003.[111]

A problem with illegal cocaine use, especially in the higher volumes used to combat fatigue (rather than increase euphoria) by long-term users, is the risk of ill effects or damage caused by the compounds used in adulteration. Cutting or "stepping on" the drug is commonplace, using compounds which simulate ingestion effects, such as Novocain (procaine) producing temporary anesthaesia, as many users believe a strong numbing effect is the result of strong and/or pure cocaine, ephedrine or similar stimulants that are to produce an increased heart rate. The normal adulterants for profit are inactive sugars, usually mannitol, creatine or glucose, so introducing active adulterants gives the illusion of purity and to 'stretch' or make it so a dealer can sell more product than without the adulterants.[*citation needed*] The adulterant of sugars allows the dealer to sell the product for a higher price because of the illusion of purity and allows to sell more of the product at that higher price, enabling dealers to significantly increase revenue with little additional cost for the adulterants. A 2007 study by the European Monitoring Centre for Drugs and Drug Addiction showed that the purity levels for street purchased cocaine was often under 5% and on average under 50% pure.[112]

# Society and culture

## Legal status

*Main article: Legal status of cocaine*

The production, distribution, and sale of cocaine products is restricted (and illegal in most contexts) in most countries as regulated by the Single Convention on Narcotic Drugs, and the United Nations Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances. In the United States the manufacture, importation, possession, and distribution of cocaine are additionally regulated by the 1970 Controlled Substances Act.

Some countries, such as Peru and Bolivia permit the cultivation of coca leaf for traditional consumption by the local indigenous population, but nevertheless, prohibit the production, sale, and consumption of cocaine.[113] The provisions as to how much a coca farmer can yield annually is protected by laws such as the Bolivian Cato accord.[114] In addition, some parts of Europe and Australia allow processed cocaine for medicinal uses only.

## Australia

Cocaine is a Schedule 8 prohibited substance in Australia under the Poisons Standard (July 2016).[115] A schedule 8 substance is a controlled Drug – Substances which should be available for use but require restriction of manufacture, supply, distribution, possession and use to reduce abuse, misuse and physical or psychological dependence.[115]

In Western Australia under the Misuse of Drugs Act 1981 4.0g of cocaine is the amount of prohibited drugs determining a court of trial, 2.0g is the amount of cocaine required for the presumption of intention to sell or supply and 28.0g is the amount of cocaine required for purposes of drug trafficking [116]

## United States

*See also: Cocaine in the United States*

The US federal government instituted a national labeling requirement for cocaine and cocaine-containing products through the Food and Drug Act of 1906.[117] The next important federal regulation was the Harrison Narcotics Tax Act of 1914. While this act is often seen as the start of prohibition, the act itself was not actually a prohibition on cocaine, but instead set up a regulatory and licensing regime.[118] The Harrison Act did not recognize addiction as a treatable condition and therefore the therapeutic use of cocaine, heroin

or morphine to such individuals was outlawed – leading the Journal of American Medicine to remark, "[the addict] is denied the medical care he urgently needs, open, above-board sources from which he formerly obtained his drug supply are closed to him, and he is driven to the underworld where he can get his drug, but of course, surreptitiously and in violation of the law."[119] The Harrison Act left manufacturers of cocaine untouched so long as they met certain purity and labeling standards.[120] Despite that cocaine was typically illegal to sell and legal outlets were rarer, the quantities of legal cocaine produced declined very little.[120] Legal cocaine quantities did not decrease until the Jones-Miller Act of 1922 put serious restrictions on cocaine manufactures.[120]

## Interdiction

In 2004, according to the United Nations, 589 tonnes of cocaine were seized globally by law enforcement authorities. Colombia seized 188 t, the United States 166 t, Europe 79 t, Peru 14 t, Bolivia 9 t, and the rest of the world 133 t.[121]

## Economics

Because of the drug's potential for addiction and overdose, cocaine is generally treated as a 'hard drug', with severe penalties for possession and trafficking. Demand remains high, and consequently, black market cocaine is quite expensive. Unprocessed cocaine, such as coca leaves, are occasionally purchased and sold, but this is exceedingly rare as it is much easier and more profitable to conceal and smuggle it in powdered form. The scale of the market is immense: 770 tonnes times $100 per gram retail = up to $77 billion.[*citation needed*]

## Production

Until 2012, Colombia was the world's leading producer of cocaine.[122][123] Three-quarters of the world's annual yield of cocaine has been produced in Colombia, both from cocaine base imported from Peru (primarily the Huallaga Valley) and Bolivia, and from locally grown coca. There was a 28% increase from the amount of potentially harvestable coca plants which were grown in Colombia in 1998. This, combined with crop reductions in Bolivia and Peru, made Colombia the nation with the largest area of coca under cultivation after the mid-1990s. Coca is grown for traditional purposes by indigenous communities, a use which is still present and is permitted by Colombian laws only makes up a small fragment of total coca production, most of which is used for the illegal drug trade.[*citation needed*]

An interview with a coca farmer published in 2003 described a mode of production by acid-base extraction that has changed little since 1905. Roughly 625 pounds (283 kg) of leaves were harvested per hectare, six times per year. The leaves were dried for half a day, then chopped into small pieces with a strimmer and sprinkled with a small amount of powdered cement (replacing sodium carbonate from former times). Several hundred pounds of this mixture were soaked in 50 US gallons (190 L) of gasoline for a day, then the gasoline was removed and the leaves were pressed for remaining liquid, after which they could be discarded. Then battery acid (weak sulfuric acid) was used, one bucket per 55 lb (25 kg) of leaves, to create a phase separation in which the cocaine free base in the gasoline was acidified and extracted into a few buckets of "murky-looking smelly liquid". Once powdered caustic soda was added to this, the cocaine precipitated and could be removed by filtration through a cloth. The resulting material, when dried, was termed *pasta* and sold by the farmer. The 3750 pound yearly harvest of leaves from a hectare produced 6 lb (2.5 kg) of *pasta*, approximately 40–60% cocaine. Repeated recrystallization from solvents, producing *pasta lavada* and eventually crystalline cocaine were performed at specialized laboratories after the sale.[124]

Attempts to eradicate coca fields through the use of defoliants have devastated part of the farming economy in some coca growing regions of Colombia, and strains appear to have been developed that are more resistant or immune to their use. Whether these strains are natural mutations or the product of human tampering is unclear. These strains have also shown to be more potent than those previously grown, increasing profits for the drug cartels responsible for the exporting of cocaine. Although production fell temporarily, coca crops rebounded in numerous smaller fields in Colombia, rather than the larger
[*citation needed*]

plantations.

The cultivation of coca has become an attractive economic decision for many growers due to the combination of several factors, including the lack of other employment alternatives, the lower profitability of alternative crops in official crop substitution programs, the eradication-related damages to non-drug farms, the spread of new strains of the coca plant due to persistent worldwide demand.[*citation needed*]

**Estimated Andean region coca cultivation and potential pure cocaine production**[125]

| | 2000 | 2001 | 2002 | 2003 | 2004 |
|---|---|---|---|---|---|
| Net cultivation $km^2$ (sq mi) | 1,875 (724) | 2,218 (856) | 2,007.5 (775.1) | 1,663 (642) | 1,662 (642) |
| Potential pure cocaine production (tonnes) | 770 | 925 | 830 | 680 | 645 |

The latest estimate provided by the U.S. authorities on the annual production of cocaine in Colombia refers to 290 metric tons. As of the end of 2011, the seizure operations of Colombian cocaine carried out in different countries have totaled 351.8 metric tons of cocaine, i.e. 121.3% of Colombia's annual production according to the U.S. Department of State's estimates. [126][127]

## Synthesis

Synthetic cocaine would be highly desirable to the illegal drug industry as it would eliminate the high visibility and low reliability of offshore sources and international smuggling, replacing them with clandestine domestic laboratories, as are common for illicit methamphetamine. However, natural cocaine remains the lowest cost and highest quality supply of cocaine. Actual full synthesis of cocaine is rarely done. Formation of inactive enantiomers (cocaine has 4 chiral centres – *1R*, *2R*, *3S*, and *5S* – hence a total potential of 16 possible enantiomers and diastereoisomers) plus synthetic by-products limits the yield and purity.[*citation needed*] Names like "synthetic cocaine" and "new cocaine" have been misapplied to phencyclidine (PCP) and various designer drugs.[*citation needed*]

## Trafficking and distribution

Organized criminal gangs operating on a large scale dominate the cocaine trade. Most cocaine is grown and processed in South America, particularly in Colombia, Bolivia, Peru, and smuggled into the United States and Europe, the United States being the world's largest consumer of cocaine,[90] where it is sold at huge markups; usually in the US at $80–120 for 1 gram, and $250–300 for 3.5 grams (⅛ of an ounce, or an "eight ball").[*citation needed*]

Cocaine smuggled in a charango, 2008

### Caribbean and Mexican routes

As of 2005, cocaine shipments from South America transported through Mexico or Central America were generally moved over land or by air to staging sites in northern Mexico. The cocaine is then broken down into smaller loads for smuggling across the U.S.–Mexico border. The primary cocaine importation points in the United States have been in Arizona, southern California, southern Florida, and Texas. Typically, land vehicles are driven across the U.S.–Mexico border. Sixty-five percent of cocaine enters the United States through Mexico, and the vast majority of the rest enters through Florida.[128][*page needed*] As of 2015, the Sinaloa Cartel is the most active drug cartel involved in smuggling illicit drugs like cocaine into the United States and trafficking them throughout the United States.[129]

Cocaine traffickers from Colombia and Mexico have established a labyrinth of smuggling routes throughout the Caribbean, the Bahama Island chain, and South Florida. They often hire traffickers from Mexico or the Dominican Republic to transport the drug using a variety of smuggling techniques to U.S. markets. These include airdrops of 500 to 700 kg (1,100 to 1,500 lb) in the Bahama Islands or off the coast of Puerto Rico,

mid-ocean boat-to-boat transfers of 500 to 2,000 kg (1,100 to 4,400 lb), and the commercial shipment of tonnes of cocaine through the port of Miami.[*citation needed*]

### Chilean route

Another route of cocaine traffic goes through Chile, which is primarily used for cocaine produced in Bolivia since the nearest seaports lie in northern Chile. The arid Bolivia–Chile border is easily crossed by 4×4 vehicles that then head to the seaports of Iquique and Antofagasta. While the price of cocaine is higher in Chile than in Peru and Bolivia, the final destination is usually Europe, especially Spain where drug dealing networks exist among South American immigrants.[*citation needed*]

### Techniques

Cocaine is also carried in small, concealed, kilogram quantities across the border by couriers known as "mules" (or "mulas"), who cross a border either legally, for example, through a port or airport, or illegally elsewhere. The drugs may be strapped to the waist or legs or hidden in bags, or hidden in the body. If the mule gets through without being caught, the gangs will reap most of the profits. If he or she is caught, however, gangs will sever all links and the mule will usually stand trial for trafficking alone.[*citation needed*]

Bulk cargo ships are also used to smuggle cocaine to staging sites in the western Caribbean–Gulf of Mexico area. These vessels are typically 150–250-foot (50–80 m) coastal freighters that carry an average cocaine load of approximately 2.5 tonnes. Commercial fishing vessels are also used for smuggling operations. In areas with a high volume of recreational traffic, smugglers use the same types of vessels, such as go-fast boats, as those used by the local populations.[*citation needed*]

Sophisticated drug subs are the latest tool drug runners are using to bring cocaine north from Colombia, it was reported on 20 March 2008. Although the vessels were once viewed as a quirky sideshow in the drug war, they are becoming faster, more seaworthy, and capable of carrying bigger loads of drugs than earlier models, according to those charged with catching them.[130]

## Sales to consumers

Cocaine adulterated with fruit flavoring

Cocaine is readily available in all major countries' metropolitan areas. According to the *Summer 1998 Pulse Check*, published by the U.S. Office of National Drug Control Policy, cocaine use had stabilized across the country, with a few increases reported in San Diego, Bridgeport, Miami, and Boston. In the West, cocaine usage was lower, which was thought to be due to a switch to methamphetamine among some users; methamphetamine is cheaper, three and a half times more powerful, and lasts 12–24 times longer with each dose.[131][132] Nevertheless, the number of cocaine users remain high, with a large concentration among urban youth.

In addition to the amounts previously mentioned, cocaine can be sold in "bill sizes": As of 2007 for example, $10 might purchase a "dime bag", a very small amount (0.1–0.15 g) of cocaine. Twenty dollars might purchase 0.15–0.3 g. However, in lower Texas, it is sold cheaper due to it being easier to receive: a dime for $10 is 0.4 g, a 20 is 0.8–1.0 g and an 8-ball (3.5 g) is sold for $60 to $80, depending on the quality and dealer.[*citation needed*] These amounts and prices are very popular among young people because they are inexpensive and easily concealed on one's body. Quality and price can vary dramatically depending on supply and demand, and on geographic region.[133]

In 2008, the European Monitoring Centre for Drugs and Drug Addiction reports that the typical retail price of cocaine varied between €50 and €75 per gram in most European countries, although Cyprus, Romania, Sweden and Turkey reported much higher values.[134]

## Consumption

World annual cocaine consumption, as of 2000, stood at around 600 tonnes, with the United States

consuming around 300 t, 50% of the total, Europe about 150 t, 25% of the total, and the rest of the world the remaining 150 t or 25%.[135]

The 2010 UN World Drug Report concluded that "it appears that the North American cocaine market has declined in value from US$47 billion in 1998 to US$38 billion in 2008. Between 2006 and 2008, the value of the market remained basically stable."[136]

## Research

In 2005, researchers proposed the use of cocaine in conjunction with phenylephrine administered in the form of an eye drop as a diagnostic test for Parkinson's disease.[137]

# Dapsone

From Wikipedia, the free encyclopedia

**Dapsone**, also known as **diaminodiphenyl sulfone** (**DDS**),[1] is an antibiotic commonly used in combination with rifampicin and clofazimine for the treatment of leprosy.[2] It is a second-line medication for the treatment and prevention of pneumocystis pneumonia and for the prevention of toxoplasmosis in those who have poor immune function.[2] Additionally, it has been used for acne, dermatitis herpetiformis, and various other skin conditions.[3] Dapsone is available both topically and by mouth.[4]

Severe side effects may include: a decrease in blood cells, red blood cell breakdown especially in those with glucose-6-phosphate dehydrogenase deficiency (G-6-PD), or hypersensitivity.[2] Common side effects include nausea and loss of appetite.[4] Other side effects include liver inflammation and a number of types of skin rashes.[2] While it is not entirely clear the safety of use during pregnancy some physicians recommend that it be continued in those with leprosy.[2] It is of the sulfone class.[2]

Dapsone was first studied as an antibiotic in 1937.[3] Its use for leprosy began in 1945.[3] It is on the World Health Organization's List of Essential Medicines, the most important medications needed in a basic health system.[5] The oral form is available as a generic drug and not very expensive.[2][6]

# Medical uses [edit]

## Infections [edit]

Dapsone is commonly used in combination with rifampicin and clofazimine for the treatment of leprosy.[2] It is also used to both treat and prevent pneumocystis pneumonia (PCP).[2][7] It is also used for toxoplasmosis in people unable to tolerate trimethoprim with sulfamethoxazole.[7]

Dapsone by mouth was one of the first medications used to treat moderate to severe acne vulgaris, and is still occasionally prescribed for the treatment of severe cases.[8][9] A topical form of dapsone is also effective with potentially less side effects.[10]

It is unclear if the combination with pyrimethamine is useful in the prevention of malaria.[11]

## Other [edit]

Dermatitis herpetiformis, often in combination with a gluten-free diet.[2]

Dapsone may be used to treat brown recluse spider bites that become necrotic.[12]

Dapsone is the recommended treatment for erythema elevatum diutinum, as a review found that using oral dapsone alone was effective in 80% of early cases of the disease. However, dapsone can potentially cause severe side effects, meaning that sometimes steroids or other antibiotics should be used instead, although these alternative treatments are much less effective.[13]

An August 2015 review notes that dapsone is reported to be effective against generalized granuloma annulare.[14]

# Adverse effects [edit]

The dapsone hypersensitivity syndrome develops in 0.5–3.6% of persons treated with the drug, and is associated with a mortality of 9.9%.[15]

## Blood [edit]

The most prominent side-effects of this drug are dose-related hemolysis (which may lead to hemolytic anemia) and methemoglobinemia.[16] About 20% of patients treated with dapsone suffer hemolysis[17] and the side-effect is more common and severe in those with glucose-6-phosphate dehydrogenase deficiency, leading to the dapsone-containing antimalarial combination Lapdap being withdrawn from clinical use.[18][19] A case of hemolysis in a neonate from dapsone in breast milk has been reported.[20] Agranulocytosis occurs rarely when dapsone is used alone but more frequently in combination regimens for malaria prophylaxis.[21] Abnormalities in white blood cell formation, including aplastic anemia, are rare, yet are the cause of the majority of deaths attributable to dapsone therapy.[22][23][24]

## Liver [edit]

Toxic hepatitis and cholestatic jaundice have been reported by the manufacturer. Jaundice may also occur as part of the dapsone reaction or dapsone syndrome (see below). Dapsone is metabolized by the Cytochrome P450 system, specifically isozymes CYP2D6, CYP2B6, CYP3A4, and CYP2C19.[25] Dapsone metabolites produced by the cytochrome P450 2C19 isozyme are associated with the methemoglobinemia side effect of the drug.

### Skin [edit]

When used topically, dapsone can cause mild skin irritation, redness, dry skin, burning and itching. When used together with benzoyl peroxide products, temporary yellow or orange skin discolorations can occur.[26][27]

### Other adverse effects [edit]

Other adverse effects include nausea, headache, and rash (which are common), and insomnia, psychosis, and peripheral neuropathy. Effects on the lung occur rarely and may be serious, though are generally reversible.[28]

### Dapsone reaction [edit]

Hypersensitivity reactions occur in some patients. This reaction may be more frequent in patients receiving multiple-drug therapy.[29][30][31]

The reaction always involves a rash and may also include fever, jaundice, and eosinophilia.[32][33][34][35][36] In general, these symptoms will occur within the first six weeks of therapy or not at all, and may be ameliorated by corticosteroid therapy.[7]

## Mechanism of action [edit]

As an antibacterial, dapsone inhibits bacterial synthesis of dihydrofolic acid, via competition with para-aminobenzoate for the active site of dihydropteroate synthase.[37] Though structurally distinct from dapsone, the sulfonamide group of antibacterial drugs also work in this way.

As an anti-inflammatory, dapsone inhibits the enzyme myeloperoxidase. As part of the respiratory burst that neutrophils use to kill bacteria, myeloperoxidase converts hydrogen peroxide ($H_2O_2$) into hypochlorous acid (HOCl). HOCl is the most potent oxidant generated by neutrophils, and can cause significant tissue damage during inflammation. Dapsone arrests myeloperoxidase in an inactive intermediate form, reversibly inhibiting the enzyme. This prevents accumulation of hypochlorous acid, and reduces tissue damage during inflammation.[38][39][40][41][42] Myeloperoxidase inhibition has also been suggested as a neuron-sparing mechanism for reducing inflammation in neurodegenerative diseases such as Alzheimer's disease and stroke.[43]

When used for the treatment of skin conditions in which bacteria do not have a role, the mechanism or action of dapsone is not well understood. Dapsone has anti-inflammatory and immunomodulatory effects,[44] which are thought to come from the drug's blockade of myeloperoxidase. This is thought to be its mechanism of action in treating dermatitis herpetiformis.[45]

Dapsone is an odorless white to creamy-white crystalline powder with a slightly bitter taste.

## Specific considerations [edit]

Certain patients are at higher risks of adverse effects when using dapsone. Some specific issues that should be considered are:[7]

- Related to the blood (a full blood count should be obtained prior to initiating therapy):

- Porphyria
- Anemia
- Cardiac disease
- Pulmonary disease
- HIV infection
- G6PD deficiency

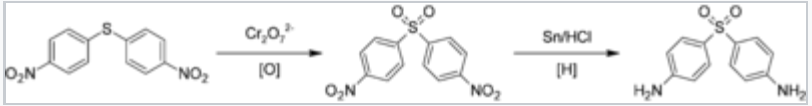
- Related to the liver (obtain liver function tests before starting therapy):
  - Liver impairment
- Related to allergy:
  - Sulfonamide allergy is associated with dapsone allergy

HbA1c may be an unreliable measure of glycemic control in people with diabetes mellitus taking dapsone due to increased red cell turnover.

# History [edit]

## Discovery [edit]

In the early 20th century, the German chemist Paul Ehrlich was developing theories of selective toxicity based largely on the ability of certain dyes to kill microbes. Gerhard Domagk, who would later win a Nobel Prize for his efforts, made a major breakthrough in 1932 with the discovery of the antibacterial prontosil red (sulfonamidochrysoidine). Further investigation into the involved chemicals opened the way to sulfa drug and sulfone therapy, first with the discovery of sulfanilamide, the active agent of prontosil, by Daniel Bovet and his team at Pasteur Institute (1935),[46] then with of dapsone independently by Ernest Fourneau[47] in France and Gladwin Buttle[48] in United-Kingdom.[49]



First synthesis of Dapsone from 4,4'-Thiodianiline
Fromm & Wittman, 1908

## Proposed use in antimalarial drugs [edit]

The spread of drug-resistant malaria in Africa has encouraged the development of new, low-cost antimalarial drugs. *Plasmodium falciparum*, one of the *Plasmodium* species that causes malaria, has developed resistance both to chloroquine and sulfadoxine/pyrimethamine, two of the most common treatments for malaria. Artemisinin, another antimalarial drug, had been developed in the 1980s but was too expensive for large-scale use. This led GlaxoSmithKline to develop Lapdap, a combination drug consisting of chlorproguanil and dapsone. Lapdap was licensed in the United Kingdom starting in October 2003.[19]

One advantage of Lapdap had was that chlorproguanil and dapsone are both low-cost drugs. Another was that by virtue of being of a combination drug, it was less likely to cause drug resistance. However, because dapsone causes hemolytic anemia in patients with G6PD deficiency, and because G6PD deficiency affects 10-25% of the population of sub-Saharan Africa, it was discovered that Lapdap is not safe for use in Africa. It was available in many African countries for four years before GlaxoSmithKline took it off the market in February 2008.[19]

## Dapsone gel [edit]

Dapsone had been reported in a few cases to effectively treat acne, but the risk of hemolytic anemia kept it from being widely used for this purpose. For many years scientists attempted to develop a topical formulation of dapsone that would be as effective against acne as oral dapsone, but without the hemolysis

side effect. This was difficult to accomplish because dapsone is highly insoluble in aqueous solvents. In the early 2000s QLT USA developed Aczone, a 5% dapsone gel that was shown to be effective against acne without causing clinically significant declines in hemoglobin levels, even in subjects with G6PD deficiency.[50] In February 2016, the FDA approved a 7.5% dapsone gel. This higher strength has the advantage of a once-daily application, versus twice-daily application of the 5% formulation.[51]

# Diazepam

From Wikipedia, the free encyclopedia

**Diazepam**, first marketed as **Valium**, is a medication of the benzodiazepine family that typically produces a calming effect. It is commonly used to treat a range of conditions including anxiety, alcohol withdrawal syndrome, benzodiazepine withdrawal syndrome, muscle spasms, seizures, trouble sleeping, and restless legs syndrome.[3] It may also be used to cause memory loss during certain medical procedures.[4][5] It can be taken by mouth, inserted into the rectum, injected into muscle, or injected into a vein.[5] When given into a vein, effects begin in one to five minutes and last up to an hour.[5] By mouth, effects may take 40 minutes to begin.[6]

Common side effects include sleepiness and trouble with coordination.[5] Serious side effects are rare.[3] They include suicide, decreased breathing, and an increased risk of seizures if used too frequently in those with epilepsy.[3][5] Occasionally excitement or agitation may occur.[7][8] Long term use can result in tolerance, dependence, and withdrawal symptoms on dose reduction. Abrupt stopping after long-term use can be potentially dangerous.[3] After stopping, cognitive problems may persist for six months or longer.[7] It is not recommended during pregnancy or breastfeeding.[5] Its mechanism of action is by increasing the effect of the neurotransmitter *gamma*-Aminobutyric acid (GABA).[7]

Diazepam was first synthesized by Leo Sternbach, and was first manufactured by Hoffmann-La Roche. It has been one of the most frequently prescribed medications in the world since its launch in 1963. In the United States it was the highest selling medication between 1968 and 1982, selling more than two billion tablets in 1978 alone. In 1985 the patent ended, and there are now more than 500 brands available on the market.[3] Diazepam is on the World Health Organization's List of Essential Medicines, the most important medications needed in a basic health system.[9] The wholesale cost in the developing world is about 0.01 USD per dose as of 2014.[10] In the United States it is about 0.40 USD per dose.[5]

## Medical uses [edit]

Diazepam is mainly used to treat anxiety, insomnia, panic attacks and symptoms of acute alcohol withdrawal. It is also used as a premedication for inducing sedation, anxiolysis, or amnesia before certain medical procedures (e.g., endoscopy).[11][12] Diazepam is the drug of choice for treating benzodiazepine dependence with its long half-life allowing easier dose reduction. Benzodiazepines have a relatively low toxicity in overdose.[7]

Diazepam has a number of uses including:

- Treatment of anxiety, panic attacks, and states of agitation[11]
- Treatment of neurovegetative symptoms associated with vertigo[13]
- Treatment of the symptoms of alcohol, opiate, and benzodiazepine withdrawal[11][14]
- Short-term treatment of insomnia[11]
- Treatment of tetanus, together with other measures of intensive treatment[15]
- Adjunctive treatment of spastic muscular paresis (paraplegia/tetraplegia) caused by cerebral or spinal cord conditions such as stroke, multiple sclerosis, or spinal cord injury (long-term treatment is coupled with other rehabilitative measures)[16]
- Palliative treatment of stiff person syndrome[17]
- Pre- or postoperative sedation, anxiolysis and/or amnesia (e.g., before endoscopic or surgical procedures)[16]
- Treatment of complications with a hallucinogen crisis and stimulant overdoses and psychosis, such as LSD, cocaine, or methamphetamine[18]

- Preventative treatment of oxygen toxicity during hyperbaric oxygen therapy[19]

Dosages should be determined on an individual basis, depending on the condition being treated, severity of symptoms, patient body weight, and any other conditions the person may have.[18]

## Seizures [edit]

Intravenous diazepam or lorazepam are first-line treatments for status epilepticus.[7][20] However, lorazepam has advantages over diazepam, including a higher rate of terminating seizures and a more prolonged anticonvulsant effect.[21][*needs update*] Diazepam is rarely used for the long-term treatment of epilepsy because tolerance to its anticonvulsant effects usually develops within six to 12 months of treatment, effectively rendering it useless for that purpose.[18][22]

The anticonvulsant effects of diazepam can help in the treatment of seizures due to a drug overdose or chemical toxicity as a result of exposure to sarin, VX, or soman (or other organophosphate poisons), lindane, chloroquine, physostigmine, or pyrethroids.[18][23]

It is sometimes used intermittently for the prevention of febrile seizures that may occur in children under five years of age.[7] This use, however, is not typically recommended as the benefits are small and side effects are common.[24] Long-term use of diazepam for the management of epilepsy is not recommended; however, a subgroup of individuals with treatment-resistant epilepsy benefit from long-term benzodiazepines, and for such individuals, clorazepate has been recommended due to its slower onset of tolerance to the anticonvulsant effects.[7]

Diazepam tablets (2, 5, and 10 mg)

## Other [edit]

Diazepam is used for the emergency treatment of eclampsia, when IV magnesium sulfate and blood-pressure control measures have failed.[25][26] Benzodiazepines do not have any pain-relieving properties themselves, and are generally recommended to avoid in individuals with pain.[27] However, benzodiazepines such as diazepam can be used for their muscle-relaxant properties to alleviate pain caused by muscle spasms and various dystonias, including blepharospasm.[28][29] Tolerance often develops to the muscle relaxant effects of benzodiazepines such as diazepam.[30] Baclofen[31] or tizanidine is sometimes used as an alternative to diazepam.

## Availability [edit]

Diazepam is marketed in over 500 brands throughout the world.[32] It is supplied in oral, injectable, inhalation, and rectal forms.[18][33][34]

The United States military employs a specialized diazepam preparation known as Convulsive Antidote, Nerve Agent (CANA), which contains diazepam. One CANA kit is typically issued to service members, along with three Mark I NAAK kits, when operating in circumstances where chemical weapons in the form of nerve agents are considered a potential hazard. Both of these kits deliver drugs using autoinjectors. They are intended for use in "buddy aid" or "self aid" administration of the drugs in the field prior to decontamination and delivery of the patient to definitive medical care.[35]

# Contraindications [edit]

Use of diazepam should be avoided, when possible, in individuals with:[36]

- Ataxia
- Severe hypoventilation
- Acute narrow-angle glaucoma
- Severe hepatic deficiencies (hepatitis and liver cirrhosis decrease elimination by a factor of two)
- Severe renal deficiencies (for example, patients on dialysis)
- Liver disorders
- Severe sleep apnea
- Severe depression, particularly when accompanied by suicidal tendencies
- Psychosis
- Pregnancy or breast feeding
- Caution required in elderly or debilitated patients
- Coma or shock
- Abrupt discontinuation of therapy
- Acute intoxication with alcohol, narcotics, or other psychoactive substances (with the exception of some hallucinogens and/or stimulants, where it is occasionally used as a treatment for overdose)
- History of alcohol or drug dependence
- Myasthenia gravis, an autoimmune disorder causing marked fatiguability
- Hypersensitivity or allergy to any drug in the benzodiazepine class

## Caution [edit]

- Benzodiazepine abuse and misuse should be checked if used in the alcohol- or drug-dependent people or those with comorbid psychiatric disorders.[37]
- Pediatric patients
  - Less than 18 years of age, this treatment is usually not indicated, except for treatment of epilepsy, and pre- or postoperative treatment. The smallest possible effective dose should be used for this group of patients.[38]
  - Under 6 months of age, safety and effectiveness have not been established; diazepam should not be given to those in this age group.[17][38]
- Elderly and very ill patients can possibly suffer apnea or cardiac arrest. Concomitant use of other central nervous system depressants increases this risk. The smallest possible effective dose should be used for this group of people.[38][39] The elderly metabolise benzodiazepines much more slowly than younger adults, and are also more sensitive to the effects of benzodiazepines, even at similar blood plasma levels. Doses of diazepam are recommended to be about half of those given to younger people, and treatment limited to a maximum of two weeks. Long-acting benzodiazepines such as diazepam are not recommended for the elderly.[7] Diazepam can also be dangerous in geriatric patients owing to a significant increased risk of falls.[40]
- Intravenous or intramuscular injections in hypotensive people or those in shock should be administered carefully and vital signs should be monitored.[39]
- Benzodiazepines such as diazepam are lipophilic and rapidly penetrate membranes, so rapidly cross over into the placenta with significant uptake of the drug. Use of benzodiazepines including diazepam in late pregnancy, especially high doses, can result in floppy infant syndrome.[41] Diazepam when taken late in pregnancy, during the third trimester, causes a definite risk of a severe benzodiazepine withdrawal syndrome in the neonate with symptoms including hypotonia, and reluctance to suck, to apnoeic spells, cyanosis, and impaired metabolic responses to cold stress. Floppy infant syndrome and sedation in the newborn may also occur. Symptoms of floppy infant syndrome and the neonatal benzodiazepine withdrawal syndrome have been reported to persist from hours to months after birth.[42]

# Adverse effects [edit]

Adverse effects of benzodiazepines such as diazepam include anterograde amnesia and confusion (especially pronounced in higher doses) and sedation. The elderly are more prone to adverse effects of diazepam, such as confusion, amnesia, ataxia, and hangover effects, as well as falls. Long-term use of benzodiazepines such as diazepam is associated with drug tolerance, benzodiazepine dependence, and benzodiazepine withdrawal syndrome.[7] Like other benzodiazepines, diazepam can impair short-term memory and learning of new information. While benzodiazepine drugs such as diazepam can cause anterograde amnesia, they do not cause retrograde amnesia; information learned before using benzodiazepines is not impaired. Tolerance to the cognitive-impairing effects of benzodiazepines does not tend to develop with long-term use, and the elderly are more sensitive to them.[43] Additionally, after cessation of benzodiazepines, cognitive deficits may persist for at least six months; it is unclear whether these impairments take longer than six months to abate or if they are permanent. Benzodiazepines may also cause or worsen depression.[7] Infusions or repeated intravenous injections of diazepam when managing seizures, for example, may lead to drug toxicity, including respiratory depression, sedation and hypotension. Drug tolerance may also develop to infusions of diazepam if it is given for longer than 24 hours.[7] Adverse effects such as sedation, benzodiazepine dependence, and abuse potential limit the use of benzodiazepines.[44]

Diazepam has a range of side effects common to most benzodiazepines, including:

- Suppression of REM sleep
- Impaired motor function
  - Impaired coordination
  - Impaired balance
  - Dizziness
- Depression[45]
- Reflex tachycardia[46]

Less commonly, paradoxical side effects can occur, including nervousness, irritability, excitement, worsening of seizures, insomnia, muscle cramps, changes in libido, and in some cases, rage and violence. These adverse reactions are more likely to occur in children, the elderly, and individuals with a history of drug or alcohol abuse and or aggression.[7][47][48][49] Diazepam may increase, in some people, the propensity toward self-harming behaviours and, in extreme cases, may provoke suicidal tendencies or acts.[50] Very rarely dystonia can occur.[51]

Diazepam may impair the ability to drive vehicles or operate machinery. The impairment is worsened by consumption of alcohol, because both act as central nervous system depressants.[17]

During the course of therapy, tolerance to the sedative effects usually develops, but not to the anxiolytic and myorelaxant effects.[52]

Patients with severe attacks of apnea during sleep may suffer respiratory depression (hypoventilation), leading to respiratory arrest and death.

Diazepam in doses of 5 mg or more causes significant deterioration in alertness performance combined with increased feelings of sleepiness.[53]

## Tolerance and dependence [edit]

Diazepam, as with other benzodiazepine drugs, can cause tolerance, physical dependence, substance use disorder, and benzodiazepine withdrawal syndrome. Withdrawal from diazepam or other benzodiazepines often leads to withdrawal symptoms similar to those seen during barbiturate or alcohol withdrawal. The higher the dose and the longer the drug is taken, the greater the risk of experiencing unpleasant withdrawal symptoms.

Withdrawal symptoms can occur from standard dosages and also after short-term use, and can range from insomnia and anxiety to more serious symptoms, including seizures and psychosis. Withdrawal symptoms can sometimes resemble pre-existing conditions and be misdiagnosed. Diazepam may produce less intense withdrawal symptoms due to its long elimination half-life.

Benzodiazepine treatment should be discontinued as soon as possible by a slow and gradual dose reduction regimen.[7][54] Tolerance develops to the therapeutic effects of benzodiazepines; for example tolerance occurs to the anticonvulsant effects and as a result benzodiazepines are not generally recommended for the long-term management of epilepsy. Dose increases may overcome the effects of tolerance, but tolerance may then develop to the higher dose and adverse effects may increase. The mechanism of tolerance to benzodiazepines includes uncoupling of receptor sites, alterations in gene expression, down-regulation of receptor sites, and desensitisation of receptor sites to the effect of GABA. About one-third of individuals who take benzodiazepines for longer than four weeks become dependent and experience withdrawal syndrome on cessation.[7]

Differences in rates of withdrawal (50–100%) vary depending on the patient sample. For example, a random sample of long-term benzodiazepine users typically finds around 50% experience few or no withdrawal symptoms, with the other 50% experiencing notable withdrawal symptoms. Certain select patient groups show a higher rate of notable withdrawal symptoms, up to 100%.[55]

Rebound anxiety, more severe than baseline anxiety, is also a common withdrawal symptom when discontinuing diazepam or other benzodiazepines.[56] Diazepam is therefore only recommended for short-term therapy at the lowest possible dose owing to risks of severe withdrawal problems from low doses even after gradual reduction.[57] The risk of pharmacological dependence on diazepam is significant, and patients experience symptoms of benzodiazepine withdrawal syndrome if it is taken for six weeks or longer.[58] In humans, tolerance to the anticonvulsant effects of diazepam occurs frequently.[59]

### Dependence [edit]

Improper or excessive use of diazepam can lead to dependence.[60] At a particularly high risk for diazepam misuse, abuse or dependence are:

- People with a history of alcohol or drug abuse or dependence[17][61] Diazepam increases craving for alcohol in problem alcohol consumers. Diazepam also increases the volume of alcohol consumed by problem drinkers.[62]
- People with severe personality disorders, such as borderline personality disorder[63]

Patients from the aforementioned groups should be monitored very closely during therapy for signs of abuse and development of dependence. Therapy should be discontinued if any of these signs are noted, although if dependence has developed, therapy must still be discontinued gradually to avoid severe withdrawal symptoms. Long-term therapy in these people is not recommended.[17][61]

People suspected of being dependent on benzodiazepine drugs should be very gradually tapered off the drug. Withdrawals can be life-threatening, particularly when excessive doses have been taken for extended periods of time. Equal prudence should be used whether dependence has occurred in therapeutic or recreational contexts.

## Overdose [edit]

*Main article: Benzodiazepine overdose*

An individual who has consumed too much diazepam typically displays one or more of these symptoms in a period of approximately four hours immediately following a suspected overdose:[17][64]

- Drowsiness
- Mental confusion
- Hypotension
- Impaired motor functions
  - Impaired reflexes
  - Impaired coordination
  - Impaired balance
  - Dizziness

- Coma

Although not usually fatal when taken alone, a diazepam overdose is considered a medical emergency and generally requires the immediate attention of medical personnel. The antidote for an overdose of diazepam (or any other benzodiazepine) is flumazenil (Anexate). This drug is only used in cases with severe respiratory depression or cardiovascular complications. Because flumazenil is a short-acting drug, and the effects of diazepam can last for days, several doses of flumazenil may be necessary. Artificial respiration and stabilization of cardiovascular functions may also be necessary. Though not routinely indicated, activated charcoal can be used for decontamination of the stomach following a diazepam overdose. Emesis is contraindicated. Dialysis is minimally effective. Hypotension may be treated with levarterenol or metaraminol.[17][18][64][65]

The oral $LD_{50}$ (lethal dose in 50% of the population) of diazepam is 720 mg/kg in mice and 1240 mg/kg in rats.[17] D. J. Greenblatt and colleagues reported in 1978 on two patients who had taken 500 and 2000 mg of diazepam, respectively, went into moderately deep comas, and were discharged within 48 hours without having experienced any important complications, in spite of having high concentrations of diazepam and its metabolites desmethyldiazepam, oxazepam, and temazepam, according to samples taken in the hospital and as follow-up.[66]

Overdoses of diazepam with alcohol, opiates and/or other depressants may be fatal.[65][67]

## Interactions [edit]

If diazepam is administered concomitantly with other drugs, attention should be paid to the possible pharmacological interactions. Particular care should be taken with drugs that potentiate the effects of diazepam, such as barbiturates, phenothiazines, opioids, and antidepressants.[17]

Diazepam does not increase or decrease hepatic enzyme activity, and does not alter the metabolism of other compounds. No evidence would suggest diazepam alters its own metabolism with chronic administration.[18]

Agents with an effect on hepatic cytochrome P450 pathways or conjugation can alter the rate of diazepam metabolism. These interactions would be expected to be most significant with long-term diazepam therapy, and their clinical significance is variable.[18]

- Diazepam increases the central depressive effects of alcohol, other hypnotics/sedatives (e.g., barbiturates), other muscle relaxants, certain antidepressants, sedative antihistamines, opioids, and antipsychotics, as well as anticonvulsants such as phenobarbital, phenytoin, and carbamazepine. The euphoriant effects of opioids may be increased, leading to increased risk of psychological dependence.[7][38][68]
- Cimetidine, omeprazole, oxcarbazepine, ticlopidine, topiramate, ketoconazole, itraconazole, disulfiram, fluvoxamine, isoniazid, erythromycin, probenecid, propranolol, imipramine, ciprofloxacin, fluoxetine, and valproic acid prolong the action of diazepam by inhibiting its elimination.[7][18][33]
- Alcohol in combination with diazepam may cause a synergistic enhancement of the hypotensive properties of benzodiazepines and alcohol.[69]
- Oral contraceptives significantly decrease the elimination of desmethyldiazepam, a major metabolite of diazepam.[38][70]
- Rifampin, phenytoin, carbamazepine, and phenobarbital increase the metabolism of diazepam, thus decreasing drug levels and effects.[18] Dexamethasone and St John's wort also increase the metabolism of diazepam.[7]
- Diazepam increases the serum levels of phenobarbital.[71]
- Nefazodone can cause increased blood levels of benzodiazepines.[38]
- Cisapride may enhance the absorption, and therefore the sedative activity, of diazepam.[72]
- Small doses of theophylline may inhibit the action of diazepam.[73]
- Diazepam may block the action of levodopa (used in the treatment of Parkinson's disease).[68]
[18]

- Diazepam may alter digoxin serum concentrations.
- Other drugs that may have interactions with diazepam include antipsychotics (e.g. chlorpromazine), MAO inhibitors, and ranitidine.[38]
- Because it acts on the GABA receptor, the herb valerian may produce an adverse effect.[74]
- Foods that acidify the urine can lead to faster absorption and elimination of diazepam, reducing drug levels and activity.[68]
- Foods that alkalinize the urine can lead to slower absorption and elimination of diazepam, increasing drug levels and activity.[18]
- Reports conflict as to whether food in general has any effects on the absorption and activity of orally administered diazepam.[68]

# Pharmacology [edit]

Diazepam is a long-acting "classical" benzodiazepine. Other classical benzodiazepines include chlordiazepoxide, clonazepam, lorazepam, oxazepam, nitrazepam, temazepam, flurazepam, bromazepam, and clorazepate.[75] Diazepam has anticonvulsant properties.[76] Diazepam has no effect on GABA levels and no effect on glutamate decarboxylase activity, but has a slight effect on gamma-aminobutyric acid transaminase activity. It differs from some other anticonvulsive drugs with which it was compared.[77] Benzodiazepines act via micromolar benzodiazepine binding sites as Ca2+ channel blockers and significantly inhibit depolarization-sensitive Calcium uptake in rat nerve cell preparations.[78]

5 mg Valium Roche packaging Australia

Diazepam inhibits acetylcholine release in mouse hippocampal synaptosomes. This has been found by measuring sodium-dependent high-affinity choline uptake in mouse brain cells *in vitro*, after pretreatment of the mice with diazepam *in vivo*. This may play a role in explaining diazepam's anticonvulsant properties.[79]

Diazepam binds with high affinity to glial cells in animal cell cultures.[80] Diazepam at high doses has been found to decrease histamine turnover in mouse brain via diazepam's action at the benzodiazepine-GABA receptor complex.[81] Diazepam also decreases prolactin release in rats.[82]

## Mechanism of action [edit]

*See also: Benzodiazepine*

Benzodiazepines are positive allosteric modulators of the GABA type A receptors (GABAA). The GABAA receptors are ligand-gated chloride-selective ion channels that are activated by GABA, the major inhibitory neurotransmitter in the brain. Binding of benzodiazepines to this receptor complex promotes binding of GABA, which in turn increases the total conduction of chloride ions across the neuronal cell membrane. This increased chloride ion influx hyperpolarizes the neuron's membrane potential. As a result, the difference between resting potential and threshold potential is increased and firing is less likely.

The GABAA receptor is a heteromer composed of five subunits, the most common ones being two αs, two βs, and one γ (α2β2γ). For each subunit, many subtypes exist (α1–6, β1–3, and γ1–3). GABAA receptors containing the α1 subunit mediate the sedative, the anterograde amnesic, and partly the anticonvulsive effects of diazepam. GABAA receptors containing α2 mediate the anxiolytic actions and to a large degree the myorelaxant effects. GABAA receptors containing α3 and α5 also contribute to benzodiazepines myorelaxant actions, whereas GABAA receptors comprising the α5 subunit were shown to modulate the temporal and spatial memory effects of benzodiazepines.[83] Diazepam is not the only drug to target these GABAA receptors. Drugs like Flumazenil also bind to GABAA to induce their effects. [84]

Diazepam appears to act on areas of the limbic system, thalamus, and hypothalamus, inducing anxiolytic effects. Benzodiazepine drugs including diazepam increase the inhibitory processes in the cerebral [85]

cortex.

The anticonvulsant properties of diazepam and other benzodiazepines may be in part or entirely due to binding to voltage-dependent sodium channels rather than benzodiazepine receptors. Sustained repetitive firing seems limited by benzodiazepines' effect of slowing recovery of sodium channels from inactivation.[86]

The muscle relaxant properties of diazepam are produced via inhibition of polysynaptic pathways in the spinal cord.[87]

### Pharmacokinetics [edit]

Diazepam can be administered orally, intravenously (must be diluted, as it is painful and damaging to veins), intramuscularly (IM), or as a suppository.[18]

When administered orally, it is rapidly absorbed and has a fast onset of action. The onset of action is one to five minutes for IV administration and 15–30 minutes for IM administration. The duration of diazepam's peak pharmacological effects is 15 minutes to one hour for both routes of administration.[46] The bioavailability after oral administration is 100%, and 90% after rectal administration. Peak plasma levels occur between 30 and 90 minutes after oral administration and between 30 and 60 minutes after intramuscular administration; after rectal administration, peak plasma levels occur after 10 to 45 minutes. Diazepam is highly protein-bound, with 96 to 99% of the absorbed drug being protein-bound. The distribution half-life of diazepam is two to 13 minutes.[7]

When diazepam is administered IM, absorption is slow, erratic, and incomplete.[11]

Diazepam is highly lipid-soluble, and is widely distributed throughout the body after administration. It easily crosses both the blood–brain barrier and the placenta, and is excreted into breast milk. After absorption, diazepam is redistributed into muscle and adipose tissue. Continual daily doses of diazepam quickly build to a high concentration in the body (mainly in adipose tissue), far in excess of the actual dose for any given day.[7][18]

Diazepam is stored preferentially in some organs, including the heart. Absorption by any administered route and the risk of accumulation is significantly increased in the neonate, and withdrawal of diazepam during pregnancy and breast feeding is clinically justified.[88]

Diazepam undergoes oxidative metabolism by demethylation (CYP 2C9, 2C19, 2B6, 3A4, and 3A5), hydroxylation (CYP 3A4 and 2C19) and glucuronidation in the liver as part of the cytochrome P450 enzyme system. It has several pharmacologically active metabolites. The main active metabolite of diazepam is desmethyldiazepam (also known as nordazepam or nordiazepam). Its other active metabolites include the minor active metabolites temazepam and oxazepam. These metabolites are conjugated with glucuronide, and are excreted primarily in the urine. Because of these active metabolites, the serum values of diazepam alone are not useful in predicting the effects of the drug. Diazepam has a biphasic half-life of about one to three days, and two to seven days for the active metabolite desmethyldiazepam.[7] Most of the drug is metabolised; very little diazepam is excreted unchanged.[18] The elimination half-life of diazepam and also the active metabolite desmethyldiazepam increases significantly in the elderly, which may result in prolonged action, as well as accumulation of the drug during repeated administration.[89]

## Physical and chemical properties [edit]

Diazepam occurs as solid white or yellow crystals with a melting point of 131.5 to 134.5 °C. It is odorless, and has a slightly bitter taste. The British Pharmacopoeia lists it as being very slightly soluble in water, soluble in alcohol, and freely soluble in chloroform. The United States Pharmacopoeia lists diazepam as soluble 1 in 16 ethyl alcohol, 1 in 2 of chloroform, 1 in 39 ether, and practically insoluble in water. The pH of diazepam is neutral (i.e., pH = 7). Due to additives such as benzoic acid/benzoate in the injectable form. (Plumb's, 6th edition page 372) Diazepam has a shelf life of five years for oral tablets and three years for IV/IM solutions.[18] Diazepam should be stored at room temperature (15–30 °C). The solution for parenteral injection should be protected from light and kept from freezing. The oral forms should be stored [33]

in air-tight containers and protected from light.

Diazepam can absorb into plastics, so liquid preparations should not be kept in plastic bottles or syringes, etc. As such, it can leach into the plastic bags and tubing used for intravenous infusions. Absorption appears to depend on several factors, such as temperature, concentration, flow rates, and tube length. Diazepam should not be administered if a precipitate has formed and does not dissolve.[33]

### Detection in body fluids [edit]

Diazepam may be quantified in blood or plasma to confirm a diagnosis of poisoning in hospitalized patients, provide evidence in an impaired driving arrest, or to assist in a medicolegal death investigation. Blood or plasma diazepam concentrations are usually in a range of 0.1–1.0 mg/l in persons receiving the drug therapeutically, 1–5 mg/l in those arrested for impaired driving, and 2–20 mg/l in victims of acute overdose. Most commercial immunoassays for the benzodiazepine class of drugs cross-react with diazepam, but confirmation and quantitation are usually performed using chromatographic techniques.[90][91][92]

## History [edit]

Diazepam was the second benzodiazepine invented by Dr. Leo Sternbach of Hoffmann-La Roche at the company's Nutley, New Jersey, facility[93] following chlordiazepoxide (Librium), which was approved for use in 1960. Released in 1963 as an improved version of Librium, diazepam became incredibly popular, helping Roche to become a pharmaceutical industry giant. It is 2.5 times more potent than its predecessor, which it quickly surpassed in terms of sales. After this initial success, other pharmaceutical companies began to introduce other benzodiazepine derivatives.[94]

The benzodiazepines gained popularity among medical professionals as an improvement over barbiturates, which have a comparatively narrow therapeutic index, and are far more sedative at therapeutic doses. The benzodiazepines are also far less dangerous; death rarely results from diazepam overdose, except in cases where it is consumed with large amounts of other depressants (such as alcohol or opioids).[65] Benzodiazepine drugs such as diazepam initially had widespread public support, but with time the view changed to one of growing criticism and calls for restrictions on their prescription.[95]

Diazepam was the top-selling pharmaceutical in the United States from 1969 to 1982, with peak sales in 1978 of 2.3 billion tablets.[94] Diazepam, along with oxazepam, nitrazepam and temazepam, represents 82% of the benzodiazepine market in Australia.[96] While psychiatrists continue to prescribe diazepam for the short-term relief of anxiety, neurology has taken the lead in prescribing diazepam for the palliative treatment of certain types of epilepsy and spastic activity, for example, forms of paresis. It is also the first line of defense for a rare disorder called stiff-person syndrome.[16]

## Society and culture [edit]

### Recreational use [edit]

*See also: Benzodiazepine drug misuse*

Diazepam is a drug of potential abuse and can cause drug dependence. Urgent action by national governments has been recommended to improve prescribing patterns of benzodiazepines such as diazepam.[97][98] A single dose of diazepam modulates the dopamine system in similar ways to how morphine and alcohol modulate the dopaminergic pathways.[99] Between 50 and 64% of rats will self-administer diazepam.[100] Diazepam has been shown to be able to substitute for the behavioural effects of barbiturates in a primate study.[101] Diazepam has been found as an adulterant in heroin.[102]

Diazepam drug misuse can occur either through recreational misuse where the drug is taken to achieve a high or when the drug is continued long term against medical advice.[103]

Sometimes, it is used by stimulant users to "come down" and sleep and to help control the urge to binge.[104]

A large-scale study in the US, conducted by SAMHSA, using data from 2011, determined benzodiazepines were present in 28.7% of emergency department visits involving nonmedical use of pharmaceuticals. In this regard, benzodiazepines are second only to opiates, the study found in 39.2% of visits. About 29.3% of drug-related suicide attempts involve benzodiazepines, making them the most frequently represented class in drug-related suicide attempts. Males abuse benzodiazepines as commonly as females.[105]

Benzodiazepines, including diazepam, nitrazepam, and flunitrazepam, account for the largest volume of forged drug prescriptions in Sweden, a total of 52% of drug forgeries being for benzodiazepines.[106]

Diazepam was detected in 26% of cases of people suspected of driving under the influence of drugs in Sweden, and its active metabolite nordazepam was detected in 28% of cases. Other benzodiazepines and zolpidem and zopiclone also were found in high numbers. Many drivers had blood levels far exceeding the therapeutic dose range, suggesting a high degree of abuse potential for benzodiazepines and zolpidem and zopiclone.[90] In Northern Ireland in cases where drugs were detected in samples from impaired drivers who were not impaired by alcohol, benzodiazepines were found in 87% of cases. Diazepam was the most commonly detected benzodiazepine.[107]

### Legal status [edit]

Diazepam is regulated in most countries as a prescription drug:

- International: diazepam is a Schedule IV controlled drug under the Convention on Psychotropic Substances.[108]
- UK: classified as a controlled drug, listed under Schedule IV, Part I (CD Benz POM) of the Misuse of Drugs Regulations 2001, allowing possession with a valid prescription. The Misuse of Drugs Act 1971 makes it illegal to possess the drug without a prescription, and for such purposes it is classified as a Class C drug.[109]
- Germany: classified as a prescription drug, or in high dosage as a restricted drug (*Betäubungsmittelgesetz, Anhang III*).[110]
- Australia: Diazepam is Schedule 4 substance under the Poisons Standard (October 2015).[111] A schedule 4 drug is outlined in the Poisons Act 1964 as, "Substances, the use or supply of which should be by or on the order of persons permitted by State or Territory legislation to prescribe and should be available from a pharmacist on prescription." [111]
- US: Diazepam is controlled as a Schedule IV substance under the Controlled Substances Act of 1970

### Judicial executions [edit]

The states of California and Florida offer diazepam to condemned inmates as a pre-execution sedative as part of their lethal injection program, although the state of California has not executed a prisoner since 2006.[112][113]

## Veterinary uses [edit]

Diazepam is used as a short-term sedative and anxiolytic for cats and dogs,[114] sometimes used as an appetite stimulant.[114][115] It can also be used to stop seizures in dogs and cats.[116][117]

# Hydrochlorothiazide

From Wikipedia, the free encyclopedia

**Hydrochlorothiazide** (abbreviated **HCTZ**, **HCT**, or **HZT**), is a diuretic medication often used to treat high blood pressure and swelling due to fluid build up.[2] Other uses include diabetes insipidus, renal tubular acidosis, and to decrease the risk of kidney stones in those with high calcium level in the urine.[2] For high blood pressure it is often recommended as a first line treatment.[2][3] HCTZ is taken by mouth and may be combined with other blood pressure medications as a single pill to increase the effectiveness.[2]

Potential side effects include poor kidney function, electrolyte imbalances especially low blood potassium and less commonly low blood sodium, gout, high blood sugar, and feeling faint initially upon standing up.[2] While allergies to HCTZ are reported to occur more often in those with allergies to sulfa drugs this association is not well supported.[2] It may be used during pregnancy but is not a first line medication in this group.[2]

It is in the thiazide medication class and acts by decreasing the kidneys' ability to retain water.[2] This initially reduces blood volume, decreasing blood return to the heart and thus cardiac output.[4] Long term, however, it is believed to lower peripheral vascular resistance.[4]

Two companies, Merck and Ciba, state they discovered the medication which became commercially available in 1959.[5] It is on the World Health Organization's List of Essential Medicines, the most important medications needed in a basic health system.[6] In 2008 it was the second most commonly used blood pressure medication in the United States.[4] It is available as a generic drug[2] and is relatively affordable.[7]

| **Excretion** | Primarily kidney (>95% as unchanged drug) |

## Medical uses [edit]

Hydrochlorothiazide is frequently used for the treatment of hypertension, congestive heart failure, symptomatic edema, *diabetes insipidus*, renal tubular acidosis.[2] It is also used for the prevention of kidney stones in those who have high levels of calcium in their urine.[2]

Most of the research supporting the use of thiazide diuretics in hypertension was done using chlorthalidone, a different medication in the same class. Some more recent studies have suggested that chlorthalidone might be the more effective thiazide diuretic.[8]

It is also sometimes used for treatment of hypoparathyroidism,[9] hypercalciuria, Dent's disease, and Ménière's disease. For *diabetes insipidus*, the effect of thiazide diuretics is presumably mediated by a hypovolemia-induced increase in proximal sodium and water reabsorption, thereby diminishing water delivery to the ADH-sensitive sites in the collecting tubules and increasing the urine osmolality.

Thiazides are also used in the treatment of osteoporosis. Thiazides decrease mineral bone loss by promoting calcium retention in the kidney, and by directly stimulating osteoblast differentiation and bone mineral formation.[10]

It may be given together with other antihypertensive agents in fixed-dose combination preparations, such as in losartan/hydrochlorothiazide (see below).

## Adverse effects [edit]

- Hypokalemia, or low blood levels of potassium are an occasional side effect. It can be usually prevented by potassium supplements or by combining hydrochlorothiazide with a potassium-sparing diuretic
- Other disturbances in the levels of serum electrolytes including hypomagnesemia (low magnesium), hyponatremia (low sodium), and hypercalcemia (high calcium)
- Hyperuricemia, high levels of uric acid in the blood
- Hyperglycemia, high blood sugar
- Hyperlipidemia, high cholesterol and triglycerides
- Headache
- Nausea/vomiting
- Photosensitivity
- Weight gain
- Gout
- Pancreatitis

These side effects increase with the dose of the medication and are most common at doses of greater than 25 mg per day.

Package inserts, based on case reports and observational studies, have reported that an allergy to a sulfa drug predisposes the patient to cross sensitivity to a thiazide diuretic. A 2005 review of the literature did not find support for this cross-sensitivity.[11]

# Mechanism of action [edit]

Hydrochlorothiazide belongs to thiazide class of diuretics. It reduces blood volume by acting on the kidneys to reduce sodium ($Na^+$) reabsorption in the distal convoluted tubule. The major site of action in the nephron appears on an electroneutral NaCl co-transporter by competing for the chloride site on the transporter. By impairing $Na^+$ transport in the distal convoluted tubule, hydrochlorothiazide induces a natriuresis and concomitant water loss. Thiazides increase the reabsorption of calcium in this segment in a manner unrelated to sodium transport.[12] Additionally, by other mechanisms, HCTZ is believed to lower peripheral vascular resistance.[13]

# Society and culture [edit]

## Trade names [edit]

Hydrochlorothiazide is available as a generic drug under a large number of brand names, including Apo-Hydro, Aquazide, BPZide, Dichlotride, Esidrex, Hydrochlorot, Hydrodiuril, HydroSaluric, Hypothiazid, Microzide, Oretic and many others.

To reduce pill burden and in order to reduce side effects, hydrochlorothiazide is often used in fixed-dose combinations with many other classes of antihypertensive drugs such as:

- ACE inhibitors — e.g. Prinzide or Zestoretic (with lisinopril), Co-Renitec (with enalapril), Capozide (with captopril), Accuretic (with quinapril), Monopril HCT (with fosinopril), Lotensin HCT (with benazepril), etc.
- Angiotensin receptor blockers — e.g. Hyzaar (with losartan), Co-Diovan or Diovan HCT (with valsartan), Teveten Plus (with eprosartan), Avalide or CoAprovel (with irbesartan), Atacand HCT or Atacand Plus (with candesartan), etc.
- Beta blockers — e.g. Ziac or Lodoz (with bisoprolol), Nebilet Plus or Nebilet HCT (with nebivolol), Dutoprol or Lopressor HCT (with metoprolol), etc.
- Direct renin inhibitors — e.g. Co-Rasilez or Tekturna HCT (with aliskiren)
- Potassium sparing diuretics: Dyazide and Maxzide triamterene[14]

Co-Diovan (valsartan and HCTZ)

Two generic benazepril HCl 20 mg and HCTZ 25 mg oral tablets

## Sport [edit]

Hydrochlorothiazide was detected in the urine of the Russian cyclist Alexandr Kolobnev during the 2011 Tour de France.[15] Kolobnev was the only cyclist to leave the 2011 race in connection with adverse findings at a doping control.[16] While hydrochlorothiazide is not itself a performance-enhancing drug, it may be used to mask the use of performance-enhancing drugs, and is classed by the World Anti-Doping Agency as a "specified substance". Kolobnev was subsequently cleared of all charges of intentional doping.[17][18]

# Ibuprofen

From Wikipedia, the free encyclopedia

**Ibuprofen** is a medication in the nonsteroidal anti-inflammatory drug (NSAID) class that is used for treating pain, fever, and inflammation.[4] This includes painful menstrual periods, migraines, and rheumatoid arthritis.[4] About 60% of people improve with any given NSAID, and it is recommended that if one does not work then another should be tried.[5] It may also be used to close a patent ductus arteriosus in a premature baby. It can be used by mouth or intravenously. It typically begins working within an hour.[4]

Common side effects include heartburn and a rash.[4] Compared to other NSAIDs it may have fewer side effects such as gastrointestinal bleeding.[5] It increases the risk of heart failure, kidney failure, and liver failure.[4] At low doses, it does not appear to increase the risk of myocardial infarction, however, at higher doses it may. Ibuprofen can also result in worsened asthma.[5] While it is unclear if it is safe in early pregnancy,[4] it appears to be harmful in later pregnancy and therefore is not recommended.[6] Like other NSAIDs, it works by inhibiting the making of prostaglandins by decreasing the activity of the enzyme cyclooxygenase.[4] Ibuprofen might be a weaker anti-inflammatory than other NSAIDs.[5]

Ibuprofen was discovered in 1961 by Stewart Adams and marketed as **Brufen**.[7] It is available under a number of trade names, including **Advil** and **Motrin**.[4][8] It was first marketed in 1969 in the United Kingdom and in the United States in 1974.[4][7] It is on the WHO Model List of Essential Medicines, the most important medications needed in a basic health system.[9] It is available as a generic medication.[4] The wholesale cost in the developing world is between 0.01 and 0.04 USD per dose.[10] In the United States it costs about 0.05 USD per dose.[4]

## Medical uses [edit]

Ibuprofen is used primarily to treat fever (including postimmunisation fever), mild to moderate pain (including pain relief after surgery), painful menstruation, osteoarthritis, dental pain, headaches, and pain from kidney stones. About 60% of people respond to any NSAID; those who do not respond well to a particular one may respond to another.[11]

It is used for inflammatory diseases such as juvenile idiopathic arthritis and rheumatoid arthritis.[12][13] It is also used for pericarditis and patent ductus arteriosus.[14]

### Ibuprofen lysine [edit]

In some countries, ibuprofen lysine (the lysine salt of ibuprofen, sometimes called "ibuprofen lysinate") is licensed for treatment of the same conditions as ibuprofen; the lysine salt is used because it is more water-soluble.[15] In 2006, ibuprofen lysine was approved in the US by the Food and Drug Administration (FDA) for closure of *patent ductus arteriosus* in premature infants weighing between 500 and 1,500 grams (1 and 3 lb), who are no more than 32 weeks gestational age when usual medical management (such as fluid restriction, diuretics, and respiratory support) is not effective.[16]

## Adverse effects [edit]

Adverse effects include nausea, dyspepsia, diarrhea, constipation, gastrointestinal ulceration/bleeding, headache, dizziness, rash, salt and fluid retention, and hypertension.[13][17]

Infrequent adverse effects include esophageal ulceration, heart failure, hyperkalemia, renal impairment, confusion, and bronchospasm.[13] Ibuprofen can exacerbate asthma, sometimes fatally.[18]

Ibuprofen may be quantified in blood, plasma, or serum to demonstrate the presence of the drug in a person having experienced an anaphylactic reaction, confirm a diagnosis of poisoning in hospitalized patients, or assist in a medicolegal death investigation. A monograph relating ibuprofen plasma concentration, time since ingestion, and risk of developing

renal toxicity in overdose patients has been published.[19]

## Cardiovascular risk [edit]

Along with several other NSAIDs, chronic ibuprofen use has been found correlated with risk of hypertension[20] and myocardial infarction (heart attack),[21] particularly among those chronically using high doses. In older hypertensive patients treated with hydrochlorothiazide, ibuprofen at a high daily dose was found to significantly increase systolic blood pressure.[22] On 9 July 2015, the US FDA toughened warnings of increased heart attack and stroke risk associated with ibuprofen and related NSAIDs; the NSAID aspirin is not included in this warning.[23]

## Skin [edit]

Along with other NSAIDs, ibuprofen has been associated with the onset of bullous pemphigoid or pemphigoid-like blistering.[24] As with other NSAIDs, ibuprofen has been reported to be a photosensitising agent,[25] but it is considered a weak photosensitising agent compared to other members of the 2-arylpropionic acid class. Like other NSAIDs, ibuprofen is an extremely rare cause of the autoimmune disease Stevens–Johnson syndrome (SJS).[26][27] Ibuprofen is also an extremely rare cause of Lyell's Syndrome (toxic epidermal necrolysis).[28]

## Interactions [edit]

Drinking alcohol when taking ibuprofen may increase the risk of stomach bleeding.[29]

According to the US Food and Drug Administration, "ibuprofen can interfere with the antiplatelet effect of low-dose aspirin, potentially rendering aspirin less effective when used for cardioprotection and stroke prevention." Allowing sufficient time between doses of ibuprofen and immediate-release (IR) aspirin can avoid this problem. The recommended elapsed time between a dose of ibuprofen and a dose of aspirin depends on which is taken first. It would be 30 minutes or more for ibuprofen taken after IR aspirin, and 8 hours or more for ibuprofen taken before IR aspirin. However, this timing cannot be recommended for enteric-coated aspirin. But, if ibuprofen is taken only occasionally without the recommended timing, the reduction of the cardioprotection and stroke prevention of a daily aspirin regimen is minimal.[30]

## Overdose [edit]

Ibuprofen overdose has become common since it was licensed for OTC use. Many overdose experiences are reported in the medical literature, although the frequency of life-threatening complications from ibuprofen overdose is low.[31] Human response in cases of overdose ranges from absence of symptoms to fatal outcome despite intensive-care treatment. Most symptoms are an excess of the pharmacological action of ibuprofen, and include abdominal pain, nausea, vomiting, drowsiness, dizziness, headache, tinnitus, and nystagmus. Rarely, more severe symptoms, such as gastrointestinal bleeding, seizures, metabolic acidosis, hyperkalaemia, hypotension, bradycardia, tachycardia, atrial fibrillation, coma, hepatic dysfunction, acute renal failure, cyanosis, respiratory depression, and cardiac arrest have been reported.[32] The severity of symptoms varies with the ingested dose and the time elapsed; however, individual sensitivity also plays an important role. Generally, the symptoms observed with an overdose of ibuprofen are similar to the symptoms caused by overdoses of other NSAIDs.

Correlation between severity of symptoms and measured ibuprofen plasma levels is weak. Toxic effects are unlikely at doses below 100 mg/kg, but can be severe above 400 mg/kg (around 150 tablets of 200 mg units for an average man);[33] however, large doses do not indicate the clinical course is likely to be lethal.[34] A precise lethal dose is difficult to determine, as it may vary with age, weight, and concomitant conditions of the individual person.

Therapy is largely symptomatic. In cases presenting early, gastric decontamination is recommended. This is achieved using activated charcoal; charcoal adsorbs the drug before it can enter the systemic circulation. Gastric lavage is now rarely used, but can be considered if the amount ingested is potentially life-threatening, and it can be performed within 60 minutes of ingestion. Emesis is not recommended.[35] The majority of ibuprofen ingestions produce only mild effects and the management of overdose is straightforward. Standard measures to maintain normal urine output should be instituted and renal function monitored.[33] Since ibuprofen has acidic properties and is also excreted in the urine, forced alkaline diuresis is theoretically beneficial. However, because ibuprofen is highly protein-bound in the blood, renal excretion of unchanged drug is minimal. Forced alkaline diuresis is, therefore, of limited benefit.[36] Symptomatic therapy for hypotension, gastrointestinal bleeding, acidosis, and renal toxicity may be indicated. On occasion, close monitoring in an intensive-care unit for several days is necessary. A patient who survives the acute intoxication usually experiences no late sequelae.

### Miscarriage [edit]

A study of pregnant woman suggests those taking any type or amount of NSAIDs (including ibuprofen, diclofenac and naproxen) were 2.4 times more likely to miscarry than those not taking the drugs.[37] However, an Israeli study found no increased risk of miscarriage in the group of mothers using NSAIDs.[38]

## Mechanism of action [edit]

Nonsteroidal anti-inflammatory drugs such as ibuprofen work by inhibiting the cyclooxygenase (COX) enzymes, which convert arachidonic acid to prostaglandin $H_2$ ($PGH_2$). $PGH_2$, in turn, is converted by other enzymes to several other prostaglandins (which are mediators of pain, inflammation, and fever) and to thromboxane $A_2$ (which stimulates platelet aggregation, leading to the formation of blood clots).

Like aspirin and indometacin, ibuprofen is a nonselective COX inhibitor, in that it inhibits two isoforms of cyclooxygenase, COX-1 and COX-2. The analgesic, antipyretic, and anti-inflammatory activity of NSAIDs appears to operate mainly through inhibition of COX-2, which decreases the synthesis of prostaglandins involved in mediating inflammation, pain, fever, and swelling. Antipyretic effects may be due to action on the hypothalamus, resulting in an increased peripheral blood flow, vasodilation, and subsequent heat dissipation. Inhibition of COX-1 instead would be responsible for unwanted effects on the gastrointestinal tract.[39] However, the role of the individual COX isoforms in the analgesic, anti-inflammatory, and gastric damage effects of NSAIDs is uncertain and different compounds cause different degrees of analgesia and gastric damage.[40]

Ibuprofen is administered as a racemic mixture. The R-enantiomer undergoes extensive interconversion to the S-enantiomer *in vivo*. The S-enantiomer is believed to be the more pharmacologically active enantiomer.[41] The R-enantiomer is converted through a series of three main enzymes. These enzymes include acyl-CoA-synthetase, which converts the R-enantiomer to (-)-R-ibuprofen I-CoA; 2-arylpropionyl-CoA epimerase, which converts (-)-R-ibuprofen I-CoA to (+)-S-Ibuprofen I-CoA; and hydrolase, which converts (+)-S-ibuprofen I-CoA to the S-enantiomer.[28] In addition to the conversion of ibuprofen to the S-enantiomer, the body can metabolize ibuprofen to several other compounds, including numerous hydroxyl, carboxyl and glucuronyl metabolites. Virtually all of these have no pharmacological effects.[28]

## Chemistry [edit]

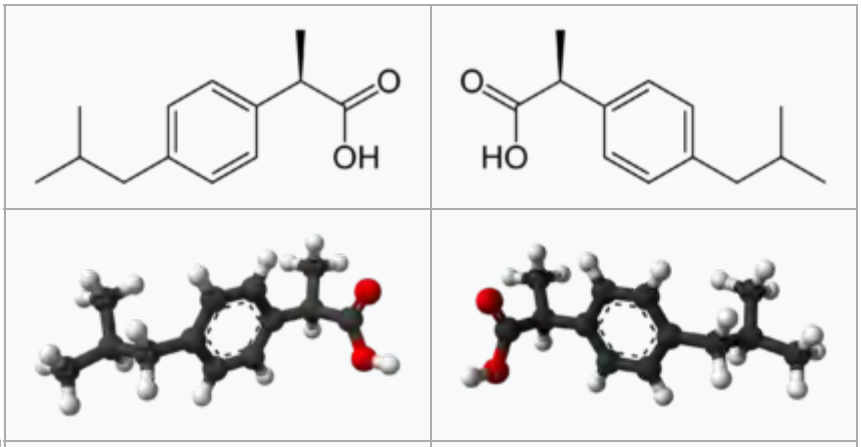
It is practically insoluble in water, but very soluble in most organic solvents (ethanol, methanol, acetone and dichloromethane).[42]

The original synthesis of ibuprofen by the Boots Group started with the compound 2-methylpropylbenzene. The synthesis took six steps. A modern, greener technique for the synthesis involves only three steps.[43]

### Stereochemistry [edit]

It is an optically active compound with both *S* and *R*-isomers, of which the *S* (dextrorotatory) isomer is the more biologically active; this isomer has also been isolated and used medically (see dexibuprofen for details).[42]

Ibuprofen is produced industrially as a racemate. The compound, like other 2-arylpropionate derivatives (including ketoprofen, flurbiprofen, naproxen, etc.), does contain a chiral center in the α-position of the propionate moiety. So two enantiomers of ibuprofen occur, with the potential for different biological effects and metabolism for each enantiomer. Indeed, the (*S*)-(+)-ibuprofen (dexibuprofen) was found to be the active form both *in vitro* and *in vivo*.



(*R*)-ibuprofen | (*S*)-ibuprofen

An isomerase (alpha-methylacyl-CoA racemase) converts (*R*)-ibuprofen to the active (*S*)-enantiomer.[44][45][46]

## History [edit]

Ibuprofen was derived from propionic acid by the research arm of Boots Group during the 1960s.[47] Its discovery was the result of research during the 1950s and 1960s to find a safer alternative to aspirin.[7][48] It was discovered by a team led by Stewart Adams and the patent application was filed in 1961.[7] Adams initially tested the drug as treatment for his hangover.[49] The drug was launched as a treatment for rheumatoid arthritis in the United Kingdom in 1969, and in the United States in 1974. Later, in 1983 and 1984, it became the first NSAID (other than aspirin) to be available over the counter (OTC) in these two countries.[7][48] Dr. Adams was subsequently awarded an OBE in 1987. Boots was awarded the Queen's Award for Technical Achievement for the development of the drug in 1987.[7]

## Marketing [edit]

*See also: Ibuprofen brand names*

Ibuprofen was made available under prescription in the United Kingdom in 1969, and in the United States in 1974.[50] In the years since, the good tolerability profile, along with extensive experience in the population, as well as in so-called phase-IV trials (postapproval studies), have resulted in the availability of ibuprofen OTC in pharmacies worldwide, as well as in supermarkets and other general retailers.[*citation needed*] Ibuprofen is its INN, BAN, AAN and USAN approved name. Advil is manufactured by Pfizer and has been on the market since 1984.

A bottle of generic ibuprofen

### North America [edit]

Ibuprofen is commonly available in the United States up to the FDA's 1984 dose limit OTC, rarely used higher by prescription.[51] In 2009, the first injectable formulation of ibuprofen was approved in the United States, under the trade name Caldolor.[52][53]

## Research [edit]

Ibuprofen is sometimes used for the treatment of acne because of its anti-inflammatory properties, and has been sold in Japan in topical form for adult acne.[54][55] As with other NSAIDs, ibuprofen may be useful in the treatment of severe orthostatic hypotension (low blood pressure when standing up).[56] In some studies, ibuprofen showed superior results compared with a placebo in the prevention of Alzheimer's disease, when given in low doses over a long time.[57][58]

Ibuprofen has been associated with a lower risk of Parkinson's disease, and may delay or prevent it. Aspirin, other NSAIDs, and paracetamol (acetaminophen) had no effect on the risk for Parkinson's.[59] In March 2011, researchers at Harvard Medical School announced in *Neurology* that ibuprofen had a neuroprotective effect against the risk of developing Parkinson's disease.[60][61][62] People regularly consuming ibuprofen were reported to have a 38% lower risk of developing Parkinson's disease, but no such effect was found for other pain relievers, such as aspirin and paracetamol. Use of ibuprofen to lower the risk of Parkinson's disease in the general population would not be problem-free, given the possibility of adverse effects on the urinary and digestive systems.[63]

| v · t · e | **Non-steroidal anti-inflammatory drugs (NSAIDs) (primarily M01A and M02A, also N02BA)** |
|---|---|
| **Pyrazolones /** | Aminophenazone · Ampyrone · Azapropazone · Clofezone · Difenamizole · Famprofazone · Feprazone · Kebuzone · Metamizole · Mofebutazone · Morazone · Nifenazone · |

| | |
|---|---|
| **Pyrazolidines** | Oxyphenbutazone · Phenazone · **Phenylbutazone** · Propyphenazone · Sulfinpyrazone · Suxibuzone‡ · |
| **Salicylates** | **Aspirin (acetylsalicylic acid)**# · Aloxiprin · Benorylate · Carbasalate calcium · Diflunisal · Dipyrocetyl · Ethenzamide · Guacetisal · Magnesium salicylate · Methyl salicylate · Salsalate · Salicin · Salicylamide · Salicylic acid (salicylate) · Sodium salicylate · |
| **Acetic acid derivatives and related substances** | Aceclofenac · Acemetacin · Alclofenac · Amfenac · Bendazac · Bromfenac · Bumadizone · Bufexamac · **Diclofenac** · Difenpiramide · Etodolac · Felbinac · Fenclozic acid · Fentiazac · Indomethacin · Indomethacin farnesil · Isoxepac · Ketorolac · Lonazolac · Oxametacin · Prodolic acid · Proglumetacin · Sulindac · Tiopinac · Tolmetin · Zomepirac† · |
| **Oxicams** | Ampiroxicam · Droxicam · Isoxicam · Lornoxicam · Meloxicam · **Piroxicam** · Tenoxicam · |
| **Propionic acid derivatives (profens)** | Alminoprofen · Benoxaprofen† · Carprofen‡ · Dexibuprofen · Dexketoprofen · Fenbufen · Fenoprofen · Flunoxaprofen · Flurbiprofen · **Ibuprofen**# · Ibuproxam · Indoprofen† · Ketoprofen · Loxoprofen · Miroprofen · **Naproxen** · Oxaprozin · Pirprofen · Suprofen · Tarenflurbil · Tepoxalin‡ · Tiaprofenic acid · Vedaprofen‡ · *COX-inhibiting nitric oxide donator*: Naproxcinod · |
| ***N*-Arylanthranilic acids (fenamates)** | Azapropazone · Clonixin · Etofenamate · Flufenamic acid · Flunixin · Meclofenamic acid · **Mefenamic acid** · Morniflumate · Niflumic acid · Tolfenamic acid · Flutiazin · |
| **Coxibs** | Apricoxib · **Celecoxib** · Cimicoxib‡ · Deracoxib‡ · Etoricoxib · Firocoxib‡ · Lumiracoxib† · Mavacoxib‡ · Parecoxib · Robenacoxib‡ · Rofecoxib† · Valdecoxib† · |
| **Other** | Aminopropionitrile · Benzydamine · Chondroitin sulfate · Diacerein · Fluproquazone · Glucosamine · Glycosaminoglycan · Hyperforin · Nabumetone · Nimesulide · Oxaceprol · Proquazone · Superoxide dismutase/Orgotein · Tenidap · |

Items listed in **bold** indicate initially developed compounds of specific groups. #WHO-EM †Withdrawn drugs. ‡Veterinary use medications.

| v · t · e · | **Topical products for joint and muscular pain (M02)** | |
|---|---|---|
| **Anti-inflammatory preparations, non-steroids** | **Pyrazolidines** | Clofezone · Mofebutazone · Oxyphenbutazone · Phenylbutazone · |
| | **Acetic acid derivatives** | Diclofenac · Fentiazac · Tolmetin · |
| | **Other** | Bendazac · Benzydamine · Bufexamac · Etofenamate · Felbinac · Feprazone · Flurbiprofen · **Ibuprofen** · Indometacin · Ketoprofen · Meclofenamic acid · Naproxen · Nifenazone · Niflumic acid · Piketoprofen · Piroxicam · Suxibuzone · |
| **Capsaicin derivatives** | Zucapsaicin · | |
| **Other** | Dimethyl sulfoxide · Idrocilamide · Tolazoline · | |

| v · t · e · | **Analgesics (N02A, N02B)** | |
|---|---|---|
| | **Opiates/opium** | Codeine# (+paracetamol, +aspirin) · Morphine# (+naltrexone) · Opium · Laudanum · Paregoric · |
| | | Acetyldihydrocodeine · Benzylmorphine · Buprenorphine (+naloxone) · |

| | | |
|---|---|---|
| **Opioids** | **Semisynthetic** | Desomorphine · Diamorphine (heroin) · Dihydrocodeine (+paracetamol) · Dihydromorphine · Ethylmorphine · Hydrocodone (+paracetamol, +ibuprofen, +aspirin) · Hydromorphinol · Hydromorphone · Nicocodeine · Nicodicodeine · Nicomorphine · Oxycodone (+paracetamol, +aspirin, +ibuprofen, +naloxone, +naltrexone) · Oxymorphone · Thebacon · |
| | **Synthetic** | Alphaprodine · Anileridine · Butorphanol · Dextromoramide · Dextropropoxyphene · Dezocine · Fentanyl (+fluanisone) · Ketobemidone · Levorphanol · Meptazinol · Methadone · Nalbuphine · Pentazocine · Pethidine · Phenadoxone · Phenazocine · Piminodine · Piritramide · Propiram · Tapentadol · Tilidine · Tramadol · |
| **Paracetamol-type** | | Acetanilide‡ · Bucetin‡ · Butacetin‡ · Paracetamol (acetaminophen)# · Parapropamol‡ · Phenacetin‡ · Propacetamol‡ · |
| **NSAIDs** | **Propionates** | Fenoprofen · Flurbiprofen · **Ibuprofen**# · Ketoprofen · Naproxen · Oxaprozin · |
| | **Oxicams** | Meloxicam · Piroxicam · |
| | **Acetates** | Diclofenac · Indometacin · Ketorolac · Nabumetone · Sulindac · Tolmetin · |
| | **COX-2 inhibitors** | Celecoxib · Etoricoxib · Lumiracoxib · Parecoxib · Rofecoxib ‡ · Valdecoxib ‡ · |
| | **Fenamates** | Meclofenamic acid · Mefenamic acid · |
| | **Salicylates** | Aspirin (acetylsalicylic acid)# (+paracetamol/caffeine) · Benorylate · Diflunisal · Ethenzamide · Magnesium salicylate · Salicin · Salicylamide · Salsalate · Wintergreen (methyl salicylate) · |
| | **Pyrazolones** | Aminophenazone‡ · Ampyrone · Metamizole (dipyrone) · Nifenazone · Phenazone · Propyphenazone · |
| | **Others** | Glafenine · |
| **Cannabinoids** | | Cannabidiol · Cannabis · Nabilone · Nabiximols · Tetrahydrocannabinol (dronabinol) · |
| **Ion channel modulators** | **Calcium blockers** | Gabapentin · Gabapentin enacarbil · Pregabalin · Ziconotide · |
| | **Sodium blockers** | Carbamazepine · Lacosamide · Local anesthetics (e.g., cocaine, lidocaine) · Mexiletine · Nefopam · Tricyclic antidepressants (e.g., amitriptyline#) · *$Na_v1.7/1.8$-selective:* DSP-2230§ · Funapide§ · PF-05089771§ · Raxatrigine§ · |
| | **Potassium openers** | Flupirtine · |
| **Myorelaxants** | | Carisoprodol · Chlorzoxazone · Cyclobenzaprine · Mephenoxalone · Methocarbamol · Orphenadrine · |
| **Others** | | Camphor · Capsaicin · Clonidine · Ketamine · Menthol · Methoxyflurane · Nefopam · Proglumide · Tricyclic antidepressants (e.g., amitriptyline#) · |

# Influenza vaccine

From Wikipedia, the free encyclopedia

**Influenza vaccines**, also known as **flu shots** or **jabs**, are vaccines that protect against influenza.[2] A new version of the vaccine is developed twice a year as the influenza virus rapidly changes.[2] While their effectiveness varies from year to year, most provide moderate to high protection against influenza.[2][3] They decrease the number of missed days of work by a half day on average.[4] Vaccinating children may protect those around them.[2] The effectiveness in those under 2 years old and over 65 years old is unknown due to the low quality of the research.[5][6][7]

The Centers for Disease Control and Prevention recommends nearly all people over the age of 6 months get the vaccine yearly.[8] The World Health Organization also recommends yearly vaccination, especially in those at high risk.[2] These groups include pregnant women, children between six months and five years of age, those with other health problems, Native Americans, and those who work in healthcare.[1][2]

The vaccines are generally safe. In children, fever occurs in 5 to 10%, as may muscle pains or feeling tired. In certain years, the vaccine causes Guillain–Barré syndrome in older people in about one per million doses. It should not be given to those with severe allergies to eggs or to previous versions of the vaccine. The vaccines come in both inactive and weakened viral forms. The inactive version should be used for those who are pregnant. They come in forms that are injected into a muscle, sprayed into the nose, or injected into the middle layer of the skin.[2]

Vaccination against influenza began in the 1930s with large scale availability in the United States beginning in 1945.[9][10] It is on the World Health Organization's List of Essential Medicines, the most important medications recommended for a basic health system.[11] The wholesale price in the developing world is about $5.25 USD per dose as of 2014.[12] In the United States, it costs less than $25 USD.[13]

## Medical uses [edit]

The Centers for Disease Control and Prevention, recommend the flu vaccine as the best way to protect people against the flu and prevent its spread. The flu vaccine can also reduce the severity of the flu if a person contracts a flu strain that the vaccine did not contain.[14] It takes about two weeks following vaccination for protective antibodies to form.[15]

A 2012 meta-analysis found that flu vaccination was effective 67 percent of the time; the populations that benefited the most were HIV-positive adults ages 18 to 55 (76 percent), healthy adults ages 18 to 46 (approximately 70 percent), and healthy children ages 6 to 24 months (66 percent).[16]

### Effectiveness [edit]

A vaccine is assessed by its *efficacy*; the extent to which it reduces risk of disease under controlled conditions, and its *effectiveness*, the observed reduction in risk after the vaccine is put into use.[17] In the case of influenza, effectiveness is expected to be lower than the efficacy because it is measured using the rates of influenza-like illness, which is not always caused by influenza.[4] Influenza vaccines generally show high efficacy, as measured by the antibody production in animal models or vaccinated people.[18] However, studies on the effectiveness of flu vaccines in the real world are difficult; vaccines may be imperfectly matched, virus prevalence varies widely between years, and influenza is often confused with other influenza-like illnesses.[19] However, in most years (16 of the 19 years before 2007), the flu vaccine strains have been a good match for the circulating strains,[20] and even a mismatched vaccine can often provide

cross-protection.[21]

Trials of both live and inactivated influenza vaccines against seasonal influenza have been summarized in several 2012 meta-analyses. Studies on live vaccines have very limited data, but these preparations may be more effective than inactivated vaccines.[22] The meta-analyses examined the efficacy and effectiveness of inactivated vaccines against seasonal influenza in adults,[4] children,[23] and the elderly.[24][25]

## Children [edit]

The CDC recommend that everyone except children under the age of six months should receive the seasonal influenza vaccine.[8] Vaccination campaigns usually focus special attention on people who are at high risk of serious complications if they catch the flu, such as pregnant women, children over six months, the elderly, and people living with chronic illness or those with weakened immune systems, as well as those to whom they are exposed, such as health care workers.[8][26]

As the death rate is also high among infants who catch influenza, the household contacts and caregivers of infants should be vaccinated to reduce the risk of passing an influenza infection to the infant.[26]

In children, vaccines again showed high efficacy, but low effectiveness in preventing "flu-like illness".[23] In children under the age of two, the data are extremely limited, but vaccination appeared to confer no measurable benefit.[23]

## Adults [edit]

In unvaccinated adults, 16% get symptoms similar to the flu, while about 10% of vaccinated adults do.[4] Vaccination decreased confirmed cases of influenza from about 2.4% to 1.1%.[4] No effect on hospitalization was found.[4]

In working adults a review by the Cochrane Collaboration found that vaccination resulted in a modest decrease in both influenza symptoms and working days lost, without affecting transmission or influenza-related complications.[4] In healthy working adults, influenza vaccines can provide moderate protection against virologically confirmed influenza, though such protection is greatly reduced or absent in some seasons.[5]

In health care workers, a 2006 review found a net benefit.[27] Of the eighteen studies in this review, only two also assessed the relationship of patient mortality relative to staff influenza vaccine uptake; both found that higher rates of health care worker vaccination correlated with reduced patient deaths.[27] A 2014 review found benefits to patients when health care workers were immunized, as supported by moderate evidence[28] based in part on the observed reduction in all-cause deaths in patients whose health care workers were given immunization compared with comparison patients in which the health care workers were not offered vaccine.[29]

## Elderly [edit]

Evidence for an effect in adults over 65 years old is unclear.[30] Systematic reviews examining both randomized controlled and case control studies found a lack of high-quality evidence.[5][31] Reviews of case control studies found effects against laboratory-confirmed influenza, pneumonia, and death among the community-dwelling elderly.[32][33]

The group most vulnerable to non-pandemic flu, the elderly, benefits least from the vaccine. There are multiple reasons behind this steep decline in vaccine efficacy, the most common of which are the declining immunological function and frailty associated with advanced age.[34] In a non-pandemic year, a person in the United States aged 50–64 is nearly ten times more likely to die an influenza-associated death than a younger person, and a person over age 65 is over ten times more likely to die an influenza-associated death than the 50–64 age group.[35]

[36]

There is a new high-dose flu vaccine specifically formulated to provide a stronger immune response. Available evidence indicates that vaccinating the elderly with the high-dose vaccine leads to a stronger immune response against influenza than the regular-dose vaccine.[37]

Vaccinating health care workers who work with elderly people is recommended in many countries, with the goal of reducing influenza outbreaks in this vulnerable population.[38][39][40] While there is no conclusive evidence from randomized clinical trials that vaccinating health care workers helps protect the elderly people from influenza, there is tentative evidence of benefit.[41]

### Pregnancy [edit]

As well as protecting mother and child from the effects of an influenza infection, the immunization of pregnant women tends to increase their chances of experiencing a successful full-term pregnancy.[42]

The trivalent inactivated influenza vaccine is protective in pregnant women infected with HIV.[43]

## Safety [edit]

*See also: Vaccine controversies*

While side effects of the flu vaccine may occur, they are usually minor and the safety of flu vaccines is high. The flu vaccine can cause serious side effects, including an allergic reaction, but this is rare. Furthermore, the common side effects and risks of inoculation are mild and temporary when compared to the risks and severe health effects of the annual influenza epidemic's well-documented toll of illness, hospitalization, and death.[44]

Flu vaccination may lead to side effects such as runny nose and sore throat, which can last for up to several days. Egg allergy may also be a concern, since flu vaccines are typically made using eggs;[45][46] however, research into egg-allergy and influenza vaccination[47] has led some advisory groups to recommend vaccine for those with mild allergies and monitored vaccination for those with severe.[48] A large study of nearly 800 children in the UK with egg allergy, including over 250 with previous anaphylactic reactions, had zero systemic allergic reactions when given the live attenuated flu vaccine.[49][50] On January 17, 2013, the U.S. FDA approved Flublok, a faster-turnaround influenza vaccine which is the first grown in insect cells instead of eggs. Since eggs are not used in its production, it avoids any problem with egg allergies.[51]

Although Guillain–Barré syndrome had been feared as a complication of vaccination, the CDC states that most studies on modern influenza vaccines have seen no link with Guillain–Barré.[52][53] Infection with influenza virus itself increases both the risk of death (up to 1 in 10,000) and increases the risk of developing Guillain–Barré syndrome to a far higher level than the highest level of suspected vaccine involvement (approximately 10 times higher by 2009 estimates).[54][55]

Although one review gives an incidence of about one case of Guillain–Barré per million vaccinations,[56] a large study in China, reported in *The New England Journal of Medicine* covering close to 100 million doses of vaccine against the 2009 H1N1 "swine" flu found only eleven cases of Guillain–Barré syndrome, (0.1 per million doses) total incidence in persons vaccinated, actually lower than the normal rate of the disease in China, and no other notable side effects; "The risk-benefit ratio, which is what vaccines and everything in medicine is about, is overwhelmingly in favor of vaccination."[57][58] Several studies have identified an increased incidence of narcolepsy among recipients of the pandemic H1N1 influenza ASO3-adjuvanted vaccine,[59] efforts to identify a mechanism for this suggest that narcolepsy is autoimmune, and that the ASO3-adjuvanted H1N1 vaccine may mimic hypocretin, serving as a trigger.[60]

Some injection-based flu vaccines intended for adults in the United States contain thiomersal (also known as thimerosal), a mercury-based preservative. Despite some controversy in the media,[61] the World Health Organization's Global Advisory Committee on Vaccine Safety has concluded that there is no evidence of toxicity from thiomersal in vaccines and no reason on grounds of safety to change to more-expensive [62]

single-dose administration.

## Injection versus nasal spray [edit]

Flu vaccines are available either as

- a trivalent or quadrivalent injection (TIV or QIV), which contains the inactivated form of the virus.
- a nasal spray of live attenuated influenza vaccine (LAIV, Q/LAIV), which contains the attenuated or weakened form of the virus.

TIV induces protection after injection (typically intramuscular, though subcutaneous and intradermal routes can also be protective)[63] based on an immune response to the antigens present on the inactivated virus, while cold-adapted LAIV works by establishing infection in the nasal passages.[64]

## Recommendations [edit]

Various public health organizations, including the World Health Organization, have recommended that yearly influenza vaccination be routinely offered, particularly to people at risk of complications of influenza and those individuals who live with or care for high-risk individuals, including:

- the elderly (UK recommendation is those aged 65 or above)
- people with chronic lung diseases (asthma, COPD, etc.)
- people with chronic heart diseases (congenital heart disease, chronic heart failure, ischaemic heart disease)
- people with chronic liver diseases (including cirrhosis)
- people with chronic kidney diseases (such as the nephrotic syndrome)
- people who are immunosuppressed (those with HIV or who are receiving drugs to suppress the immune system such as chemotherapy and long-term steroids) and their household contacts
- people who live together in large numbers in an environment where influenza can spread rapidly, such as prisons, nursing homes, schools, and dormitories.[65]
- healthcare workers (both to prevent sickness and to prevent spread to patients)[66][67]
- pregnant women. However, a 2009 review concluded that there was insufficient evidence to recommend routine use of trivalent influenza vaccine during the first trimester of pregnancy.[68] Influenza vaccination during flu season is part of recommendations for influenza vaccination of pregnant women in the United States.[69]

Both types of flu vaccines are contraindicated for those with severe allergies to egg proteins and people with a history of Guillain–Barré syndrome.[70]

### World Health Organization [edit]

As of 2012, the UN World Health Organization recommends annual vaccinations:

> Annual vaccination (or re-vaccination, if the vaccine strains are identical) is recommended, particularly for high-risk groups.

High risk groups include, in order of priority:[71]

1. nursing-home residents (the elderly or disabled)
2. people with chronic medical conditions
3. elderly individuals
4. other groups such as pregnant women, health care workers, those with essential functions in society, as well as children from 6 to 24 months.

### Canada [edit]

In 2008, the National Advisory Committee on Immunization, the group that advises the Public Health

Agency of Canada, recommended that everyone aged 2 to 64 years be encouraged to receive annual influenza vaccination, and that children between the age of six and 24 months, and their household contacts, should be considered a high priority for the flu vaccine.[72] The NACI also recommends the flu vaccine for:[73]

- People at high risk of influenza-related complications or hospitalization, including the morbidly obese, healthy pregnant women, children 6 to 59 months, the elderly, aboriginals, and people suffering from one of an itemized list of chronic health conditions
- People capable of transmitting influenza to those at high risk, including household contacts and healthcare workers
- People who provide essential community services
- Certain poultry workers

## Europe [edit]

The European Center for Disease Prevention and Control recommends vaccinating the elderly as a priority, with a secondary priority people with chronic medical conditions and healthcare workers.[74]

The influenza vaccination strategy is generally that of protecting vulnerable people, rather than limiting influenza circulation or totally eliminating human influenza sickness. This is in contrast with the high herd immunity strategies for other Infectious diseases such as polio and measles.[75] This is also due in part to the financial and logistics burden associated with the need of an annual injection.[76]

## United States [edit]

In the United States routine influenza vaccination is recommended for all persons aged ≥ 6 months.[77][78][79]

According to the CDC, the live attenuated virus (which comes in the form of the nasal spray in the US) should be avoided by:

- Children younger than 2 years
- Adults 50 years and older
- People with a history of severe allergic reaction to any component of the vaccine or to a previous dose of any influenza vaccine
- People with asthma
- Children or adolescents on long-term aspirin treatment.
- Children and adults who have chronic pulmonary, cardiovascular (except isolated hypertension), renal, hepatic, neurologic/neuromuscular, hematologic, or metabolic disorders
- Children and adults who have immunosuppression (including immunosuppression caused by medications or by HIV)
- Pregnant women[80]

A young woman shows off her flu shot after receiving vaccine at a local drug store.

Within its blanket recommendation for general vaccination in the United States, the Centers for Disease Control and Prevention (CDC), which began recommending the influenza vaccine to health care workers in 1981, emphasizes to clinicians the special urgency of vaccination for members of certain vulnerable groups, and their caregivers:

Vaccination is especially important for people at higher risk of serious influenza complications or people who live with or care for people at higher risk for serious complications.[81] In 2009, a new high-dose formulation of the standard influenza vaccine was approved. The Fluzone High Dose is specifically for people 65 and older; the difference is that it has four times the antigen dose of the standard Fluzone.[82]

The U.S. government requires hospitals to report worker vaccination

rates. Some U.S. states and hundreds of U.S. hospitals require health-care workers to either get vaccinations or wear masks during flu season. These requirements occasionally engender union lawsuits on narrow collective bargaining grounds, but proponents note that courts have generally endorsed forced vaccination laws affecting the general population during disease outbreaks.[83]

Vaccination against influenza is especially important for members of high-risk groups who would be likely to have complications from influenza, for example pregnant women[77][84] and children and teenagers from six months to 18 years of age;[85]

- In raising the upper age limit to 18 years, the aim is to reduce both the time children and parents lose from visits to pediatricians and missing school and the need for antibiotics for complications[86]
- An added benefit expected from the vaccination of children is a reduction in the number of influenza cases among parents and other household members, and of possible spread to the general community.[86]

In USA : The CDC has indicated that live attenuated influenza vaccine (LAIV), also called the nasal spray vaccine, is not recommended for the 2016-2017 flu season, in the United States.[87]

Furthermore, health care personnel who care for severely immunocompromised persons should receive injections (TIV or QIV) rather than LAIV.[88]

## Uptake [edit]

### At risk groups [edit]

Uptake of flu vaccination, both seasonally and during pandemics, is often low.[89] Systematic reviews of pandemic flu vaccination uptake have identified several personal factors that may influence uptake, including gender (higher uptake in men), ethnicity (higher in people from ethnic minorities) and having a chronic illness.[90][91] Beliefs in the safety and effectiveness of the vaccine are also important.[89]

### Healthcare workers [edit]

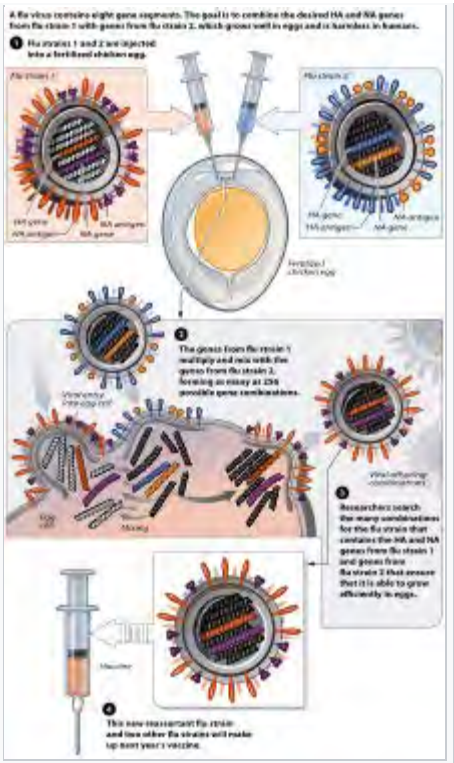
Frontline healthcare workers are often recommended to get seasonal and any pandemic flu vaccination. For example, in the UK, all healthcare workers involved in patient care are recommended to receive the seasonal flu vaccine and were also recommended to receive the swine flu vaccine during the 2009 pandemic. However, uptake is often low.[67] During the 2009 pandemic, low uptake by healthcare workers was seen in countries including the UK,[67] Italy,[92] Greece,[93] and Hong Kong.[94]

In a 2010 survey of United States healthcare workers, 63.5% reported that they received the flu vaccine during the 2010–11 season, an increase from 61.9% reported the previous season. US Health professionals with direct patient contact had higher vaccination uptake, such as physicians and dentists (84.2%) and nurse practitioners (82.6%).[95][96][97]

The main reason to vaccinate healthcare workers is to prevent staff from spreading flu to their patients and to reduce staff absence at a time of high service demand, but the reasons healthcare workers state for their decisions to accept vaccination or not may more often be to do with perceived personal benefits.[67]

## Manufacturing [edit]

Flu vaccine is usually grown by vaccine manufacturers in fertilized chicken eggs.[98][99] In the Northern hemisphere, the manufacturing process begins following the announcement (typically in February) of the WHO recommended strains for the winter flu season.[98][100] Three strains (representing an H1N1, an H3N2, and a B strain) of flu are



Schematic of influenza vaccine creation

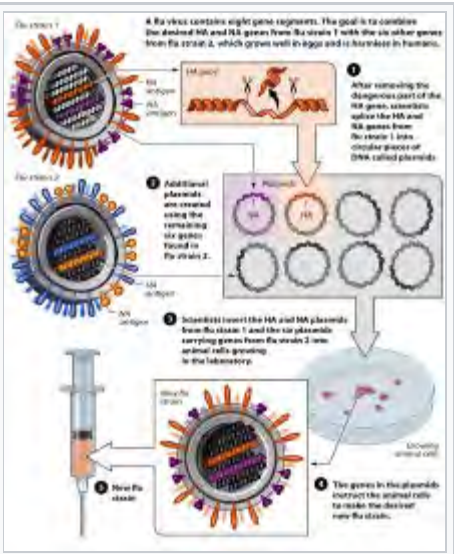
selected and chicken eggs inoculated separately, these monovalent harvests are then combined to make the trivalent vaccine.[101]

As of November 2007, both the conventional injection and the nasal spray are manufactured using chicken eggs.[99] The European Union has also approved Optaflu, a vaccine produced by Novartis using vats of animal cells.[99] This technique is expected to be more scalable and avoid problems with eggs, such as allergic reactions and incompatibility with strains that affect avians like chickens.[99] Research continues into the idea of a "universal" influenza vaccine that would not require tailoring to a particular strain, but would be effective against a broad variety of influenza viruses. However, no vaccine candidates had been announced by Nov 2007.[99]

A DNA-based vaccination, which is hoped to be even faster to manufacture, is as of 2011 in clinical trials, determining safety and efficacy.[102]

On November 20, 2012, Novartis received FDA approval for the first cell-culture vaccine.[103][104][105]

In a 2007 report, the global capacity of approximately 826 million seasonal influenza vaccine doses (inactivated and live) was double the production of 413 million doses. In an aggressive scenario of producing pandemic influenza vaccines by 2013, only 2.8 billion courses could be produced in a six-month time frame. If all high- and upper-middle-income countries sought vaccines for their entire populations in a pandemic, nearly 2 billion courses would be required. If China pursued this goal as well, more than 3 billion courses would be required to serve these populations.[106] Vaccine research and development is ongoing to identify novel vaccine approaches that could produce much greater quantities of vaccine at a price that is affordable to the global population.



Avian flu vaccine development by reverse genetics technique

Methods of vaccine generation that bypass the need for eggs include the construction of influenza virus-like particles (VLP). VLP resemble viruses, but there is no need for inactivation, as they do not include viral coding elements, but merely present antigens in a similar manner to a virion. Some methods of producing VLP include cultures of Spodoptera frugiperda Sf9 insect cells and plant-based vaccine production (e.g., production in *Nicotiana benthamiana*). There is evidence that some VLPs elicit antibodies that recognize a broader panel of antigenically distinct viral isolates compared to other vaccines in the hemagglutination-inhibition assay (HIA).[107]

Influenza vaccines are produced in pathogen-free eggs that are 11 to 12 days old.[108] The top of the egg is disinfected by wiping it with alcohol and then the egg is candled to identify a non-veinous area in the allantoic cavity where a small hole is poked to serve as a pressure release.[109] A second hole is made at the top of the egg, where the influenza virus is injected in the allantoic cavity, past the chorioallantoic membrane. The two holes are then sealed with melted paraffin and the inoculated eggs are incubated for 48 hours at 37 degrees Celsius.[108] During incubation time, the virus replicates and newly replicated viruses are released into the allantoic fluid [110]

After the 48 hour incubation period, the top of the egg is cracked and the 10 milliliters of allantoic fluid is removed, from which about 15 micrograms of the flu vaccine can be obtained. At this point, the viruses have been weakened or killed and the viral antigen is purified and placed inside vials, syringes, or nasal sprayers.[110] Done on a large scale, this method is used to produce the flu vaccine for the human population.

## Annual reformulation [edit]

*Further information: Historical annual reformulations of the influenza vaccine*
*See also: 2009 flu pandemic vaccine*

Each year, three strains are chosen for selection in that year's flu vaccination by the WHO Global Influenza Surveillance Network. The chosen strains are the H1N1, H3N2, and Type-B strains thought most likely to cause significant human suffering in the coming season. Starting with the 2012–2013 Northern Hemisphere influenza season (coincident with the approval of quadrivalent influenza vaccines), the WHO has also recommended a 2nd B-strain for use in quadrivalent vaccines. The World Health Organization coordinates the contents of the vaccine each year to contain the most likely strains of the virus to attack the next year.

> "The WHO Global Influenza Surveillance Network was established in 1952. The network comprises 4 WHO Collaborating Centres (WHO CCs) and 112 institutions in 83 countries, which are recognized by WHO as WHO National Influenza Centres (NICs). These NICs collect specimens in their country, perform primary virus isolation and preliminary antigenic characterization. They ship newly isolated strains to WHO CCs for high level antigenic and genetic analysis, the result of which forms the basis for WHO recommendations on the composition of influenza vaccine for the Northern and Southern Hemisphere each year."[111]

The Global Influenza Surveillance Network's selection of viruses for the vaccine manufacturing process is based on its best estimate of which strains will predominate the next year, amounting in the end to well-informed but fallible guesswork.[112]

Formal WHO recommendations were first issued in 1973. Beginning in 1999 there have been two recommendations per year: one for the northern hemisphere (N) and the other for the southern hemisphere (S).[113]

Historical annual reformulations of the influenza vaccine are listed in a separate article. Recent WHO seasonal influenza vaccine composition recommendations:

## 2016–2017 Northern Hemisphere influenza season [edit]

The composition of trivalent virus vaccines for use in the 2016–2017 Northern Hemisphere influenza season recommended by the World Health Organization on February 25, 2016 was:

- an A/California/7/2009 (H1N1)pdm09-like virus†
- an A/Hong Kong/4801/2014 (H3N2)-like virus
- a B/Brisbane/60/2008-like virus

The WHO recommends that quadrivalent vaccines containing two influenza B viruses contain the above three viruses and a B/Phuket/3073/2013-like virus.[114]

## 2016 Southern Hemisphere influenza season [edit]

The composition of virus vaccines for use in the 2016 Southern Hemisphere influenza season recommended by the World Health Organisation on September 24, 2015 was:

- an A/California/7/2009 (H1N1)pdm09-like virus†
- an A/Hong Kong/4801/2014 (H3N2)-like virus
- a B/Brisbane/60/2008-like virus

WHO recommended that quadrivalent vaccines containing two influenza B viruses should contain the above three viruses and a B/Phuket/3073/2013-like virus.[115]

†Strain A(H1N1)pdm09 is a newer name for the strain used in the 2009 flu pandemic vaccine.[116]

### 2017 Southern Hemisphere influenza season [edit]

The composition of virus vaccines for use in the 20167Southern Hemisphere influenza season recommended by the World Health Organisation on September 29, 2016 was:

- an A/Michigan/45/2015 (H1N1)pdm09-like virus†
- an A/Hong Kong/4801/2014 (H3N2)-like virus
- a B/Brisbane/60/2008-like virus

WHO recommended that quadrivalent vaccines containing two influenza B viruses should contain the above three viruses and a B/Phuket/3073/2013-like virus.[117]

†Strain A(H1N1)pdm09 is a newer name for the strain used in the 2009 flu pandemic vaccine.[116]

## History [edit]

*See also: Timeline of vaccines*

Vaccines are used in both humans and nonhumans. Human vaccine is meant unless specifically identified as a veterinary, poultry or livestock vaccine.

### Origins and development [edit]

In the worldwide Spanish flu pandemic of 1918, "Physicians tried everything they knew, everything they had ever heard of, from the ancient art of bleeding patients, to administering oxygen, to developing new vaccines and sera (chiefly against what we now call *Hemophilus influenzae*—a name derived from the fact that it was originally considered the etiological agent—and several types of pneumococci). Only one therapeutic measure, transfusing blood from recovered patients to new victims, showed any hint of success."[118]

In 1931, viral growth in embryonated hens' eggs was reported by Ernest William Goodpasture and colleagues at Vanderbilt University. The work was extended to growth of influenza virus by several workers, including Thomas Francis, Jonas Salk, Wilson Smith and Macfarlane Burnet, leading to the first experimental influenza vaccines.[119] In the 1940s, the US military developed the first approved inactivated vaccines for influenza, which were used in the Second World War.[120] Hen's eggs continued to be used to produce virus used in influenza vaccines, but manufacturers made improvements in the purity of the virus by developing improved processes to remove egg proteins and to reduce systemic reactivity of the vaccine.[121] Recently, the US FDA has approved influenza vaccines made by growing virus in cell cultures[122] and influenza vaccines made from recombinant proteins[123] have been approved, with plant-based influenza vaccines being tested in clinical trials.[124]

### Acceptance [edit]

According to the CDC: "Influenza vaccination is the primary method for preventing influenza and its severe complications. [...] Vaccination is associated with reductions in influenza-related respiratory illness and physician visits among all age groups, hospitalization and death among persons at high risk, otitis media among children, and work absenteeism among adults. Although influenza vaccination levels increased substantially during the 1990s, further improvements in vaccine coverage levels are needed".[125]

The egg-based technology (still in use as of 2005) for producing influenza vaccine was created in the 1950s.[126] In the U.S. swine flu scare of 1976, President Gerald Ford was confronted with a potential swine flu pandemic. The vaccination program was rushed, yet plagued by delays and public relations problems. Meanwhile, maximum military containment efforts succeeded unexpectedly in confining the new strain to the single army base where it had originated. On that base a number of soldiers fell severely ill, but only one died. The program was canceled, after about 24% of the population had received

vaccinations. An excess in deaths of twenty-five over normal annual levels as well as 400 excess hospitalizations, both from Guillain–Barré syndrome, were estimated to have occurred from the vaccination program itself, illustrating that vaccine itself is not free of risks. The result has been cited to stoke lingering doubts about vaccination.[127] In the end, however, even the maligned 1976 vaccine may have saved lives. A 2010 study found a significantly enhanced immune response against the 2009 pandemic H1N1 in study participants who had received vaccination against the swine flu in 1976.[128]

# Society and culture [edit]

## Evaluation of evidence [edit]

Tom Jefferson, who has led Cochrane Collaboration reviews of flu vaccines, has called clinical evidence concerning flu vaccines "rubbish" and has therefore declared them to be ineffective; he has called for placebo-controlled randomized clinical trials. His views on clinical trials are considered unethical by mainstream medicine and his views on the efficacy of vaccines are rejected by medical institutions including the CDC and the National Institutes of Health, and by key figures in the field like Anthony Fauci.[129]

Michael Osterholm who has led the Center for Infectious Disease Research and Policy 2012 review on flu vaccines recommends getting the vaccine but criticizes its promotion "We have overpromoted and overhyped this vaccine...it does not protect as promoted. It's all a sales job: it's all public relations".[130]

## Cost-effectiveness [edit]

The cost-effectiveness of seasonal influenza vaccination has been widely evaluated for different groups and in different settings.[131] In the elderly (aged over 65 years) the majority of published studies have found that vaccination is cost saving, with the cost savings associated with influenza vaccination (e.g. prevented health care visits) outweighing the cost of vaccination.[132] In older adults (aged 50–64 years), several published studies have found that influenza vaccination is likely to be cost-effective, however the results of these studies were often found to be dependent on key assumptions used in the economic evaluations.[133] The uncertainty in influenza cost-effectiveness models can partially be explained by the complexities involved in estimating the disease burden,[134] as well as the seasonal variability in the circulating strains and the match of the vaccine.[135][136] In healthy working adults (aged 18–49 years), a 2012 review found that vaccination was generally not cost-saving, with the suitability for funding being dependent on the willingness to pay to obtain the associated health benefits.[137] In children, the majority of studies have found that influenza vaccination was cost-effective, however many of the studies included (indirect) productivity gains, which may not be given the same weight in all settings.[138] Several studies have attempted to predict the cost-effectiveness of interventions (including prepandemic vaccination) to help protect against a future pandemic, however estimating the cost-effectiveness has been complicated by uncertainty as to the severity of a potential future pandemic and the efficacy of measures against it.[139]

# Research [edit]

Influenza research includes molecular virology, molecular evolution, pathogenesis, host immune responses, genomics, and epidemiology. These help in developing influenza countermeasures such as vaccines, therapies and diagnostic tools. Improved influenza countermeasures require basic research on how viruses enter cells, replicate, mutate, evolve into new strains and induce an immune response. The Influenza Genome Sequencing Project is creating a library of influenza sequences[140] that will help us understand what makes one strain more lethal than another, what genetic determinants most affect immunogenicity, and how the virus evolves over time. Solutions to limitations in current[*when?*] vaccine methods are being researched.

A different approach is where Internet content is used to estimate the impact of an influenza vaccination campaign. More specifically, researchers have used data from Twitter and Bing, and proposed a statistical

framework which, after a series of operations, maps this information to estimates of the percentage of influenza-like illness in areas, where vaccinations have been performed. Their impact estimates were in accordance with estimations from Public Health England.[141]

### Rapid response to pandemic flu [edit]

The rapid development, production, and distribution of pandemic influenza vaccines could potentially save millions of lives during an influenza pandemic. Due to the short time frame between identification of a pandemic strain and need for vaccination, researchers are looking at novel technologies for vaccine production that could provide better "real-time" access and be produced more affordably, thereby increasing access for people living in low- and moderate-income countries, where an influenza pandemic may likely originate, such as live attenuated (egg-based or cell-based) technology and recombinant technologies (proteins and virus-like particles).[142] As of July 2009, more than 70 known clinical trials have been completed or are ongoing for pandemic influenza vaccines.[143] In September 2009, the US Food and Drug Administration approved four vaccines against the 2009 H1N1 influenza virus (the 2009 pandemic strain), and expected the initial vaccine lots to be available within the following month.[144]

### Quadrivalent vaccines for seasonal flu [edit]

A quadrivalent flu vaccine administered by nasal mist was approved by the U.S. Food and Drug Administration (FDA) in March 2012.[145][146] Fluarix Quadrivalent was approved by the FDA in December 2012.[147]

### Universal flu vaccines [edit]

A "universal vaccine" that would not have to be designed and made for each flu season in each hemisphere would be useful, in order to stabilize the supply and to ensure against error in the design or escape of the circulating strains by mutation. Such a vaccine has been the subject of research for decades.[148]

One promising approach is using broadly neutralizing antibodies that unlike the vaccine used today, which provoke the body to generate an immune response, instead provide a component of the immune response itself. The first neutralizing antibodies were identified in 1993 via experimentation; with time researchers understood that the flu neutralizing antibodies were binding to the stalk of the Hemagglutinin protein; later researchers identified antibodies that could bind to the head of those proteins. Later yet, researchers identified the highly conserved M2 proton channel as a potential target for broadly neutralizing antibodies.[148][149]

The challenges for researchers have been identifying single antibodies that could neutralize many subtypes of the virus, so that they could be useful in any season, and that target conserved domains that are resistant to antigenic drift.[148]

Another approach has been taking the conserved domains identified from these projects, and delivering groups of these antigens to provoke an immune response; various approaches with different antigens, presented different ways (as fusion proteins, mounted on virus-like particles, on non-pathogenic viruses, as DNA, and others), are under development.[149][150][151]

Efforts have also been undertaken to develop universal vaccines that specifically activate a T-cell response, based on clinical data showing that people with a strong, early T-cell response have better outcomes when infected with influenza and because T-cells respond to conserved epitopes. The challenge for developers is that these epitopes are on internal protein domains that are only mildly immunogenic.[149]

Along with the rest of the vaccine field, people working on universal vaccines have been experimenting with vaccine adjuvants to improve the ability of their vaccines to create a sufficiently powerful and enduring immune response.[149][152]

## Veterinary use [edit]

*See also: Influenza A virus and Influenza § Infection in other animals*

"Vaccination in the veterinary world pursues four goals: (i) protection from clinical disease, (ii) protection from infection with virulent virus, (iii) protection from virus excretion, and (iv) serological differentiation of infected from vaccinated animals (so-called DIVA principle). In the field of influenza vaccination, neither commercially available nor experimentally tested vaccines have been shown so far to fulfill all of these requirements."[153]

## Horses [edit]

Horses with horse flu can run a fever, have a dry hacking cough, have a runny nose, and become depressed and reluctant to eat or drink for several days but usually recover in two to three weeks. "Vaccination schedules generally require a primary course of 2 doses, 3–6 weeks apart, followed by boosters at 6–12 month intervals. It is generally recognized that in many cases such schedules may not maintain protective levels of antibody and more frequent administration is advised in high-risk situations."[154]

It is a common requirement at shows in the United Kingdom that horses be vaccinated against equine flu and a vaccination card must be produced; the International Federation for Equestrian Sports (FEI) requires vaccination every six months.[155][156]

## Poultry [edit]

Poultry vaccines for bird flu are made inexpensively and are not filtered and purified like human vaccines to remove bits of bacteria or other viruses. They usually contain whole virus, not just hemagglutinin as in most human flu vaccines. Purification to standards needed for humans is far more expensive than the original creation of the unpurified vaccine from eggs. There is no market for veterinary vaccines that are that expensive. Another difference between human and poultry vaccines is that poultry vaccines are adjuvated with mineral oil, which induces a strong immune reaction but can cause inflammation and abscesses. "Chicken vaccinators who have accidentally jabbed themselves have developed painful swollen fingers or even lost thumbs, doctors said. Effectiveness may also be limited. Chicken vaccines are often only vaguely similar to circulating flu strains — some contain an H5N2 strain isolated in Mexico years ago. 'With a chicken, if you use a vaccine that's only 85 percent related, you'll get protection,' Dr. Cardona said. 'In humans, you can get a single point mutation, and a vaccine that's 99.99 percent related won't protect you.' And they are weaker [than human vaccines]. 'Chickens are smaller and you only need to protect them for six weeks, because that's how long they live till you eat them,' said Dr. John J. Treanor, a vaccine expert at the University of Rochester. Human seasonal flu vaccines contain about 45 micrograms of antigen, while an experimental A(H5N1) vaccine contains 180. Chicken vaccines may contain less than 1 microgram. 'You have to be careful about extrapolating data from poultry to humans,' warned Dr. David E. Swayne, director of the agriculture department's Southeast Poultry Research Laboratory. 'Birds are more closely related to dinosaurs.'"[157]

Researchers, led by Nicholas Savill of the University of Edinburgh in Scotland, used mathematical models to simulate the spread of H5N1 and concluded that "at least 95 percent of birds need to be protected to prevent the virus spreading silently. In practice, it is difficult to protect more than 90 percent of a flock; protection levels achieved by a vaccine are usually much lower than this."[158] The Food and Agriculture Organization of the United Nations has issued recommendations on the prevention and control of avian influenza in poultry, including the use of vaccination.[159]

A filtered and purified Influenza A vaccine for humans is being developed[*when?*] and many countries have recommended it be stockpiled so if an Avian influenza pandemic starts jumping to humans, the vaccine can quickly be administered to avoid loss of life. Avian influenza is sometimes called avian flu, and commonly bird flu.[160]

## Pigs [edit]

Swine influenza vaccines are extensively used in pig farming in Europe and North America. Most swine flu vaccines include an H1N1 and an H3N2 strain.

Swine influenza has been recognized as a major problem since the outbreak in 1976. Evolution of the virus has resulted in inconsistent responses to traditional vaccines. Standard commercial swine flu vaccines are effective in controlling the problem when the virus strains match enough to have significant cross-protection. Customised (autogenous) vaccines made from the specific viruses isolated, are made and used in the more difficult cases.[161] The vaccine manufacturer Novartis claims that the H3N2 strain (first identified in 1998) has brought major losses to pig farmers. Abortion storms are a common sign and sows stop eating for a few days and run a high fever. The mortality rate can be as high as 15%.[162]

### Dogs [edit]

In 2004, influenza A virus subtype H3N8 was discovered to cause canine influenza. Because of the lack of previous exposure to this virus, dogs have no natural immunity to this virus. However, a vaccine is now available.[163]

"Seasonal influenza and 2009 H1N1 influenza vaccination coverage among pregnant women – 10 states, 2009–10 influenza season" (PDF). *MMWR Morb Mortal Wkly Rep*. **59** (47): 1541–5. PMID 21124293. "Because pregnant women are at increased risk for severe disease associated with influenza infection, the American College of Obstetricians and Gynecologists and the Advisory Committee on Immunization Practices have recommended seasonal influenza vaccination for women while pregnant, regardless of trimester (1,2). In 2009, a novel strain of influenza A (H1N1) virus was identified (3), and pregnant women also were found at greater risk for influenza-related complications from this new virus (4). As a result, during the 2009–10 influenza season, two separate influenza vaccines were recommended to pregnant women: inactivated trivalent 2009–10 seasonal vaccine and influenza A (H1N1) 2009 monovalent vaccine (2,5)"

# Ipratropium bromide

From Wikipedia, the free encyclopedia

**Ipratropium bromide**, sold under the trade name **Atrovent** among others, is a medication which opens up the medium and large airways in the lungs.[1] It is used to treat the symptoms of chronic obstructive pulmonary disease and asthma. It is used by inhaler or nebulizer. Onset of action is typically within 15 to 30 minutes and lasts for three to five hours.[1]

Common side effects include dry mouth, cough, and inflammation of the airways. Potentially serious side effects include urinary retention, worsening spasms of the airways, and a severe allergic reaction.[1] It appears to be safe in pregnancy and breastfeeding.[1][2] Ipratropium is an anticholinergic and muscarinic antagonist which works by causing smooth muscles to relax.[1]

Ipratropium bromide was developed in Germany in 1976.[3] It was approved for medical use in the United States in 1986.[1] It is on the World Health Organization's List of Essential Medicines, the most important medications needed in a basic health system.[4] Ipratropium is available as a generic medication.[1] The wholesale price in the developing world is about 6.60 USD for a 200 dose inhaler.[5] In the United States, a month worth of medication costs 100 to 200 USD.[6]

Contents

## Medical uses [edit]

Ipratropium is administered by inhalation for the treatment of chronic obstructive pulmonary disease (COPD). For that purpose, it is supplied in a canister for use in an inhaler or in single dose vials for use in a nebulizer.[7]

It is also used to treat and prevent minor and moderate bronchial asthma, especially asthma that is accompanied by

cardiovascular system diseases.[*citation needed*]

It is also combined with salbutamol (albuterol — USAN) under the trade names Combivent (metered-dose inhaler or MDI) and Duoneb (nebulizer) for the management of COPD and asthma, and with fenoterol (trade names Duovent and Berodual N) for the management of asthma.

Ipratropium as a nasal solution sprayed into the nostrils can reduce rhinorrhea but will not help nasal congestion.[8]

Combination with beta-adrenergic agonists, increases the dilating effect on the bronchi.

## Contraindications [edit]

The main contraindication for inhaled ipratropium is hypersensitivity to atropine and related substances. For oral administration, contraindications are similar to other anticholinergics; they include narrow angle glaucoma and obstructions in the gastrointestinal tract and urinary system.[9][10]

### Peanut allergy [edit]

Previously atrovent inhalers used chlorofluorocarbon (CFC) as a propellant and contained soy lecithin in the propellant ingredients. In 2008 all CFC inhalers were phased out and hydrofluoroalkane (HFA) inhalers replaced them. Allergy to peanuts was noted for the inhaler as a contraindication but now is not. It has never been a contraindication when administered as a nebulized solution.[11]

## Side effects [edit]

If ipratropium is inhaled, side effects resembling those of other anticholinergics are minimal. However, dry mouth and sedation have been reported. Also, effects such as skin flushing, tachycardia, acute angle-closure glaucoma, nausea, palpitations and headache have been observed. Inhaled ipratropium does not decrease mucociliary clearance.[10] The inhalation itself can cause headache and irritation of the throat in a few percent of patients.[9]

Urinary retention has been reported in patients receiving doses by nebulizer. As a result, caution may be warranted, especially by men with prostatic hypertrophy.[12]

## Interactions [edit]

Interactions with other anticholinergics like tricyclic antidepressants, antiparkinson drugs and quinidine, which theoretically increase side effects, are clinically irrelevant when ipratropium is administered as an inhalant.[9][10]

## Pharmacology [edit]

Ipratropium exhibits broncholytic action by reducing cholinergic influence on the bronchial musculature. It blocks muscarinic acetylcholine receptors, without specificity for subtypes, and therefore promotes the degradation of cyclic guanosine monophosphate (cGMP), resulting in a decreased intracellular concentration of cGMP.[13] Most likely due to actions of cGMP on intracellular calcium, this results in decreased

contractility of smooth muscle in the lung, inhibiting bronchoconstriction and mucus secretion. It is a nonselective muscarinic antagonist,[9] and does not diffuse into the blood, which prevents systemic side effects. Ipratropium is a derivative of atropine[14] but is a quaternary amine and therefore does not cross the blood–brain barrier, which prevents central side effects (anticholinergic syndrome). Ipratropium is not considered a short-acting bronchodilator and should never be used in place of salbutamol (albuterol) as a rescue medication.

# Ketamine

From Wikipedia, the free encyclopedia

*For the functional group referred to as ketimine, see imine.*

**Ketamine**, sold under the brand name **Ketalar** among others, is a medication mainly used for starting and maintaining anesthesia.[4] It induces a trance-like state while providing pain relief, sedation, and memory loss.[5] Other uses include for chronic pain and for sedation in intensive care.[6][7] Heart function, breathing, and airway reflexes generally remain functional.[5] Effects typically begin within five minutes when given by injection with the main effects lasting up to 25 minutes.[3][4]

Common side effects include psychological reactions as the medication wears off.[8] These reactions may include agitation, confusion, or hallucinations.[4][8][9] Elevated blood pressure and muscle tremors are relatively common, while low blood pressure and a decrease in breathing are less so.[4][9] Spasms of the larynx may rarely occur.[4] Ketamine has been classified as an NMDA receptor antagonist; it also acts on opioid receptors and monoamine transporters among others.[10]

Ketamine was discovered in 1962.[3] It is on the World Health Organization's List of Essential Medicines, of the most important medications needed in a basic health system.[11] It is available as a generic medication.[4] The wholesale cost in the developing world is between 0.08 and 0.32 USD per dose.[12] Ketamine is also used as a recreational drug.[13]

## Uses [edit]

### Medical [edit]

#### Anesthesia [edit]

Uses as an anaesthetic:

- Anesthesia in children, as the sole anesthetic for minor procedures or as an induction agent followed by muscle relaxant and tracheal intubation
- Asthmatics or people with chronic obstructive airway disease
- As a sedative for physically painful procedures in emergency departments[5]
- Emergency surgery in field conditions in war zones
- To supplement spinal or epidural anesthesia/analgesia using low doses

Since it suppresses breathing much less than most other available anaesthetics,[14] ketamine is used in medicine as an anesthetic; however, due to the hallucinations it may cause, it is not typically used as a primary anesthetic, although it is the anaesthetic of choice when reliable ventilation equipment is not available.

Ketamine is frequently used in severely injured people and appears to be safe in this group.[15] A 2011 clinical practice guideline supports the use of ketamine as a dissociative sedative in emergency medicine.[5] It is the drug of choice for people in traumatic shock who are at risk of hypotension.[16] Low blood pressure is harmful in people with severe head injury[17] and ketamine is least likely to cause low blood pressure, often even able to prevent it.[18][19]

The effect of ketamine on the respiratory and circulatory systems is different from that of other anesthetics. When used at anesthetic doses, it will usually stimulate rather than depress the circulatory system.[20] It is sometimes possible to perform ketamine anesthesia without protective measures to the airways.[*citation needed*] Ketamine is considered relatively safe because protective airway reflexes are preserved.[21]

Ketamine is used as a bronchodilator in the treatment of severe [22] [22][23]

1000mg/10ml vial of ketamine

asthma. However, evidence of clinical benefit is limited.

## Pain management [edit]

Ketamine may be used for postoperative pain management. Low doses of ketamine reduce morphine use and nausea and vomiting after surgery.[24] High quality evidence in acute pain is insufficient to determine if ketamine is useful in this situation.[25]

It may also be used as an intravenous analgesic with opiates to manage otherwise intractable pain, particularly if this pain is neuropathic. It has the added benefit of counteracting spinal sensitization or wind-up phenomena experienced with chronic pain. At these doses, the psychotropic side effects are less apparent and well managed with benzodiazepines.[26] Ketamine is an analgesic that is most effective when used alongside a low-dose opioid; because, while it does have analgesic effects by itself, the doses required for adequate pain relief when it is used as the sole analgesic agent are considerably higher and far more likely to produce disorienting side effects.[26] A review article in 2013 concluded, "despite limitations in the breadth and depth of data available, there is evidence that ketamine may be a viable option for treatment-refractory cancer pain".[27]

Low-dose ketamine is sometimes used in the treatment of complex regional pain syndrome (CRPS).[28] A 2013 systematic review found only low-quality evidence to support the use of ketamine for CRPS.[29]

## Depression [edit]

*See also: Rapid-acting antidepressant*

Ketamine has been tested in treatment-resistant bipolar disorder, major depressive disorder, and people in a suicidal crisis in emergency rooms.[30] Benefit is often of a short duration.[31] The quality of the evidence supporting benefit is generally low.[31]

The drug is given by a single intravenous infusion at doses less than those used in anesthesia, and preliminary data indicate it produces a rapid (within 2 hours) and relatively sustained (about 1–2 weeks long) reduction in symptoms in some people.[32] Initial studies have resulted in interest due to its rapid onset,[33] and because it appears to work by blocking NMDA receptors for glutamate, a different mechanism from most modern antidepressants that operate on other targets.[31][34]

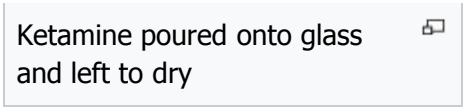
## Recreational [edit]

*Main article: Recreational use of ketamine*

Ketamine use as a recreational drug has been implicated in deaths globally, with more than 90 deaths in England and Wales in the years of 2005-2013.[35] They include accidental poisonings, drownings, traffic accidents, and suicides.[35] The majority of deaths were among young people.[36] This has led to increased regulation (e.g., upgrading ketamine from a Class C to a Class B banned substance in the U.K.).[37]

Unlike the other well-known dissociatives phencyclidine (PCP) and dextromethorphan (DXM), ketamine is very short-acting. It takes effect within about 10 minutes,[38] while its hallucinogenic effects last 60

minutes when insufflated or injected and up to two hours when ingested orally.[39]



Ketamine poured onto glass and left to dry

At anaesthetic doses, under-dosaged from a medical point of view, ketamine produces a dissociative state, characterised by a sense of detachment from one's physical body and the external world which is known as depersonalization and derealization.[40] At sufficiently high doses, users may experience what is called the "K-hole", a state of extreme dissociation with visual and auditory hallucinations.[41] John C. Lilly, Marcia Moore and D. M. Turner (amongst others) have written extensively about their own entheogenic use of, and psychonautic experiences with ketamine.[42] Both Moore and Turner died prematurely (due to hypothermia and drowning respectively) during presumed unsupervised ketamine use.[43]

## Side effects [edit]

Ketamine is generally safe for those critically ill, when administered by trained medical professionals.[44] Even in these cases, there are known side effects that include one or more of the following:[45]

- Cardiovascular: abnormal heart rhythms, slow heart rate or fast heart rate, high blood pressure or low blood pressure
- Central nervous system: Ketamine is traditionally avoided in people with or at risk of intracranial hypertension (ICP) due to concerns about ketamine causing increased intracranial pressure. It does not increase ICP more than opioids.[46]
- Dermatologic: Transient erythema, transient morbilliform rash
- Gastrointestinal: Anorexia, nausea, increased salivation, vomiting
- Local: Pain or exanthema of the injection site
- Neuromuscular and skeletal: Increased skeletal muscle tone (tonic-clonic movements)
- Ocular: Double vision, increased intraocular pressure, nystagmus, tunnel vision
- Respiratory: Airway obstruction, apnea, increased bronchial secretions, respiratory depression, laryngospasm
- Other: Anaphylaxis, dependence, emergence reaction

In 10-20% of patients at anesthetic doses experience adverse reactions that occur during emergence from anesthesia, reactions that can manifest as seriously as hallucinations and delirium.[8] These reactions may be less common in some patients subpopulations, and when administered intramuscularly, and can occur up to 24 hours postoperatively; the chance of this occurring can be reduced by minimizing stimulation to the patient during recovery and pretreating with a benzodiazepine, alongside a lower dose of ketamine.[8] Patients who experience severe reactions may require treatment with a small dose of a short- or ultrashort-acting barbiturate.[45]

Tonic-clonic movements are reported at higher anesthetic doses in greater than 10% of patients.[47]

### Neurological effects [edit]

In 1989, psychiatry professor John Olney reported ketamine caused irreversible changes in two small areas of the rat brain. However, the rat brain has significant differences in metabolism from the human brain, therefore such changes may not occur in humans.[48]

The first large-scale, longitudinal study of ketamine users found current frequent (averaging 20 days/month) ketamine users had increased depression and impaired memory by several measures, including verbal, short-term memory, and visual memory. Current infrequent (averaging 3.25 days/month) ketamine users and former ketamine users were not found to differ from controls in memory, attention, and psychological well-being tests. This suggests the infrequent use of ketamine does not cause cognitive deficits, and that any deficits that might occur may be reversible when ketamine use is discontinued. However, abstinent, frequent, and infrequent users all scored higher than controls on a test of delusional symptoms.[49]

Short-term exposure of cultures of GABAergic neurons to ketamine at high concentrations led to a significant loss of differentiated cells in one study, and noncell-death-inducing concentrations of ketamine (10 μg/ml) may still initiate long-term alterations of dendritic arbor in differentiated neurons. The same study also demonstrated chronic (>24 h) administration of ketamine at concentrations as low as 0.01 μg/ml can interfere with the maintenance of dendritic arbor architecture. These results raise the possibility that chronic exposure to low, subanesthetic concentrations of ketamine, while not affecting cell survival, could still impair neuronal maintenance and development.[50][51]

More recent studies of ketamine-induced neurotoxicity have focused on primates in an attempt to use a more accurate model than rodents. One such study administered daily ketamine doses consistent with typical recreational doses (1 mg/kg IV) to adolescent cynomolgus monkeys for varying periods of time.[52] Decreased locomotor activity and indicators of increased cell death in the prefrontal cortex were detected in monkeys given daily injections for six months, but not those given daily injections for one month.[52] A study conducted on rhesus monkeys found a 24-hour intravenous infusion of ketamine caused signs of brain damage in five-day-old but not 35-day-old animals.[53] Some neonatal experts do not recommend the use of ketamine as an anesthetic agent in human neonates because of the potential adverse effects it may have on the developing brain. These neurodegenerative changes in early development have been seen with other drugs that share the same mechanism of action of NMDA receptor antagonism as ketamine.[54]

The acute effects of ketamine cause cognitive impairment, including reductions in vigilance, verbal fluency, short-term memory, and executive function, as well as schizophrenia-like perceptual changes.[55]

## Urinary tract effects [edit]

A 2011 systematic review examined 110 reports of irritative urinary tract symptoms from ketamine recreational use.[56] Urinary tract symptoms have been collectively referred as "ketamine-induced ulcerative cystitis" or "ketamine-induced vesicopathy", and they include urge incontinence, decreased bladder compliance, decreased bladder volume, detrusor overactivity, and painful haematuria (blood in urine). Bilateral hydronephrosis and renal papillary necrosis have also been reported in some cases.[56][57] The pathogenesis of papillary necrosis has been investigated in mice, and mononuclear inflammatory infiltration in the renal papilla resulting from ketamine dependence has been suggested as a possible mechanism.[58]

The time of onset of lower urinary tract symptoms varies depending, in part, on the severity and chronicity of ketamine use; however, it is unclear whether the severity and chronicity of ketamine use corresponds linearly to the presentation of these symptoms. All reported cases where the user consumed greater than 5 g/day reported symptoms of the lower urinary tract.[56] Urinary tract symptoms appear to be most common in daily ketamine users who have used the drug recreationally for an extended period of time.[57] These symptoms have presented in only one case of medical use of ketamine. However, following dose reduction, the symptoms remitted.[57]

Management of these symptoms primarily involves ketamine cessation, for which compliance is low. Other treatments have been used, including antibiotics, NSAIDs, steroids, anticholinergics, and cystodistension.[56] Both hyaluronic acid instillation and combined pentosan polysulfate and ketamine cessation have been shown to provide relief in some patients, but in the latter case, it is unclear whether relief resulted from ketamine cessation, administration of pentosan polysulfate, or both. Further follow-up is required to fully assess the efficacy of these treatments.[56]

## Liver problems [edit]

In case reports of three patients treated with esketamine for relief of chronic pain, liver enzyme abnormalities occurred following repeat treatment with ketamine infusions, with the liver enzyme values returning below the upper reference limit of normal range on cessation of the drug. The result suggests liver enzymes must be monitored during such treatment.[59]

## Interactions [edit]

Other drugs which increase blood pressure may interact with ketamine in having an additive effect on blood pressure including: stimulants, SNRI antidepressants, and MAOIs. Increase blood pressure and heart rate, palpitations, and arrhythmias may be potential effects.

Ketamine may increase the effects of other sedatives in a dose dependent manner, including, but not limited to: alcohols,[60] benzodiazepines,[61] opioids,[62] quinazolinones, phenothiazines, anticholinergics and barbiturates.[63]

# Pharmacology [edit]

## Pharmacodynamics [edit]

Ketamine acts primarily as an antagonist of the NMDA receptor, and this action accounts for most of its effects.[10] However, the complete pharmacology of ketamine is more complex, and it is known to directly interact with a variety of other sites to varying degrees.[10]

A study conducted in mice found that ketamine's antidepressant activity is not caused by ketamine inhibiting NMDAR, but rather by sustained activation of a different glutamate receptor, the AMPA receptor, by a metabolite, (2R,6R)-hydroxynorketamine.[64][65]

Known actions of ketamine include:

- Non-competitive antagonist of the NMDA receptor (NMDAR)[10][66]
- Negative allosteric modulator of the nACh receptor[10]
- Weak agonist of the μ-opioid and κ-opioid receptors (10- and 20-fold less affinity relative to NMDAR, respectively),[10] and very weak agonist of the δ-opioid receptor[10]
- Agonist of the $D_2$ receptor[67]
- Weak mACh receptor antagonist (10- to 20-fold less affinity relative to NMDAR)[10]
- Inhibitor of the reuptake of serotonin, dopamine, and norepinephrine[10]
- Voltage-gated sodium channel and L-type calcium channel blocker,[10][68] and HCN1 cation channel blocker[69]
- Inhibitor of nitric oxide synthase[10][70]
- σ receptor 1 and 2 agonist (μM affinities).[10][70][71]
- Activation of AMPA receptors[72]

Ketamine appears to inhibit the NMDAR by binding both in the open channel and at an allosteric site.[73] The S(+) and R(-) stereoisomers bind with different affinities: $K_i$ = 3200 and 1100 nM, respectively.[74]

The significance of these additional mechanisms in the therapeutic effects of ketamine is poorly understood due to its relatively complex pharmacological profile.

## Effects in central nervous system [edit]

NMDAR antagonism is responsible for the anesthetic, amnesic, dissociative, and hallucinogenic effects of ketamine, although activation of κ-opioid receptors and possibly sigma and mACh receptors may also contribute to its hallucinogenic properties.[10] Dopamine reuptake inhibition is likely to underlie the euphoria the drug produces, although an additional involvement of μ-opioid receptor activation cannot be excluded.[10] The mechanisms of action for the possible antidepressant effects of ketamine at lower doses have yet to be elucidated.[75]

NMDAR antagonism results in analgesia by preventing central sensitization in dorsal horn neurons; in other words, ketamine's actions interfere with pain transmission in the spinal cord.[47] Inhibition of nitric oxide synthase lowers the production of nitric oxide – a neurotransmitter involved in pain perception, hence further contributing to analgesia.[76] The action of ketamine at sigma and μ-opioid receptors is relatively [10][77]

weak, and evidence is mixed as to whether the latter is of significance to its analgesic effects.

Ketamine also interacts with a host of other targets to cause analgesia. In particular, it blocks voltage-dependent calcium channels and sodium channels, attenuating hyperalgesia; it alters cholinergic neurotransmission, which is implicated in pain mechanisms; and it inhibits the reuptake of serotonin and norepinephrine, which are involved in descending antinociceptive pathways.[47][78]

### Effects in peripheral systems [edit]

Ketamine affects catecholaminergic transmission as noted above, producing measurable changes in peripheral organ systems, including the cardiovascular, gastrointestinal, and respiratory systems:[76]

- Cardiovascular: Ketamine inhibits the reuptake of catecholamines, stimulating the sympathetic nervous system, resulting in cardiovascular symptoms.
- Gastrointestinal: Serotonin reuptake inhibition is thought to underlie nausea and vomiting.[10]
- Respiratory: Catecholamine elevation and stimulation of $\beta_2$ adrenergic receptors probably causes bronchodilation, although other processes may also be involved. The exact mechanism is not fully understood.

### Pharmacokinetics [edit]

Ketamine is absorbable by intravenous, intramuscular, oral, and topical routes due to both its water and lipid solubilities.[76] When administered orally, it undergoes first-pass metabolism, where it is biotransformed in the liver by CYP3A4 (major), CYP2B6 (minor), and CYP2C9 (minor) isoenzymes into norketamine (through N-demethylation) and finally dehydronorketamine.[79] Intermediate in the biotransformation of norketamine into dehydronorketamine is the hydroxylation of norketamine into hydroxynorketamine by CYP2B6 and CYP2A6. Dehydronorketamine, followed by norketamine, is the most prevalent metabolite detected in urine.[80] As the major metabolite of ketamine, norketamine is one-third to one-fifth as potent anesthetically, and plasma levels of this metabolite are three times higher than ketamine following oral administration.[76][81] Bioavailability through the oral route reaches 17–20%; bioavailability through other routes are: 93% intramuscularly, 25–50% intranasally, 30% sublingually, and 30% rectally.[47][79] Peak plasma concentrations are reached within a minute intravenously, 5–15 min intramuscularly, and 30 min orally.[81] Ketamine's duration of action in a clinical setting is 30 min to 2 h intramuscularly and 4–6 h orally.[47]

Plasma concentrations of ketamine are increased by diazepam and other CYP3A4 inhibitors due to inhibition of conversion to norketamine.[47]

### Administration [edit]

In medical settings, ketamine is usually injected intravenously or intramuscularly.[82]

Ketamine can be started using the oral route, or people may be changed from a subcutaneous infusion once pain is controlled. Bioavailability of oral ketamine hydrochloride is around 20%

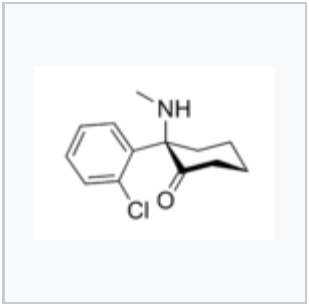
- Oral ketamine is easily broken down by bile acids, thus has a low bioavailability (about 20%). Often, lozenges or "gummies" for sublingual or buccal absorption prepared by a compounding pharmacy are used to combat this issue.
- Some specialists stop the subcutaneous infusion when the first dose of oral ketamine is given. Others gradually reduce the infusion dose as the oral dose is increased.[83]

## Chemistry [edit]

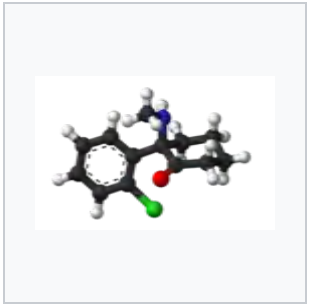
### Structure [edit]

In chemical structure, ketamine is an arylcyclohexylamine derivative. Ketamine is a chiral compound. Most

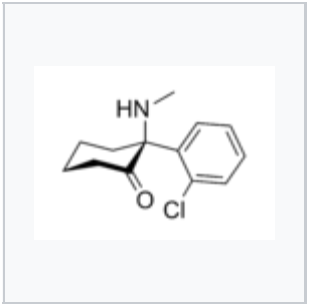
pharmaceutical preparations of ketamine are racemic; however, some brands reportedly have (mostly undocumented) differences in their enantiomeric proportions. The more active enantiomer, esketamine (*S*-ketamine), is also available for medical use under the brand name Ketanest S,[84] while the less active enantiomer, arketamine (*R*-ketamine), has never been marketed as an enantiopure drug for clinical use.



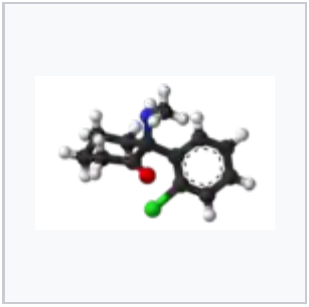
Skeletal formula of *(R)*-ketamine



Ball-and-stick model of *(R)*-ketamine

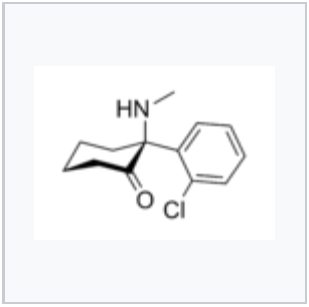


Skeletal formula of *(S)*-ketamine



Ball-and-stick model of *(S)*-ketamine

The optical rotation of a given enantiomer of ketamine can vary between its salts and free base form. The free base form of (*S*) ketamine exhibits dextrorotation and is therefore labelled (*S*) (+) ketamine. However, its hydrochloride salt shows levorotation and is thus labelled (*S*) (−) ketamine hydrochloride. The difference originates from the conformation of the cyclohexanone ring. In both the free base and the hydrochloride, the cyclohexanone ring adopts a chair conformation, but the orientation of the substituents varies. In the free base, the *o*-chlorophenyl group adopts an equatorial position and the methylamino group adopts an axial position.[85] In the hydrochloride salt, the positions are reversed, with the *o*-chlorophenyl group axial and the methylamino group equatorial.[86] Not all salts of ketamine show different optical rotation to the free base: (*S*)-ketamine (*R*,*R*)-tartrate is levorotatory, like (*S*) ketamine.[87]



*(S)*-(−)-ketamine

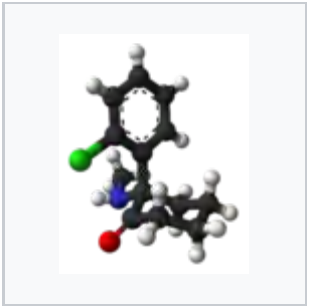
*(S)*-(−)-ketamine in the crystal structure of the free base



*(S)*-(+)-ketamine in the crystal structure of the hydrochloride

## History [edit]

### Medical use [edit]

Ketamine was first synthesized in 1962 by Calvin L. Stevens, a professor of Chemistry in Wayne State University and a Parke Davis consultant conducting research on alpha-hydroxyimine rearrangements.[88] After promising preclinical research in animals, ketamine was introduced to testing in human prisoners in 1964.[89][90] These investigations demonstrated ketamine's short duration of action and reduced behavioral toxicity made it a favorable choice over phencyclidine (PCP) as a dissociative anesthetic.[91] Following FDA approval in 1970, ketamine anesthesia was first given to American soldiers during the Vietnam War.[92]

Ketamine vials

## Nonmedical use [edit]

*Main article: Recreational use of ketamine*

See the foregoing discussion and citations regarding the increasing stringency of governmental regulation that has resulted from a number of deaths of youth and young adults by overdose, accident, and suicide in which nonmedical/recreational ketamine use is implicated (in the Recreational use section, above).

Nonmedical use of ketamine began on the West Coast of the United States in the early 1970s.[92] Early use was documented in underground literature such as *The Fabulous Furry Freak Brothers*. It was used in psychiatric and other academic research through the 1970s, culminating in 1978 with the publishing of psychonaut John Lilly's *The Scientist*, and Marcia Moore and Howard Alltounian's *Journeys into the Bright World*, which documented the unusual phenomenology of ketamine intoxication.[93] The incidence of nonmedical ketamine use increased through the end of the century, especially in the context of raves and other parties.[94] However, its emergence as a club drug differs from other club drugs (e.g. MDMA) due to its anesthetic properties (*e.g.*, slurred speech, immobilization) at higher doses;[95] in addition, there are reports of ketamine being sold as "ecstasy".[96] The use of ketamine as part of a "postclubbing experience" has also been documented.[97] Ketamine's rise in the dance culture was rapid in Hong Kong by the end of the 1990s.[95] Before becoming a federally controlled substance in the United States in 1999, ketamine was available as diverted pharmaceutical preparations and as a pure powder sold in bulk quantities from domestic chemical supply companies.[89] Much of the current ketamine diverted for nonmedical use originates in China and India.[89]

In addition to its ability to cause confusion and amnesia, ketamine can leave users vulnerable to date rape (i.e., because of the associated confusion and amnesia).[38][92]

# Society and culture [edit]

## Legal status [edit]

Ketamine is a "core" medicine in the World Health Organization's Essential Drugs List, a list of minimum medical needs for a basic healthcare system.[98]

The increase in illicit use prompted ketamine's placement in Schedule III of the United States Controlled Substance Act in August 1999.[99]

In the United Kingdom, it became labeled a Class C drug on 1 January 2006.[80][100] On 10 December 2013 the UK Advisory Council on the Misuse of Drugs (ACMD) recommended that the government reclassify ketamine to become a Class B drug,[101] and on 12 February 2014 the Home Office announced they would follow this advice "in light of the evidence of chronic harms associated with ketamine use, including chronic bladder and other urinary tract damage".[102][103]

The UK Minister of State for Crime Prevention, Norman Baker, responding to the ACMD's advice, said the issue of its rescheduling for medical and veterinary use would be addressed "separately to allow for a period of consultation."[102]

In Australia Ketamine is listed as a schedule 8 controlled drug under the Poisons Standard (October 2015).[104] A schedule 8 drug is outlined in the Poisons Act 1964 as "Substances which should be available for use but require restriction of manufacture, supply, distribution, possession and use to reduce abuse, misuse and physical or psychological dependence." [105]

In Canada, ketamine is classified as a Schedule I narcotic, since 2005.[106]

In Hong Kong, as of 2000, ketamine is regulated under Schedule 1 of Hong Kong Chapter 134 *Dangerous Drugs Ordinance*. It can only be used legally by health professionals, for university research purposes, or with a physician's prescription.[107][108] By 2002, ketamine was classified as class III in Taiwan; given the recent rise in prevalence in East Asia, however, rescheduling into class I or II is being considered.[80][109]

In December 2013, the government of India, in response to rising recreational use and the use of ketamine as a date rape drug, has added it to Schedule X of the Drug and Cosmetics Act requiring a special license for sale and maintenance of records of all sales for two years.[110][111]

Ketamine is legally marketed in many countries worldwide, under many brand names.[112]

## Research [edit]

### Treatment of addiction [edit]

Russian doctor Evgeny Krupitsky has claimed to have encouraging results by using ketamine as part of a treatment for alcohol addiction which combines psychedelic and aversive techniques.[113][114] Krupitsky and Kolp summarized their work to date in 2007.[115]

## Veterinary medicine [edit]

In veterinary anesthesia, ketamine is often used for its anesthetic and analgesic effects on cats, dogs, rabbits, rats, and other small animals. It is an important part of the "rodent cocktail", a mixture of drugs used for anesthetizing rodents.[116] Veterinarians often use ketamine with sedative drugs to produce balanced anesthesia and analgesia, and as a constant-rate infusion to help prevent pain wind-up. Ketamine is used to manage pain among large animals, though it has less effect on bovines.[*citation needed*] It is the primary intravenous anesthetic agent used in equine surgery, often in conjunction with detomidine and thiopental, or sometimes guaifenesin.

# Levofloxacin

From Wikipedia, the free encyclopedia

**Levofloxacin**, sold under the trade names **Levaquin** among others, is an antibiotic.[2] It is used to treat a number of bacterial infections including acute bacterial sinusitis, pneumonia, urinary tract infections, chronic prostatitis, and some types of gastroenteritis. Along with other antibiotics it may be used to treat tuberculosis, meningitis, or pelvic inflammatory disease. It is available by mouth or intravenously.[2]

Common side effects include nausea, diarrhea, and trouble sleeping. Serious side effects may include tendon rupture, tendon inflammation, seizures, psychosis, and potentially permanent peripheral nerve damage. Tendon damage may appear months after treatment is completed. People may also sunburn more easiiy. In people with myasthenia gravis, muscle weakness and breathing problems may worsen.[2] The risk of use during pregnancy is low and it is probably okay during breastfeeding. Levofloxacin is a broad-spectrum antibiotic of the fluoroquinolone drug class.[3] It usually results in death of the bacteria.[2] It is the left sided isomer of the medication ofloxacin.[3]

Levofloxacin was approved for medical use in the United States in 1996.[2] It is on the World Health Organization's List of Essential Medicines, the most important medications needed in a basic health system.[4] It is available as a generic medication.[2] The wholesale cost in the developing world is about 0.44 to 0.95 USD per week of treatment.[5] In the United States a week of treatment cost about 50 to 100 USD.[6]

## Medical uses [edit]

Levofloxacin is used to treat infections including: respiratory tract infections, cellulitis, urinary tract infections, prostatitis, anthrax, endocarditis, meningitis, pelvic inflammatory disease, traveler's diarrhea, tuberculosis, and plague.[2][7]

As of 2016, the US Food and Drug Administration (FDA) recommended that "serious side effects associated with fluoroquinolone antibacterial drugs generally outweigh the benefits for patients with acute sinusitis, acute bronchitis, and uncomplicated urinary tract infections who have other treatment options. For patients with these conditions, fluoroquinolones should be reserved for those who do not have alternative treatment options."[8]

Levofloxacin is used for the treatment of pneumonia, urinary tract infections, and abdominal infections. As of 2007 the Infectious Disease Society of America (IDSA) and the American Thoracic Society recommended levofloxacin and other respiratory fluoroquinolines as first line treatment for community acquired pneumonia when co-morbidities such as heart, lung, or liver disease are present or when in-patient treatment is required.[9] Levofloxacin also plays an important role in recommended treatment regimens for ventilator-associated and healthcare-associated pneumonia.[10]

As of 2010 it was recommended by the IDSA as a first-line treatment option for catheter-associated urinary tract infections in adults.[11] In combination with metronidazole it is recommended as one of several first-line treatment options for adult patients with community-acquired intra-abdominal infections of mild-to-moderate severity.[12] The IDSA also recommends it in combination with rifampicin as a first-line treatment for prosthetic joint infections.[13] The American Urological Association recommends levofloxacin as a first-line treatment to prevent bacterial prostatitis when the prostate is biopsied.[14] and as of 20054 it was recommended to treat bacterial prostatitis by the NIH research network studying the condition.[15]

Levofloxacin and other fluoroquinolones have also been widely used for the treatment of uncomplicated community-acquired respiratory and urinary tract infections, indications for which major medical societies generally recommend the use of older, narrower spectrum drugs to avoid fluoroquinolone resistance development. Due to its widespread use, common pathogens such as *Escherichia coli* and *Klebsiella pneumoniae* have developed resistance. In many countries as of 2013, resistance rates among healthcare-associated infections with these pathogens exceeded 20%.[16][17]

According to the FDA approved prescribing information, levofloxacin is pregnancy category C. This designation indicates that animal reproduction studies have shown adverse effects on the fetus and there are no adequate and well-controlled studies in humans, but the potential benefit to the mother may in some cases outweigh the risk to the fetus. Other fluoroquinolones have also been reported as being present in the mother's milk and are passed on to the nursing child.[18][19]

It is not known if levofloxacin is released in mother's milk, but other fluoroquinolones are.[7] Due to potential risks to the baby, levofloxacin is not recommended in nursing mothers.[7]

## Children [edit]

Levofloxacin is not approved in most countries for the treatment of children except in unique and life-threatening infections because it is associated with an elevated risk of musculoskeletal injury in this population, a property it shares with other fluoroquinolones.

In the United States levofloxacin is approved for the treatment of anthrax and plague in children over six months of age.[7]

Levofloxacin is recommended by the Pediatric Infectious Disease Society and the Infectious Disease Society of America as a first-line treatment for pediatric pneumonia caused by penicillin-resistant *Streptococcus pneumoniae*, and as a second-line agent for the treatment of penicillin-sensitive cases.[20]

In one study,[7][21] 1534 juvenile patients (age 6 months to 16 years) treated with levofloxacin as part of three efficacy trials were followed up to assess all musculoskeletal events occurring up to 12 months post-treatment. At 12 months follow-up the cumulative incidence of musculoskeletal adverse events was 3.4%, compared to 1.8% among 893 patients treated with other antibiotics. In the levafloxacin-treated group, approximately two-thirds of these musculoskeletal adverse events occurred in the first 60 days, 86% were mild, 17% were moderate, and all resolved without long-term sequelae.

## Spectrum of activity [edit]

Levofloxacin and later generation fluoroquinolones are collectively referred to as "respiratory quinolones" to distinguish them from earlier fluoroquinolones which exhibited modest activity toward the important respiratory pathogen *Streptococcus pneumoniae*.[22]

The drug exhibits enhanced activity against the important respiratory pathogen *Streptococcus pneumoniae* relative to earlier fluoroquinolone derivatives like ciprofloxacin. For this reason, it is considered a "respiratory fluoroquinolone" along with more recently developed fluoroquinolones such as moxifloxacin and gemifloxacin. It is less active than ciprofloxacin against Gram-negative bacteria, especially *Pseudomonas aeruginosa*, and lacks the anti-methicillin-resistant *Staphylococcus aureus* (MRSA) activity of moxifloxacin and gemifloxacin.[23][24][25][26] Levofloxacin has shown moderate activity against anaerobes, and is about twice as potent as ofloxacin against *Mycobacterium tuberculosis* and other mycobacteria, including *Mycobacterium avium* complex.[27]

Its spectrum of activity includes most strains of bacterial pathogens responsible for respiratory, urinary tract, gastrointestinal, and abdominal infections, including Gram negative (*Escherichia coli*, *Haemophilus influenzae*, *Klebsiella pneumoniae*, *Legionella pneumophila*, *Moraxella catarrhalis*, *Proteus mirabilis*, and *Pseudomonas aeruginosa*), Gram positive (methicillin-sensitive but not methicillin-resistant *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Staphylococcus epidermidis*, *Enterococcus faecalis*, and *Streptococcus pyogenes*), and atypical bacterial pathogens (*Chlamydophila pneumoniae* and *Mycoplasma pneumoniae*). Compared to earlier antibiotics of the fluoroquinoline class such as ciprofloxacin, levofloxacin exhibits greater activity towards Gram-positive bacteria[23] but lesser activity toward Gram-negative bacteria,[28] especially *Pseudomonas aeruginosa*.

## Availability [edit]

Levofloxacin is available in tablet form, injection, and oral solution.[7]

Levofloxacin and NaCl injection, specification is 100mL / 750mg

## Contraindications and drug interactions [edit]

Package inserts mention that levofloxacin is to be avoided in patients with a known hypersensitivity to levofloxacin or other quinolone drugs.[7][29]

Like all fluoroquinolines, levofloxacin is contraindicated in patients with epilepsy or other seizure disorders, and in patients who have a history of quinolone-associated tendon rupture.[7][29]

Levofloxacin may prolong the QT interval in some people, especially older ones, and levofloxacin should not be used for people with a family history of Long QT syndrome, or who have long QT, chronic low potassium,it should not be prescribed with other drugs that prolong the QT interval.[7]

Unlike ciprofloxacin, levofloxacin does not appear to deactivate the drug metabolizing enzyme CYP1A2. Therefore, drugs that use that enzyme, like theophylline, do not interact with levofloxacin. It is a weak inhibitor of CYP2C9,[30] suggesting potential to block the breakdown of warfarin and phenprocoumon. This can result in more action of drugs like warfarin, leading to more potential side effects, such as bleeding.[31]

The use of non-steroidal anti-inflammatory drugs (NSAIDs) in combination with high dose fluoroquinolone therapy may lead to seizures.[32]

When levofloxacin is taken with anti-acids containing magnesium hydroxide or aluminum hydroxide, the two combine to form insoluble salts that are difficult to absorb from the intestines. Peak serum concentrations of levofloxacin may be reduced by 90% or more, which can prevent the levofloxacin from working. Similar results have been reported when levofloxacin is taken with iron supplements and multi-vitamins containing zinc.[33][34]

A 2011 review examining musculoskeletal complications of fluoroquinolones proposed guidelines with respect to administration to athletes, that called for avoiding all use of fluoroquinolone antibiotics if possible, and if they are used: ensure there is informed consent about the musculoskeletal risks, and inform coaching staff; do not use any corticosteroids if fluoroquinolones are used; consider dietary supplements of magnesium and antioxidants during treatment; reduce training until the course of antibiotic is finished and then carefully increase back to normal; and monitor for six months after the course is finished, and stop all athletic activity if symptoms emerge.[35]

## Adverse effects [edit]

While typical drug side effects reactions are mild to moderate; sometimes serious adverse effects occur.

Prominent among these are side effects that became the subject of a black box warning by the FDA in 2016.[8] The FDA wrote: "An FDA safety review has shown that fluoroquinolones when used systemically (i.e. tablets, capsules, and injectable) are associated with disabling and potentially permanent serious side effects that can occur together. These side effects can involve the tendons, muscles, joints, nerves, and central nervous system."[8] Such injuries, including tendon rupture, has been observed up to 6 months after cessation of treatment; the elderly, transplant patients, and those with a current or historical corticosteroid use are at elevated risk.[36] A detailed overview of risk factors for fluoroquinolone-associated tendon rupture has been published; advanced age, concurrent treatment with corticosteroids, and higher doses of fluoroquinolone appear to be the most important risk factors.[37] The U.S. label for levofloxacin also contains a black box warning for the exacerbation of the symptoms of the neurological disease myasthenia gravis.[7][38]

Increasing age and concomitant corticosteroid use appears to increase the risk of musculoskeletal complications.[35]

A wide variety of other uncommon but serious adverse events have been associated with fluoroquinolone use, with varying degrees of evidence supporting causation. These include anaphylaxis, hepatotoxicity, central nervous system effects including seizures and psychiatric effects, prolongation of the QT interval, blood glucose disturbances, and photosensitivity, among others.[7][29] Levofloxacin may produce fewer of these rare serious adverse effects than other fluoroquinolones.[39]

There is some disagreement in the medical literature regarding whether and to what extent levofloxacin and other fluoroquinolones produce serious adverse effects more frequently than other broad spectrum antibacterial drugs.[40][41][42][43]

With regard to more usual side effects, in pooled results from 7537 patients exposed to levofloxcacin in 29 clinical trials, 4.3% discontinued treatment due to adverse drug reactions. The most common adverse reactions leading to discontinuation were gastrointestinal, including nausea, vomiting, and constipation. Overall, 7% of patients experienced nausea, 6% headache, 5% diarrhea, 4% insomnia, along with other adverse reactions experienced at lower rates.[7]

Administration of levofloxacin or other broad spectrum antibiotics is associated with *Clostridium difficile* associated diarrhea which may range in severity from mild diarrhea to fatal colitis. Fluoroquinoline administration may be associated with the acquisition and outgrowth of a particularly virulent *Clostridium* strain.[44]

## Overdose [edit]

Overdosing experiments in animals showed loss of body control and drooping, difficulty breathing, tremors, and convulsions. Doses in excess of 1500 mg/kg orally and 250 mg/kg IV produced significant mortality in rodents.[7]

In the event of an acute overdosage, authorities recommend unspecific standard procedures such as emptying the stomach, observing the patient and maintaining appropriate hydration. Levofloxacin is not efficiently removed by hemodialysis or peritoneal dialysis.[7]

## Mechanism of action [edit]

Levofloxacin is a broad-spectrum antibiotic that is active against both Gram-positive and Gram-negative bacteria. Like all quinolones, it functions by inhibiting the two type II topoisomerase enzymes, namely DNA gyrase and topoisomerase IV.[45] Topoisomerase IV is necessary to separate DNA that has been replicated (doubled) prior to bacterial cell division. With the DNA not being separated, the process is stopped, and the bacterium cannot divide. DNA gyrase, on the other hand, is responsible for supercoiling the DNA, so that it will fit in the newly formed cells. Both mechanisms amount to killing the bacterium. In this way, levofloxacin acts as a bactericide.[46]

As of 2011 the mechanism of action for the drug's musculoskeletal complications were not clear.[35]

## Chemical properties [edit]

Levofloxacin is the levo isomer of the racemate ofloxacin, another quinolone antimicrobial agent.[47] In layman terms, this means that levofloxacin is the 50% of ofloxacin that have been found to be effective against bacteria, while the other 50% have been removed. In chemical terms, levofloxacin, a chiral fluorinated carboxyquinolone, is the pure (−)-(*S*)-enantiomer of the racemic ofloxacin.[48][49]

The substance is used as the hemihydrate, which has the empirical formula $C_{18}H_{20}FN_3O_4 \cdot ½\ H_2O$ and a molecular mass of 370.38 g/mol. Levofloxacin is a light-yellowish-white to yellow-white crystal or crystalline

powder.[7]

## Pharmacokinetics [edit]

Levofloxacin is rapidly and essentially completely absorbed after oral administration, with a plasma concentration profile over time that is essentially identical to that obtained from intravenous administration of the same amount over 60 minutes. As such, the intravenous and oral formulations of levofloxacin are considered interchangeable.[7]

The drug undergoes widespread distribution into body tissues. Peak levels in skin are achieved 3 hours after administration and exceed those in plasma by a factor of 2. Similarly, lung tissue concentrations range from two-fold to five-fold higher than plasma concentrations in the 24 hours after a single dose.

The mean terminal plasma elimination half-life of levofloxacin ranges from approximately 6 to 8 hours following single or multiple doses of levofloxacin given orally or intravenously. Elimination occurs mainly via excretion of unmetabolized drug in the urine. Following oral administration, 87% of an administered dose was recovered in the urine as unchanged drug within 2 days. Less than 5% was recovered in the urine as the desmethyl and N-oxide metabolites, the only metabolites identified in humans.

## History [edit]

Levofloxacin is a second-generation fluoroquinolone, being one of the isomers of ofloxacin, which was a broader-spectrum analog of norfloxacin; both Ofloxacin and levofloxaxin were synthesized and developed by scientists at Daiichi Seiyaku.[50] The Daiichi scientists knew that ofloxacin was racemic, but tried unsuccessfully to separate the two isomers; in 1985 they succeeded in separately synthesizing the pure levo form and showed that it was less toxic and more potent than the other form.[51][52]

It was first approved for marketing in Japan in 1993 for oral administration, and Daiichi marketed it there under the brand name Cravit.[52] Daiichi, working with Johnson & Johnson as it had with ofloxacin, obtained FDA approval in 1996 under the brand name Levaquin[51] to treat bacterial sinusitus, bacterial exacerbations of bronchitis, community-acquired pneumonia, uncomplicated skin infections, complicated urinary tract infections, and acute pyelonephritis.[7]

Levofloxacin is marketed by Sanofi-Aventis under a license agreement signed with Daiichi in 1993 under the trade name "Tavanic".[53]

Levofloxacin had reached blockbuster status by this time; worldwide sales for J&J alone were US$1.6 billion in 2009.[53]

The term of the levofloxacin United States patent was extended by the U.S. Patent and Trademark Office 810 days under the provisions of the Hatch Waxman Amendment so that the patent would expire in 2010 instead of 2008.[51] This extension was challenged by generic drug manufacturer Lupin Pharmaceuticals, which did not challenge the validity of the patent, but only the validity of the patent extension, arguing that the patent did not cover a "product" and so Hatch-Waxman was not available for extensions.[51] The federal patent court ruled in favor of J&J and Daiichi, and generic versions of levofloxacin did not enter the U.S. market until 2009.[51][53]

## Society and culture [edit]

### Usage [edit]

The FDA estimated that in 2011 over 23 million outpatient prescriptions for fluoroquinolones, of which levofloxacin made up 28%, were filled in the United States.[54]

## Litigation [edit]

As of 2012, Johnson and Johnson was facing around 3400 state and federal lawsuits filed by people who claimed tendon damage from levofloxacin; about 1900 pending in a class action at the United States District Court in Minnesota[55] and about 1500 pending at a district court in New Jersey.[56][57]

In October 2012, J&J settled 845 cases in the Minnesota action, after Johnson and Johnson prevailed in three of the first four cases to go to trial. By May 2014, all but 363 cases had been settled or adjudicated.[57][58][59]

# Measles vaccine

From Wikipedia, the free encyclopedia

**Measles vaccine** is a vaccine that is very effective at preventing measles.[1] After one dose 85% of children nine months of age and 95% over twelve months of age are immune.[2] Nearly all of those who do not develop immunity after a single dose develop it after a second dose. When rates of vaccination within a population are greater than 93% outbreaks of measles typically no longer occur; however, they may occur again if rates of vaccination decrease. The vaccine's effectiveness lasts many years. It is unclear if it becomes less effective over time. The vaccine may also protect against the disease if given within a couple of days of being exposed.[1]

The vaccine is generally safe including in those with HIV infections. Side effects are usually mild and short lived. This may include pain at the site of injection or mild fever. Anaphylaxis has been documented in about one per hundred thousand people. Rates of Guillain–Barré syndrome, autism and inflammatory bowel disease do not appear to be increased.[1]

The vaccine is available both by itself and in combination with other vaccines. This includes with the rubella vaccine and mumps vaccine to make the MMR vaccine,[1] first made available in 1971.[3] The addition of the varicella vaccine against chickenpox to these three in 2005 gave the MMRV vaccine.[4] The vaccine works equally well in all formulations. The World Health Organization recommends it be given at nine months of age in areas of the world where the disease is common. In areas where the disease is not common, giving it at twelve months is reasonable. It is a vaccine based on a live but weakened strain of measles. It comes as a dried powder which needs to be mixed with a specific liquid before being given either just under the skin or into a muscle. Verification that the vaccine was effective can be determined by blood tests.[1]

About 85% of children globally have received this vaccine as of 2013.[5] In 2008 at least 192 countries offered two doses.[1] It was first introduced in 1963.[2] It is on the WHO Model List of Essential Medicines, the most important medication needed in a basic health system.[6] The wholesale cost in the developing world is about 0.70 USD per dose as of 2014.[1][7]

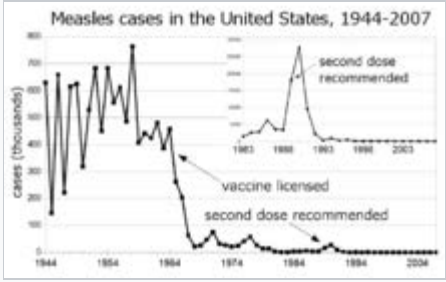
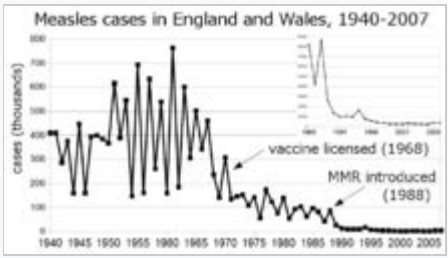
## Medical uses [edit]



Measles cases reported in the United States before and after introduction of the vaccine.



Measles cases reported in England and Wales.

Before the widespread use of the measles vaccine, its incidence was so high that infection with measles was felt to be "as inevitable as death and taxes."[8] In the United States, reported cases of measles fell from hundreds of thousands to tens of thousands per year following introduction of the vaccine in 1963 (see chart at right). Increasing uptake of the vaccine following outbreaks in 1971 and 1977 brought this down to thousands of cases per year in the 1980s. An outbreak of almost 30,000 cases in 1990 led to a renewed push for vaccination and the addition of a second vaccine to the recommended schedule. Fewer than 200 cases were reported each year from 1997 to 2013, and the disease was believed no longer endemic in the United States.[9][10][11] In 2014, 610 cases were reported.[12] Roughly 30 cases were diagnosed in January 2015, likely originating from exposure near Anaheim, California in late December 2014.

The benefit of measles vaccination in preventing illness, disability, and death has been well documented. The first 20 years of licensed measles vaccination in the U.S. prevented an estimated 52 million cases of the disease, 17,400 cases of mental retardation, and 5,200 deaths.[13] During 1999–2004, a strategy led by the World Health Organization and UNICEF led to improvements in measles vaccination coverage that averted an estimated 1.4 million measles deaths worldwide.[14] The vaccine for measles has led to the near-complete elimination of the disease in the United States and other developed countries.[15] It was introduced in 1963.[16] These impressive reductions in death and long-range after-effectiveness were initially achieved with a live virus version of the vaccine that itself caused side effects, although these are far fewer and less serious than the sickness and death caused by measles itself. While preventing many deaths and serious illnesses, the live virus version of the vaccine did cause side effects in a small percentage of recipients, ranging from rashes to, rarely, convulsions.[17]

Measles is common worldwide. Although it was declared eliminated from the U.S. in 2000, high rates of vaccination and excellent communication with those who refuse vaccination are needed to prevent outbreaks and sustain the elimination of measles in the U.S.[18] Of the 66 cases of measles reported in the U.S. in 2005, slightly over half were attributable to one unvaccinated individual who acquired measles during a visit to Romania.[19] This individual returned to a community with many unvaccinated children. The resulting outbreak infected 34 people, mostly children and virtually all unvaccinated; 9% were hospitalized, and the cost of containing the outbreak was estimated at $167,685. A major epidemic was averted due to high rates of vaccination in the surrounding communities.[18]

The live vaccine has non specific effects such as preventing respiratory infections that may be greater than those of measles prevention. These benefits were greater when used before a year of age. A high titre vaccine resulted in worse outcomes in girls and thus is no longer recommended by the world health organization.[20] As measles causes upper respiratory disease that leads to complications of pneumonia and bronchitis, measles vaccine is beneficial to reduce exacerbations of chronic obstructive pulmonary disease (COPD) and asthma.

### Schedule [edit]

The World Health Organization recommends two doses of vaccine for all children.[1] In countries with high

risk of disease the first dose should be given around nine months of age.[1] Otherwise in low risk countries it can be given at twelve months of age.[1] The second dose should be given at least one month after the first dose.[1] This is often done at age 15 to 18 months.[1]

The CDC recommends that children aged 6 to 12 months traveling outside the United States receive their first dose of MMR vaccine.[21] Otherwise the first dose is typically given between 12–18 months. A second dose is given by 7 years (on or before last day of year 6) or by Kindergarten entry.[22] Vaccine is administered in the outer aspect of the upper arm. In adults, it is give subcutaneously and a second dose 28 days apart is given. In adults greater than 50 years, only one dose is needed.

## Adverse effects [edit]

Adverse effects associated with the MMR vaccine include fever, injection site pain and, in rare cases, red or purple discolorations on the skin known as thrombocytopenic purpura, or seizures related to fever (febrile seizure).[23] Serious side effects are extremely rare.

There is no evidence of a link between the MMR vaccine and autism.[24][25][26][27] The MMR vaccine does not appear to cause subacute sclerosing panencephalitis.[28]

### Contraindications [edit]

- Pregnancy: MMR vaccine and its components should not be administered to pregnant women.[29]
- HIV-infected children may receive measles vaccines if their CD4+ lymphocyte count is greater than 15%.[30]

## History [edit]

As a fellow at Children's Hospital Boston, Dr. Thomas C. Peebles worked with Dr. John Franklin Enders. Dr. Enders became known as "The Father of Modern vaccines", and Enders shared the Nobel Prize in 1954 for his research on cultivating the polio virus that led to the development of a vaccination for the disease. Switching to study measles, Enders sent Peebles to Fay School in Massachusetts, where an outbreak of the disease was under way, and there Peebles was able to isolate the virus from some of the blood samples and throat swabs he had taken from the students. Even after Enders had taken him off the study team, Peebles was able to cultivate the virus and show that the disease could be passed on to monkeys inoculated with the material he had collected.[15] Enders was able to use the cultivated virus to develop a measles vaccine in 1963 based on the material isolated by Peebles.[31] In the late 1950s and early 1960s, nearly twice as many children died from measles as from polio.[32] The vaccine Enders developed was based on the Edmonston strain of attenuated live measles virus, which was named for the Fay student from whom Peebles had taken the culture that led to the virus's cultivation.[33]

The first ever trials of measles vaccine were undertaken by David Morley at the Wesley Guild Hospital in Ilesha, Nigeria[34] on his own children.

Dr. Maurice Hilleman at Merck & Co., a pioneer in the development of vaccinations, developed the MMR vaccine in 1971, which treats measles, mumps and rubella in a single shot followed by a booster.[17][35] One form is called "Attenuvax" with more than 40 peptide sequences.[36] The measles component of the MMR vaccine uses Attenuvax, which is grown in a chick embryo cell culture using the Enders' attenuated Edmonston strain. Merck decided not to resume production of attenuvax on October 21, 2009.[37]

## Types [edit]

Measles is seldom given as individual vaccine nowadays and is often given in combination with mumps and rubella. Two types of measles vaccines are currently available.

- Mumps Measles Rubella vaccine, live (MMR-II)
- Mumps Measles Rubella and varicella virus vaccine (Proquad)

Measles mumps rubella vaccine (MMR-II); MMR vaccine is a live attenuated viral vaccine used to induce immunity against measles, mumps and rubella.

# Metoprolol

From Wikipedia, the free encyclopedia

**Metoprolol**, marketed under the tradename **Lopressor** among others, is a selective β1 receptor blocker medication.[3] It is used to treat high blood pressure, chest pain due to poor blood flow to the heart, and a number of conditions involving an abnormally fast heart rate. It is also used to prevent further heart problems after myocardial infarction and to prevent headaches in those with migraines.[3]

It comes in formulations that can be taken by mouth or given intravenously. The medication is often taken twice a day. There is an extended release formulation that is once per day. Metoprolol may be combined with hydrochlorothiazide in a single tablet.[3]

Common side effects include trouble sleeping, feeling tired, feeling faint, and abdominal discomfort.[3] Large doses may cause serious toxicity.[4][5] Risk in pregnancy has not been ruled out.[5][6] It appears to be safe in breastfeeding.[7] Greater care is required with use in those with liver problems or asthma.[3] If stopped this should be done slowly to decrease the risk of further health problems.[3]

Metoprolol was first made in 1969.[8] It is on the World Health Organization's List of Essential Medicines, the most important medications needed in a basic health system.[9] It is available as a generic drug.[3] In 2013, metoprolol was the 19th most prescribed medication in the United States.[10]

| **CAS Number** | 51384-51-1 ✓ |

Metoprolol is used for a number of conditions, including hypertension, angina, acute myocardial infarction, supraventricular tachycardia, ventricular tachycardia, congestive heart failure, and prevention of migraine headaches.[11]

- Treatment of heart failure[12]
- Vasovagal syncope[13][14]
- Adjunct in treatment of hyperthyroidism[15]
- Long QT syndrome, especially for patients with asthma, as metoprolol's β1 selectivity tends to interfere less with asthma drugs, which are often β2-adrenergic receptor-agonist drugs[*citation needed*]
- Prevention of relapse into atrial fibrillation (controlled-release/extended-release form)[16]

Due to its selectivity in blocking the $beta_1$ receptors in the heart, metoprolol is also prescribed for off-label use in performance anxiety, social anxiety disorder, and other anxiety disorders.

## Adverse effects [edit]

Side effects, especially with higher doses, include dizziness, drowsiness, fatigue, diarrhea, unusual dreams, ataxia, trouble sleeping, depression, and vision problems. It may also reduce blood flow to the hands and feet, causing them to feel numb and cold; smoking may worsen this effect.[17] Due to the high penetration across the blood-brain barrier, lipophilic beta blockers such as propranolol and metoprolol are more likely than other less lipophilic beta blockers to cause sleep disturbances such as insomnia and vivid dreams and nightmares.[18]

Serious side effects that are advised to be reported immediately include symptoms of bradycardia (resting heart rate slower than 60 beats per minute), persistent symptoms of dizziness, fainting and unusual fatigue, bluish discoloration of the fingers and toes, numbness/tingling/swelling of the hands or feet, sexual dysfunction, erectile dysfunction (impotence), hair loss, mental/mood changes, depression, trouble breathing, cough, dyslipidemia, and increased thirst. Taking it with alcohol might cause mild body rashes, so is not recommended.[17]

### Precautions [edit]

Metoprolol may worsen the symptoms of heart failure in some patients, who may experience chest pain or discomfort, dilated neck veins, extreme fatigue, irregular breathing, an irregular heartbeat, shortness of breath, swelling of the face, fingers, feet, or lower legs, weight gain, or wheezing.[19]

This medicine may cause changes in blood sugar levels or cover up signs of low blood sugar, such as a rapid pulse rate.[19] It also may cause some people to become less alert than they are normally, making it dangerous for them to drive or use machines.[19]

### Pregnancy and lactation [edit]

It is pregnancy category C in the United States, meaning that a risk for the fetus cannot be ruled out,[3] and category C in Australia, meaning that it may be suspected of causing harmful effects on the human fetus (but no malformations).[6]

## Overdose [edit]

Excessive doses of metoprolol can cause severe hypotension, bradycardia, metabolic acidosis, seizures, and cardiorespiratory arrest. Blood or plasma concentrations may be measured to confirm a diagnosis of overdose or poisoning in hospitalized patients or to assist in a medicolegal death investigation. Plasma levels are usually less than 200 µg/l during therapeutic administration, but can range from 1–20 mg/l in overdose victims.[20][21][22]

## Pharmacology [edit]

- beta-1 selective
- moderately lipophilic
- without intrinsic sympathomimetic activity
- with weak membrane stabilizing activity
- decreases heart rate, contractility, and cardiac output, therefore decreasing blood pressure

### Pharmacokinetics [edit]

Metoprolol has a short half-life of 3 to 7 hours, and therefore is taken at least twice daily or as a slow-release preparation.

It undergoes α-hydroxylation and O-demethylation as a substrate of the cytochrome liver enzymes CYP2D6[23][24] and a small percentage by CYP3A4, resulting in inactive metabolites.

## Chemistry [edit]

Metoprolol has a very low melting point; around 120 °C (248 °F) for the tartrate, and around 136 °C (277 °F) for the succinate. Because of this, metoprolol is always manufactured in a salt-based solution, as drugs with low melting points are difficult to work with in a manufacturing environment. The free base exists as a waxy white solid, and the tartrate salt is finer crystalline material.

The active substance metoprolol is employed either as metoprolol succinate or as metoprolol tartrate (where 100 mg metoprolol tartrate corresponds to 95 mg metoprolol succinate). The tartrate is an immediate-release formulation and the succinate is an extended-release formulation.[25]

## Society and culture [edit]

### Brand names [edit]

It is marketed under the brand name Lopressor by Novartis, and Toprol-XL (in the US); Selokeen (in the Netherlands); as Minax by Alphapharm and Metrol by Arrow Pharmaceuticals (in Australia), as Betaloc by AstraZeneca, as Bloxan by Krka (company) (in Slovenia), as Neobloc by Unipharm (in Israel), Presolol by Hemofarm (in Serbia), and Corvitol by Berlin-Chemie (in Germany). In India, this drug is available under the brand names Met-XL, Metolar, Starpress, and Restopress. A number of generic products are available, as well.

Toprol XL 50 mg

# Mifepristone

From Wikipedia, the free encyclopedia

*For the song RU486 by Stone Sour, see House of Gold & Bones – Part 1.*

**Mifepristone**, also known as **RU-486**, is a medication typically used with misoprostol to bring about an abortion.[1] This combination is more than 95% effective during the first 50 days of pregnancy. It is also effective in the second trimester of pregnancy.[2][3] Two weeks after use effectiveness should be verified. It is taken by mouth.[1]

Common side effects include abdominal pain, feeling tired, and vaginal bleeding. Serious side effects may include heavy vaginal bleeding, bacterial infection, and a malformed baby if the pregnancy does not end. If used, appropriate follow up care needs to be available. Mifepristone works by blocking the effects of progesterone and causing contractions of the uterus.[1]

Mifepristone was developed in 1980 and came into use in France in 1987.[4] It became available in the United States in 2000.[2] It is on the WHO Model List of Essential Medicines, the most important medications needed in a basic health system.[5] Mifepristone was approved by Health Canada in July 2015 and is expected to become available in Canada in January 2017.[6][7][8] Cost and availability limits access in many parts of the developing world.[9][10] In the United States it costs more than US$200 (equivalent to $202.08 in 2016) a dose.[11]

# Medical uses [edit]

## Abortion [edit]

Mifepristone followed by a prostaglandin analog (misoprostol or gemeprost) is used for medical abortion.[12][13]

A 2011 evidence-based clinical guideline by the Royal College of Obstetricians and Gynaecologists (RCOG) says medical abortion using mifepristone followed by the prostaglandin analog misoprostol is effective and appropriate at any gestational age.[14]

A 2012 technical and policy guidance book and a 2014 clinical practice handbook by the World Health Organization (WHO) recommend mifepristone followed by the prostaglandin analog misoprostol for first and second trimester medical abortions.[15][16]

2013 and 2014 practice bulletins by the American College of Obstetricians and Gynecologists (ACOG) recommend mifepristone followed by the prostaglandin analog misoprostol for first and second trimester medical abortions.[17][18]

Mifepristone alone results in abortion within two weeks of 54% to 92% of pregnancies.[19]

## Cushing's syndrome [edit]

Mifepristone is used for the medical treatment of high blood sugar (hyperglycemia) caused by high cortisol levels in the blood (hypercortisolism) in adults with endogenous Cushing's syndrome who have type 2 diabetes mellitus or glucose intolerance and have failed surgery or cannot have surgery.[20][21]

## Emergency contraception [edit]

Mifepristone is used for emergency contraception.[22][23][24]

# Side effects [edit]

Nearly all women using the mifepristone/misoprostol regimen experienced abdominal pain, uterine cramping, and vaginal bleeding or spotting for an average of 9–16 days. Up to 8% of women experienced some type of bleeding for 30 days or more. Other less common side effects included nausea, vomiting, diarrhea, dizziness, fatigue, and fever.[25] Pelvic inflammatory disease is a very rare but serious complication.[26] Excessive bleeding and incomplete termination of a pregnancy require further intervention by a doctor (such as vacuum aspiration). Between 4.5 and 7.9% of women required surgical intervention in clinical trials.[25] Mifepristone

is contraindicated in the presence of an intrauterine device, as well as with ectopic pregnancy, adrenal failure, hemorrhagic disorders, inherited porphyria, and anticoagulant or long-term corticosteroid therapy.[25]

The FDA prescribing information states no data are available on the safety and efficacy of mifepristone in women with chronic medical conditions, and "women who are more than 35 years of age and who also smoke 10 or more cigarettes per day should be treated with caution because such patients were generally excluded from clinical trials of mifepristone."[25]

A postmarketing summary found, of about 1.52 million women who had received mifepristone until April 2011 in the United States, 14 were reported to have died after application. Eight of these cases were associated with sepsis; the other six had various causes such as drug abuse and suspected murder. Other incidents reported to the FDA included 612 nonlethal hospitalizations, 339 blood transfusions, 48 severe infections, and 2,207 (0.15%) adverse events altogether.[27]

### Cancer [edit]

No long-term studies to evaluate the carcinogenic potential of mifepristone have been performed. This is in accord with ICH guidelines, which do not require carcinogencity testing in nongenotoxic drugs intended for administration for less than six months.[28]

### Pregnancy [edit]

Under 49 days' gestational age, 60-80% of pregnancies will end with mifepristone alone; at any gestational age, 54-92% of pregnancies will end with mifepristone.[19][29] There is no evidence that the effects of mifepristone can be reversed.[19]

Exposure to a single large dose of mifepristone in newborn rats was not associated with any reproductive problems, although chronic low-dose exposure of newborn rats to mifepristone was associated with structural and functional reproductive abnormalities.[25]

Studies in mice, rats, and rabbits revealed teratogenicity for rabbits, but not rats or mice.[25] The rate of birth defects in human infants exposed *in utero* to mifepristone and misoprostol is very low,[30] and may be due to misoprostol alone.[31]

## Pharmacology [edit]

It is a synthetic, steroidal antiprogestogen ($IC_{50}$ = 0.025 nM for the PR), as well as an antiglucocorticoid ($IC_{50}$ = 2.2 nM for the GR) and antiandrogen ($IC_{50}$ = 10 nM for the AR) to a much lesser extent.[32] It is a 19-norsteroid with substitutions at positions C11 and C17 (17β-hydroxy-11β-(4-(dimethylamino)phenyl)-17α-(1-propynyl)estra-4,9-dien-3-one), which antagonizes cortisol action competitively at the receptor level.[33] Mifepristone is a low-efficacy partial agonist of the progesterone receptor. It is also a glucocorticoid receptor antagonist to a lesser extent.

In the presence of progesterone, mifepristone acts as a competitive progesterone receptor antagonist (in the absence of progesterone, mifepristone acts as a partial agonist). Mifepristone is a 19-nor steroid with a bulky *p*-(dimethylamino)phenyl substituent above the plane of the molecule at the 11β-position responsible for inducing or stabilizing an inactive receptor conformation and a hydrophobic 1-propynyl substituent below the plane of the molecule at the 17α-position that increases its progesterone receptor binding affinity.[34][35][36]

In addition to being an antiprogestogen, mifepristone is also an antiglucocorticoid and a weak antiandrogen. Mifepristone's relative binding affinity at the progesterone receptor is more than twice that of progesterone, its relative binding affinity at the glucocorticoid receptor is more than three times that of dexamethasone and more than ten times that of cortisol; its relative binding affinity at the androgen receptor is less than one-third that of testosterone. It does not bind to the estrogen receptor or the [37]

mineralocorticoid receptor.

Mifepristone as a regular contraceptive at 2 mg daily prevents ovulation (1 mg daily does not). A single preovulatory 10-mg dose of mifepristone delays ovulation by three to four days and is as effective an emergency contraceptive as a single 1.5-mg dose of the progestin levonorgestrel.[38]

In women, mifepristone at doses greater or equal to 1 mg/kg antagonizes the endometrial and myometrial effects of progesterone. In humans, an antiglucocorticoid effect of mifepristone is manifested at doses greater or equal to 4.5 mg/kg by a compensatory increase in ACTH and cortisol. In animals, a weak antiandrogenic effect is seen with prolonged administration of very high doses of 10 to 100 mg/kg.[39][40]

In medical abortion regimens, mifepristone blockade of progesterone receptors directly causes endometrial decidual degeneration, cervical softening and dilatation, release of endogenous prostaglandins, and an increase in the sensitivity of the myometrium to the contractile effects of prostaglandins. Mifepristone-induced decidual breakdown indirectly leads to trophoblast detachment, resulting in decreased syncytiotrophoblast production of hCG, which in turn causes decreased production of progesterone by the corpus luteum (pregnancy is dependent on progesterone production by the corpus luteum through the first nine weeks of gestation—until placental progesterone production has increased enough to take the place of corpus luteum progesterone production). When followed sequentially by a prostaglandin, mifepristone 200 mg is (100 mg may be, but 50 mg is not) as effective as 600 mg in producing a medical abortion.[34][36]

'Contragestion' is a term promoted by Étienne-Émile Baulieu in the context of his advocacy of mifepristone, defining it as inclusive of some hypothesized mechanisms of action of some contraceptives and those of mifepristone to induce abortion.[41] Baulieu's definition of a 'contragestive' included any birth control method that could possibly act after fertilization and before nine-weeks gestational age.[41]

## Usage [edit]

### United States [edit]

Medical abortions voluntarily reported by 33 U.S. states[42] to the CDC have increased as a percentage of total abortions every year since the approval of mifepristone: 1.0% in 2000, 2.9% in 2001, 5.2% in 2002, 7.9% in 2003, 9.3% in 2004, 9.9% in 2005, 10.6% in 2006, and 13.1% in 2007 (20.3% of those at less than 9 weeks gestation).[43] A Guttmacher Institute survey of abortion providers estimated that medical abortions accounted for 17% of all abortions and slightly over 25% of abortions before 9 weeks gestation in the United States in 2008 (94% of nonhospital medical abortions used mifepristone and misoprostol, 6% used methotrexate and misoprostol).[44] Medical abortions accounted for 32% of first trimester abortions at Planned Parenthood clinics in the United States in 2008.[45]

### Europe [edit]

In France, the percentage of medical abortions of all abortions continues to increase: 38% in 2003, 42% in 2004, 44% in 2005, 46% in 2006, 49% in 2007 (vs. 18% in 1996).[46] In England and Wales, 52% of early abortions (less than 9 weeks gestation) in 2009 were medical; the percentage of all abortions that are medical has increased every year for the past 14 years (from 5% in 1995 to 40% in 2009) and has more than doubled in the last five years.[47] In Scotland, 81.2% of early abortions in 2009 were medical (up from 55.8% in 1992 when medical abortion was introduced); the percentage of all abortions that are medical has increased every year for the past 17 years (from 16.4% in 1992 to 69.9% in 2009).[48] In Sweden, 85.6% of early abortions and 73.2% of abortions before the end of the 12th week of gestation in 2009 were medical; 68.2% of all abortions in 2009 were medical.[49] In Great Britain and Sweden, mifepristone is licensed for use with vaginal gemeprost or oral misoprostol. As of 2000, more than 620,000 women in Europe had had medical abortions using a mifepristone regimen.[50] In Denmark, mifepristone was used in between 3,000 and 4,000 of just over 15,000 abortions in 2005.[51]

## History [edit]

In April 1980, as part of a formal research project at the French pharmaceutical company Roussel-Uclaf for the development of glucocorticoid receptor antagonists, chemist Georges Teutsch synthesized mifepristone (RU-38486, the 38,486th compound synthesized by Roussel-Uclaf from 1949 to 1980; shortened to RU-486), which was discovered to also be a progesterone receptor antagonist.[52][53] In October 1981, endocrinologist Étienne-Émile Baulieu, a consultant to Roussel-Uclaf, arranged tests of its use for medical abortion in 11 women in Switzerland by gynecologist Walter Herrmann at the University of Geneva's Cantonal Hospital, with successful results announced on April 19, 1982.[52][54] On October 9, 1987, following worldwide clinical trials in 20,000 women of mifepristone with a prostaglandin analogue (initially sulprostone or gemeprost, later misoprostol) for medical abortion, Roussel-Uclaf sought approval in France for their use for medical abortion, with approval announced on September 23, 1988.[52][55]

On October 21, 1988, in response to antiabortion protests and concerns of majority (54.5%) owner Hoechst AG of Germany, Roussel-Uclaf's executives and board of directors voted 16 to 4 to stop distribution of mifepristone, which they announced on October 26, 1988.[52][56] Two days later, the French government ordered Roussel-Uclaf to distribute mifepristone in the interests of public health.[52][57] French Health Minister Claude Évin explained: "I could not permit the abortion debate to deprive women of a product that represents medical progress. From the moment Government approval for the drug was granted, RU-486 became the moral property of women, not just the property of a drug company."[52] Following use by 34,000 women in France from April 1988 to February 1990 of mifepristone distributed free of charge, Roussel-Uclaf began selling Mifegyne (mifepristone) to hospitals in France in February 1990 at a price (negotiated with the French government) of US$48 (equivalent to $87.99 in 2016) per 600-mg dose.[52]

Mifegyne was subsequently approved in Great Britain on July 1, 1991,[58] and in Sweden in September 1992,[59] but until his retirement in late April 1994, Hoechst AG chairman Wolfgang Hilger, a devout Roman Catholic, blocked any further expansion in availability.[52][60] On May 16, 1994, Roussel-Uclaf announced it was donating without remuneration all rights for medical uses of mifepristone in the United States to the Population Council,[61] which subsequently licensed mifepristone to Danco Laboratories, a new single-product company immune to antiabortion boycotts, which won FDA approval as Mifeprex on September 28, 2000.[62]

On April 8, 1997, after buying the remaining 43.5% of Roussel-Uclaf stock in early 1997,[63] Hoechst AG (US$30 (equivalent to $45.81 in 2016) billion annual revenue) announced the end of its manufacture and sale of Mifegyne (US$3.44 (equivalent to $5.25 in 2016) million annual revenue) and the transfer of all rights for medical uses of mifepristone outside of the United States to Exelgyn S.A., a new single-product company immune to antiabortion boycotts, whose CEO was former Roussel-Uclaf CEO Édouard Sakiz.[64] In 1999, Exelgyn won approval of Mifegyne in 11 additional countries, and in 28 more countries over the following decade.[65]

## Society and culture [edit]

Mifepristone is on the WHO Model List of Essential Medicines, the most important medications needed in a basic health system.[5] It is on the complementary list and is included with a special note "where permitted under national law and where culturally acceptable".[5]

### Legal status [edit]

### United States [edit]

Mifepristone was approved for abortion in the United States by the FDA in September 2000.[66] It is legal and available in all 50 states, Washington, D.C., Guam, and Puerto Rico.[67] It is a prescription drug, but it is not available to the public through pharmacies; its distribution is restricted to specially qualified licensed

physicians, sold by Danco Laboratories under the trade name Mifeprex.

Roussel Uclaf did not seek U.S. approval, so in the United States legal availability was not initially possible.[68] The United States banned importation of mifepristone for personal use in 1989, a decision supported by Roussel Uclaf. In 1994, Roussel Uclaf gave the U.S. drug rights to the Population Council in exchange for immunity from any product liability claims.[61][69] The Population Council sponsored clinical trials in the United States.[70] The drug went on approvable status from 1996. Production was intended to begin through the Danco Group in 1996, but they withdrew briefly in 1997 due to a corrupt business partner, delaying availability again.[71][72]

Mifepristone 200 mg tablets (Mifeprex) have a marketing authorization in the United States from the Food and Drug Administration (FDA) for early first trimester medical abortion when followed by the prostaglandin analog misoprostol through 70 days gestational age.[13][73][74]

Mifepristone 300 mg tablets (Korlym) have a marketing authorization in the United States from the FDA for the medical treatment of high blood sugar (hyperglycemia) caused by high cortisol levels in the blood (hypercortisolism) in adults with endogenous Cushing's syndrome who have type 2 diabetes mellitus or glucose intolerance and have failed surgery or cannot have surgery.[20][21]

### Subsection H [edit]

Some drugs are approved by the FDA under subsection H, which has two subparts. The first sets forth ways to rush experimental drugs, such as aggressive HIV and cancer treatments, to market when speedy approval is deemed vital to the health of potential patients. The second part of subsection H applies to drugs that not only must meet restrictions for use due to safety requirements, but also are required to meet postmarketing surveillance to establish that the safety results shown in clinical trials are seconded by use in a much wider population. Mifepristone was approved under the second part of subsection H. The result is that women cannot pick the drug up at a pharmacy, but must now receive it directly from a doctor. Due to the possibility of adverse reactions such as excessive bleeding, which may require a blood transfusion, and incomplete abortion, which may require surgical intervention, the drug is only considered safe if a physician who is capable of administering a blood transfusion or a surgical abortion is available to the patient in the event of such emergencies.[75] The approval of mifepristone under subsection H included a black box warning.

## Europe [edit]

Outside the United States, it is marketed and distributed by Exelgyn Laboratories under the tradename Mifegyne. Mifepristone was approved for use in France in 1988 (initial marketing in 1989), the United Kingdom in 1991, Sweden in 1992, then Austria, Belgium, Denmark, Finland, Germany, Greece, Luxembourg, the Netherlands, Spain, and Switzerland in 1999.[76] In 2000, it was approved in Norway, Russia and Ukraine. Serbia and Montenegro approved it in 2001,[77] Belarus and Latvia in 2002, Estonia in 2003, Moldova in 2004, Albania and Hungary in 2005, Portugal in 2007, and Romania in 2008.[65] In Italy, clinical trials have been constrained by protocols requiring women be hospitalized for three days, but the drug was finally approved on July 30, 2009 (officialized later in the year), despite strong opposition from the Vatican. In Italy, the pill must be prescribed and used in a clinical structure and is not sold at chemists.[78] It was approved in Hungary in 2005, but as of 2005 had not been released on the market yet, and was the target of protests.[79] Mifepristone is not approved in Ireland, where abortion is illegal, or Poland, where abortion is highly restricted.[80]

Mifepristone 200 mg tablets (Mifegyne, Mifepristone Linepharma, Medabon) have marketing authorizations in the European Economic Area from the European Medicines Agency (EMA) for:[12][81][82]

- early first trimester medical abortion when followed by a prostaglandin analog (misoprostol or gemeprost) through 63 days gestational age
- second trimester medical abortion when followed by a prostaglandin analog
- cervical softening and dilation prior to first trimester surgical abortion
- induction of labor after fetal death in utero when prostaglandin analogs and oxytocin are contraindicated

## Other countries [edit]

Mifepristone was banned in Australia in 1996. In late 2005, a private member's bill was introduced to the Australian Senate to lift the ban and transfer the power of approval to the Therapeutic Goods Administration. The move caused much debate in the Australian media and amongst politicians. The bill passed the Senate on 10 February 2006, and mifepristone is now legal in Australia. It is provided regularly at several specialized abortion clinics per state.[83][84] Mifepristone 200 mg tablets have marketing authorizations in Australia from the Therapeutic Goods Administration (TPA) for early first trimester medical abortion when followed by the prostaglandin analog misoprostol through 63 days gestational age[85] and second trimester medical abortion when followed by a prostaglandin analog.[86]

In New Zealand, pro-choice doctors established an import company, Istar, and submitted a request for approval to MedSafe, the New Zealand pharmaceutical regulatory agency. After a court case brought by Right to Life New Zealand failed, use of mifepristone was permitted.[87]

The drug was approved in Israel in 1999.[88]

Clinical trials of mifepristone in China began in 1985. In October 1988, China became the first country in the world to approve mifepristone. Chinese organizations tried to purchase mifepristone from Roussel Uclaf, which refused to sell it to them, so in 1992 China began its own domestic production of mifepristone. In 2000, the cost of medical abortion with mifepristone was higher than surgical abortion and the percentage of medical abortions varied greatly, ranging from 30% to 70% in cities to being almost nonexistent in rural areas.[89][90] A report from the United States Embassy in Beijing in 2000 said mifepristone had been widely used in Chinese cities for about two years, and that according to press reports, a black market had developed with many women starting to buy it illegally (without a prescription) from private clinics and drugstores for about US$15 (equivalent to $20.86 in 2016), causing Chinese authorities to worry about medical complications from use without physician supervision.[91]

In 2001, mifepristone was approved in Taiwan.[92] Vietnam included mifepristone in the National Reproductive Health program in 2002.[93]

It is approved in only one sub-Saharan African country—South Africa, where it was approved in 2001.[94] It is also approved in one north African country—Tunisia, also in 2001.[95]

Mifepristone was approved for use in India in 2002, where medical abortion is referred to as "medical termination of pregnancy". It is only available under medical supervision, not by prescription, due to adverse reactions such as excessive bleeding, and criminal penalties are given for buying or selling it on the black market or over-the-counter at pharmacies.[96]

Medical abortion used to be available in Canada but on a limited basis using methotrexate and misoprostol. Clinical trials were done in 2000 in various Canadian cities comparing methotrexate to mifepristone, after approbation by the federal government. While both drugs had overall similar results, mifepristone was found to act faster.[97] Health Canada gave approval to mifepristone in July 2015.[98]

Mifepristone was registered for use in Azerbaijan, Georgia, and Uzbekistan in 2002, in Guyana and Moldova in 2004, in Mongolia in 2005, and in Armenia in 2007.[65][99]

Low dose mifepristone tablets (Bi Yun, Fu Nai Er, Hou Ding Nuo, Hua Dian, Si Mi An) for emergency contraception are available directly from a pharmacist without a prescription and with a prescription in China.[22][23][24]

Low dose mifepristone tablets for emergency contraception are available by prescription in Armenia (Gynepriston), Russia (Agesta, Gynepriston, Mifepristone 72, Negele), Ukraine (Gynepriston), and Vietnam (Mifestad 10, Ciel EC).[22][23][24]

## Controversy [edit]

*Main article: Abortion controversy*

Many pro-life groups in the United States actively campaigned against the approval of

mifepristone[100][101][102] and continue to actively campaign for its withdrawal.[103] They cite either ethical issues with abortion or safety concerns regarding the drug and the adverse reactions associated with it.[104] Religious and pro-life groups outside the United States have also protested mifepristone, especially in Germany[105] and Australia.[106][107]

## Research [edit]

The original target for the research group was the discovery and development of compounds with antiglucocorticoid properties.[108] These antiglucocorticoid properties are of great interest in the treatment of severe mood disorders and psychosis, although a review of published articles was inconclusive on their efficacy, and considered the use of these drugs in mood disorders at 'proof of concept' stage.[109]

Mifepristone showed no detectable anti-HIV activity in clinical trials.[35][38][110][111]

Mifepristone showed initial promise in psychotic major depression, a difficult-to-treat form of depression,[112] but a phase-III clinical trial was terminated early due to lack of efficacy.[113]

Use as a cervical ripening agent has also been described.[114]

. (2008). "contragestive". *The American Heritage medical dictionary*. Boston: Houghton Mifflin. p. 124. ISBN 978-0-618-94725-6.

> *adj.* Capable of preventing gestation, either by preventing implantation or by causing the uterine lining to shed after implantation. —*n.* A contragestive drug or agent.

Ammer, Christine (2009). "contragestive". *The encyclopedia of women's health* (6th ed.). New York: Facts On File. pp. 124–125. ISBN 978-0-8160-7407-5.

> Also *contragestant*, *abortion pill*. A substance called *mifepristone*, or *RU-486*, which was developed by Dr. Etienne Baulieu and the Roussel-Uclaf company. The contragestive blocks progesterone receptors in the endometrium (uterine lining), preventing its buildup by progesterone; hence the uterus cannot sustain a pregnancy. It does not prevent fertilization or implantation, so technically it is an ABORTIFACIENT rather than a contraceptive.

# Morphine

*"Morphia" redirects here. For other uses, see Morphia (disambiguation) and Morphine (disambiguation). Not to be confused with Morphinae, Morphea, or Morpholine.*

**Morphine** is a pain medication of the opiate type which is found naturally in a number of plants and animals.[5][7] It acts directly on the central nervous system (CNS) to decrease the feeling of pain. It can be taken for both acute pain and chronic pain. Morphine is frequently used for pain from myocardial infarction and during labour. It can be given by mouth, by injection into a muscle, by injecting under the skin, intravenously, into the space around the spinal cord, or rectally.[5] Maximum effect is around 20 min when given intravenously and 60 min when given by mouth while duration of effect is between three and seven hours.[5][6] Long-acting formulations also exist.[5]

Potentially serious side effects include a decreased respiratory effort and low blood pressure. Morphine has a high potential for addiction and abuse. If the dose is reduced after long-term use, withdrawal may occur. Common side effects include drowsiness, vomiting, and constipation. Caution is advised when used during pregnancy or breast feeding, as morphine will affect the baby.[5]

Morphine was first isolated between 1803 and 1805 by Friedrich Sertürner.[8] This is generally believed to be the first isolation of an active ingredient from a plant.[9] Merck began marketing it commercially in 1827.[8] Morphine was more widely used after the invention of the hypodermic syringe in 1853–1855.[8][10] Sertürner originally named the substance *morphium* after the Greek god of dreams, Morpheus as it has a tendency to cause sleep.[10][11]

The primary source of morphine is isolation from poppy straw of the opium poppy.[12] In 2013, an estimated 523,000 kilograms of morphine were produced.[13] About 45,000 kilograms were used directly for pain, an increase over the last twenty years of four times.[13] Most use for this purpose was in the developed world.[13] About 70% of morphine is used to make other opioids such as hydromorphone, oxycodone and heroin.[13][14][15] It is a Schedule II drug in the United States, Class A in the United Kingdom,[16] and Schedule I in Canada.[17] It is on the WHO Model List of Essential Medicines, the most important medications needed in a basic

health system.[18] Morphine is sold under many trade names.[1]

# Medical uses [edit]

## Pain [edit]

Morphine is used primarily to treat both acute and chronic severe pain. It is also used for pain due to myocardial infarction and for labor pains.[19] Its duration of analgesia is about three to seven hours.[5][6]

However, concerns exist that morphine may increase mortality in the setting of non ST elevation myocardial infarction.[20] Morphine has also traditionally been used in the treatment of acute pulmonary edema.[19] A 2006 review, though, found little evidence to support this practice.[21] A 2016 Cochrane review concluded that morphine is effective in relieving cancer pain. Side-effects of nausea and constipation are rarely severe enough to warrant stopping treatment.[22]

## Shortness of breath [edit]

Immediate-release morphine is beneficial in reducing the symptom of shortness of breath due to both cancer and noncancer causes.[23][24] In the setting of breathlessness at rest or on minimal exertion from conditions such as advanced cancer or end-stage cardiorespiratory diseases, regular, low-dose sustained-release morphine significantly reduces breathlessness safely, with its benefits maintained over time.[25][26]

## Opioid use disorder [edit]

Morphine is also available as a slow-release formulation for opiate substitution therapy (OST) in Austria, Bulgaria, and Slovenia, for addicts who cannot tolerate either methadone or buprenorphine.[27]

# Contraindications [edit]

Relative contraindications to morphine include:

- respiratory depression when appropriate equipment is not available[5]
- Although it has previously been thought that morphine was contraindicated in acute pancreatitis, a review of the literature shows no evidence for this.[28]

# Adverse effects [edit]

## Constipation [edit]

Like loperamide and other opioids, morphine acts on the myenteric plexus in the intestinal tract, reducing gut motility, causing constipation. The gastrointestinal effects of morphine are mediated primarily by μ-opioid receptors in the bowel. By inhibiting gastric emptying and reducing propulsive peristalsis of the intestine, morphine decreases the rate of intestinal transit. Reduction in gut secretion and increased intestinal fluid absorption also contribute to the constipating effect. Opioids also may act on the gut indirectly through tonic gut spasms after inhibition of nitric oxide generation.[30] This effect was shown in animals when a nitric oxide precursor, L-arginine, reversed morphine-induced changes in gut motility.[31]

## Hormone imbalance [edit]

*See also: Opioid § Hormone imbalance*

Clinical studies consistently conclude that morphine, like other opioids, often causes hypogonadism and hormone imbalances in chronic users of both sexes. This side effect is dose-dependent and occurs in both therapeutic and recreational users. Morphine can interfere with menstruation in women by suppressing levels of luteinizing hormone. Many studies suggest the majority (perhaps as

much as 90%) of chronic opioid users have opioid-induced hypogonadism. This effect may cause the increased likelihood of osteoporosis and bone fracture observed in chronic morphine users. Studies suggest the effect is temporary. As of 2013, the effect of low-dose or acute use of morphine on the endocrine system is unclear.[32][33]

A localized reaction to intravenous morphine caused by histamine release in the veins

## Effects on human performance [edit]

Most reviews conclude that opioids produce minimal impairment of human performance on tests of sensory, motor, or attentional abilities. However, recent studies have been able to show some impairments caused by morphine, which is not surprising, given that morphine is a central nervous system depressant. Morphine has resulted in impaired functioning on critical flicker frequency (a measure of overall CNS arousal) and impaired performance on the Maddox wing test (a measure of deviation of the visual axes of the eyes). Few studies have investigated the effects of morphine on motor abilities; a high dose of morphine can impair finger tapping and the ability to maintain a low constant level of isometric force (i.e. fine motor control is impaired),[34] though no studies have shown a correlation between morphine and gross motor abilities.

In terms of cognitive abilities, one study has shown that morphine may have a negative impact on anterograde and retrograde memory,[35] but these effects are minimal and transient. Overall, it seems that acute doses of opioids in non-tolerant subjects produce minor effects in some sensory and motor abilities, and perhaps also in attention and cognition. It is likely that the effects of morphine will be more pronounced in opioid-naive subjects than chronic opioid users.

In chronic opioid users, such as those on Chronic Opioid Analgesic Therapy (COAT) for managing severe, chronic pain, behavioural testing has shown normal functioning on perception, cognition, coordination and behaviour in most cases. One recent study[36] analysed COAT patients to determine whether they were able to safely operate a motor vehicle. The findings from this study suggest that stable opioid use does not significantly impair abilities inherent in driving (this includes physical, cognitive and perceptual skills). COAT patients showed rapid completion of tasks that require speed of responding for successful performance (e.g., Rey Complex Figure Test) but made more errors than controls. COAT patients showed no deficits in visual-spatial perception and organization (as shown in the WAIS-R Block Design Test) but did show impaired immediate and short-term visual memory (as shown on the Rey Complex Figure Test – Recall). These patients showed no impairments in higher order cognitive abilities (i.e., planning). COAT patients appeared to have difficulty following instructions and showed a propensity toward impulsive behaviour, yet this did not reach statistical significance. It is important to note that this study reveals that COAT patients have no domain-specific deficits, which supports the notion that chronic opioid use has minor effects on psychomotor, cognitive, or neuropsychological functioning.

## Reinforcement disorders [edit]

### Addiction [edit]

Morphine is a highly addictive substance. In controlled studies comparing the physiological and subjective effects of heroin and morphine in individuals formerly addicted to opiates, subjects showed no preference for one drug over the other. Equipotent, injected doses had comparable action courses, with no difference in subjects' self-rated feelings of euphoria, ambition, nervousness, relaxation, drowsiness, or sleepiness.[37] Short-term addiction studies by the same researchers demonstrated that tolerance developed at a similar rate to both heroin and morphine. When compared to the opioids hydromorphone, fentanyl, oxycodone, and pethidine/meperidine, former addicts showed a strong preference for heroin and morphine, suggesting that heroin and morphine are particularly susceptible to abuse and addiction. Morphine

*Before the Morphine* by

Santiago Rusiñol

and heroin were also much more likely to produce euphoria and other positive subjective effects when compared to these other opioids.[37] The choice of heroin and morphine over other opioids by former drug addicts may also be because heroin (also known as morphine diacetate, diamorphine, or diacetyl morphine) is an ester of morphine and a morphine prodrug, essentially meaning they are identical drugs *in vivo*. Heroin is converted to morphine before binding to the opioid receptors in the brain and spinal cord, where morphine causes the subjective effects, which is what the addicted individuals are seeking.[38]

## Tolerance [edit]

Several hypotheses are given about how tolerance develops, including opioid receptor phosphorylation (which would change the receptor conformation), functional decoupling of receptors from G-proteins (leading to receptor desensitization),[39] μ-opioid receptor internalization or receptor down-regulation (reducing the number of available receptors for morphine to act on), and upregulation of the cAMP pathway (a counterregulatory mechanism to opioid effects) (For a review of these processes, see Koch and Hollt.[40]) CCK might mediate some counter-regulatory pathways responsible for opioid tolerance. CCK-antagonist drugs, specifically proglumide, have been shown to slow the development of tolerance to morphine.

## Dependence and withdrawal [edit]

*See also: Opioid dependence and Opioid withdrawal*

Cessation of dosing with morphine creates the prototypical opioid withdrawal syndrome, which, unlike that of barbiturates, benzodiazepines, alcohol, or sedative-hypnotics, is not fatal by itself in neurologically healthy patients without heart or lung problems.

Acute morphine withdrawal, along with that of any other opioid, proceeds through a number of stages. Other opioids differ in the intensity and length of each, and weak opioids and mixed agonist-antagonists may have acute withdrawal syndromes that do not reach the highest level. As commonly cited[*by whom?*], they are:

- **Stage I**, 6 to 14 hours after last dose: Drug craving, anxiety, irritability, perspiration, and mild to moderate dysphoria[*citation needed*]
- **Stage II**, 14 to 18 hours after last dose: Yawning, heavy perspiration, mild depression, lacrimation, crying, headaches, runny nose, dysphoria, also intensification of the above symptoms, "yen sleep" (a waking trance-like state) [*clarification needed*]
- **Stage III**, 16 to 24 hours after last dose: Rhinorrhea (runny nose) and increase in other of the above, dilated pupils, piloerection (goose bumps – a purported origin of the phrase, 'cold turkey,' but in fact the phrase originated outside of drug treatment),[41] muscle twitches, hot flashes, cold flashes, aching bones and muscles, loss of appetite, and the beginning of intestinal cramping[*citation needed*]
- **Stage IV**, 24 to 36 hours after last dose: Increase in all of the above including severe cramping and involuntary leg movements ("kicking the habit" also called restless leg syndrome), loose stool, insomnia, elevation of blood pressure, moderate elevation in body temperature, increase in frequency of breathing and tidal volume, tachycardia (elevated pulse), restlessness, nausea[*citation needed*]
- **Stage V**, 36 to 72 hours after last dose: Increase in the above, fetal position, vomiting, free and frequent liquid diarrhea, which sometimes can accelerate the time of passage of food from mouth to out of system, weight loss of 2 to 5 kg per 24 hours, increased white cell count, and other blood changes[*citation needed*]
- **Stage VI**, after completion of above: Recovery of appetite and normal bowel function, beginning of transition to postacute and chronic symptoms that are mainly psychological, but may also include increased sensitivity to pain, hypertension, colitis or other gastrointestinal afflictions related to motility, and problems with weight control in either direction[*citation needed*]

In advanced stages of withdrawal, ultrasonographic evidence of pancreatitis has been demonstrated in some patients and is presumably attributed to spasm of the pancreatic sphincter of Oddi.[42]

The withdrawal symptoms associated with morphine addiction are usually experienced shortly before the time of the next scheduled dose, sometimes within as early as a few hours (usually 6–12 hours) after the last administration. Early symptoms include watery eyes, insomnia, diarrhea, runny nose, yawning, dysphoria, sweating, and in some cases a strong drug craving. Severe headache, restlessness, irritability, loss of appetite, body aches, severe abdominal pain, nausea and vomiting, tremors, and even stronger and more intense drug craving appear as the syndrome progresses. Severe depression and vomiting are very common. During the acute withdrawal period, systolic and diastolic blood pressures increase, usually beyond premorphine levels, and heart rate increases,[43] which have potential to cause a heart attack, blood clot, or stroke.

Chills or cold flashes with goose bumps ("cold turkey") alternating with flushing (hot flashes), kicking movements of the legs ("kicking the habit"[38]) and excessive sweating are also characteristic symptoms.[44] Severe pains in the bones and muscles of the back and extremities occur, as do muscle spasms. At any point during this process, a suitable narcotic can be administered that will dramatically reverse the withdrawal symptoms. Major withdrawal symptoms peak between 48 and 96 hours after the last dose and subside after about 8 to 12 days. Sudden withdrawal by heavily dependent users who are in poor health is very rarely fatal. Morphine withdrawal is considered less dangerous than alcohol, barbiturate, or benzodiazepine withdrawal.[45][46]

The psychological dependence associated with morphine addiction is complex and protracted. Long after the physical need for morphine has passed, the addict will usually continue to think and talk about the use of morphine (or other drugs) and feel strange or overwhelmed coping with daily activities without being under the influence of morphine. Psychological withdrawal from morphine is usually a very long and painful process.[47][*unreliable medical source*] Addicts often suffer severe depression, anxiety, insomnia, mood swings, amnesia (forgetfulness), low self-esteem, confusion, paranoia, and other psychological disorders. Without intervention, the syndrome will run its course, and most of the overt physical symptoms will disappear within 7 to 10 days including psychological dependence. A high probability of relapse exists after morphine withdrawal when neither the physical environment nor the behavioral motivators that contributed to the abuse have been altered. Testimony to morphine's addictive and reinforcing nature is its relapse rate. Abusers of morphine (and heroin) have one of the highest relapse rates among all drug users, ranging up to 98% in the estimation of some medical experts.[48]

## Overdose [edit]

*See also: Opioid overdose*

A large overdose can cause asphyxia and death by respiratory depression if the person does not receive medical attention immediately.[49] Overdose treatment includes the administration of naloxone. The latter completely reverses morphine's effects, but may result in immediate onset of withdrawal in opiate-addicted subjects. Multiple doses may be needed.[49]

The minimum lethal dose is 200 mg, but in case of hypersensitivity, 60 mg can bring sudden death. In serious drug dependency (high tolerance), 2000–3000 mg per day can be tolerated.[50]

## Pharmacology [edit]

### Pharmacodynamics [edit]

*Main article: Opioid receptor*

This section's **factual accuracy may be compromised due to out-of-date information**. Please update this article to reflect recent events or newly available information. *(July 2014)*

Endogenous opioids include endorphins, enkephalins, dynorphins, and even morphine itself. Morphine

appears to mimic endorphins. Endorphins, a contraction of the term endogenous morphines, are responsible for analgesia (reducing pain), causing sleepiness, and feelings of pleasure. They can be released in response to pain, strenuous exercise, orgasm, or excitement.

Morphine is the prototype narcotic drug and is the standard against which all other opioids are tested. It interacts predominantly with the μ–δ-opioid (Mu-Delta) receptor heteromer.[51][52] The μ-binding sites are discretely distributed in the human brain, with high densities in the posterior amygdala, hypothalamus, thalamus, nucleus caudatus, putamen, and certain cortical areas. They are also found on the terminal axons of primary afferents within laminae I and II (substantia gelatinosa) of the spinal cord and in the spinal nucleus of the trigeminal nerve.[53]

Morphine is a phenanthrene opioid receptor agonist – its main effect is binding to and activating the μ-opioid receptors in the central nervous system. In clinical settings, morphine exerts its principal pharmacological effect on the central nervous system and gastrointestinal tract. Its primary actions of therapeutic value are analgesia and sedation. Activation of the μ-opioid receptors is associated with analgesia, sedation, euphoria, physical dependence, and respiratory depression. Morphine is a rapid-acting narcotic, and it is known to bind very strongly to the μ-opioid receptors, and for this reason, it often has a higher incidence of euphoria/dysphoria, respiratory depression, sedation, pruritus, tolerance, and physical and psychological dependence when compared to other opioids at equianalgesic doses. Morphine is also a κ-opioid and δ-opioid receptor agonist, κ-opioid's action is associated with spinal analgesia, miosis (pinpoint pupils) and psychotomimetic effects. δ-Opioid is thought to play a role in analgesia.[53] Although morphine does not bind to the σ-receptor, it has been shown that σ-agonists, such as (+)-pentazocine, inhibit morphine analgesia, and σ-antagonists enhance morphine analgesia,[54] suggesting downstream involvement of the σ-receptor in the actions of morphine.

The effects of morphine can be countered with opioid antagonists such as naloxone and naltrexone; the development of tolerance to morphine may be inhibited by NMDA antagonists such as ketamine or dextromethorphan.[55] The rotation of morphine with chemically dissimilar opioids in the long-term treatment of pain will slow down the growth of tolerance in the longer run, particularly agents known to have significantly incomplete cross-tolerance with morphine such as levorphanol, ketobemidone, piritramide, and methadone and its derivatives; all of these drugs also have NMDA antagonist properties. It is believed that the strong opioid with the most incomplete cross-tolerance with morphine is either methadone or dextromoramide.

## Gene expression [edit]

Studies have shown that morphine can alter the expression of a number of genes. A single injection of morphine has been shown to alter the expression of two major groups of genes, for proteins involved in mitochondrial respiration and for cytoskeleton-related proteins.[56]

## Effects on the immune system [edit]

Morphine has long been known to act on receptors expressed on cells of the central nervous system resulting in pain relief and analgesia. In the 1970s and '80s, evidence suggesting that opioid drug addicts show increased risk of infection (such as increased pneumonia, tuberculosis, and HIV/AIDS) led scientists to believe that morphine may also affect the immune system. This possibility increased interest in the effect of chronic morphine use on the immune system.

The first step of determining that morphine may affect the immune system was to establish that the opiate receptors known to be expressed on cells of the central nervous system are also expressed on cells of the immune system. One study successfully showed that dendritic cells, part of the innate immune system, display opiate receptors. Dendritic cells are responsible for producing cytokines, which are the tools for communication in the immune system. This same study showed that dendritic cells chronically treated with morphine during their differentiation produce more interleukin-12 (IL-12), a cytokine responsible for promoting the proliferation, growth, and differentiation of T-cells (another cell of the adaptive immune system) and less interleukin-10 (IL-10), a cytokine responsible for promoting a B-cell immune response (B cells produce antibodies to fight off infection).[57]

This regulation of cytokines appear to occur via the p38 MAPKs (mitogen-activated protein kinase)-dependent pathway. Usually, the p38 within the dendritic cell expresses TLR 4 (toll-like receptor 4), which is activated through the ligand LPS (lipopolysaccharide). This causes the p38 MAPK to be phosphorylated. This phosphorylation activates the p38 MAPK to begin producing IL-10 and IL-12. When the dendritic cells are chronically exposed to morphine during their differentiation process then treated with LPS, the production of cytokines is different. Once treated with morphine, the p38 MAPK does not produce IL-10, instead favoring production of IL-12. The exact mechanism through which the production of one cytokine is increased in favor over another is not known. Most likely, the morphine causes increased phosphorylation of the p38 MAPK. Transcriptional level interactions between IL-10 and IL-12 may further increase the production of IL-12 once IL-10 is not being produced. This increased production of IL-12 causes increased T-cell immune response.

Further studies on the effects of morphine on the immune system have shown that morphine influences the production of neutrophils and other cytokines. Since cytokines are produced as part of the immediate immunological response (inflammation), it has been suggested that they may also influence pain. In this way, cytokines may be a logical target for analgesic development. Recently, one study has used an animal model (hind-paw incision) to observe the effects of morphine administration on the acute immunological response. Following hind-paw incision, pain thresholds and cytokine production were measured. Normally, cytokine production in and around the wounded area increases in order to fight infection and control healing (and, possibly, to control pain), but pre-incisional morphine administration (0.1–10.0 mg/kg) reduced the number of cytokines found around the wound in a dose-dependent manner. The authors suggest that morphine administration in the acute post-injury period may reduce resistance to infection and may impair the healing of the wound.[58]

## Pharmacokinetics [edit]

## Absorption and metabolism [edit]

Morphine can be taken orally, sublingually, bucally, rectally, subcutaneously, intranasally, intravenously, intrathecally or epidurally and inhaled via a nebulizer. As a recreational drug, it is becoming more common to inhale ("Chasing the Dragon"), but, for medical purposes, intravenous (IV) injection is the most common method of administration. Morphine is subject to extensive first-pass metabolism (a large proportion is broken down in the liver), so, if taken orally, only 40–50% of the dose reaches the central nervous system. Resultant plasma levels after subcutaneous (SC), intramuscular (IM), and IV injection are all comparable. After IM or SC injections, morphine plasma levels peak in approximately 20 minutes, and, after oral administration, levels peak in approximately 30 minutes.[59] Morphine is metabolised primarily in the liver and approximately 87% of a dose of morphine is excreted in the urine within 72 hours of administration. Morphine is metabolized primarily into morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G)[60] via glucuronidation by phase II metabolism enzyme UDP-glucuronosyl transferase-2B7 (UGT2B7). About 60% of morphine is converted to M3G, and 6–10% is converted to M6G.[61] Not only does the metabolism occur in the liver but it may also take place in the brain and the kidneys. M3G does not undergo opioid receptor binding and has no analgesic effect. M6G binds to μ-receptors and is half as potent an analgesic as morphine in humans.[61] Morphine may also be metabolized into small amounts of normorphine, codeine, and hydromorphone. Metabolism rate is determined by gender, age, diet, genetic makeup, disease state (if any), and use of other medications. The elimination half-life of morphine is approximately 120 minutes, though there may be slight differences between men and women. Morphine can be stored in fat, and, thus, can be detectable even after death. Morphine can cross the blood–brain barrier, but, because of poor lipid solubility, protein binding, rapid conjugation with glucuronic acid and ionization, it does not cross easily. Diacetylmorphine, which is derived from morphine, crosses the blood–brain barrier more easily, making it more potent.[62]

## Extended-release [edit]

*Main article: Extended-release morphine*

There are extended-release formulations of orally administered morphine whose effect last longer, which [63] [63]

can be given once per day. Brand names for this formulation of morphine include Avinza, Kadian, MS Contin[63] and Dolcontin.[64] For constant pain, the relieving effect of extended-release morphine given once (for Kadian)[65] or twice (for MS Contin)[65] every 24 hours is roughly the same as multiple administrations of *immediate release* (or "regular") morphine.[66] Extended-release morphine can be administered together with "rescue doses" of immediate-release morphine as needed in case of breakthrough pain, each generally consisting of 5% to 15% of the 24-hour extended-release dosage.[66]

### Detection in body fluids [edit]

Morphine and its major metabolites, morphine-3-glucuronide and morphine-6-glucuronide, can be detected in blood, plasma, hair, and urine using an immunoassay. Chromatography can be used to test for each of these substances individually. Some testing procedures hydrolyze metabolic products into morphine before the immunoassay, which must be considered when comparing morphine levels in separately published results. Morphine can also be isolated from whole blood samples by solid phase extraction (SPE) and detected using liquid chromatography-mass spectrometry (LC-MS).

Ingestion of codeine or food containing poppy seeds can cause false positives.[67]

A 1999 review estimated that relatively low doses of heroin (which metabolizes immediately into morphine) are detectable by standard urine tests for 1-1.5 days after use.[68] A 2009 review determined that, when the analyte is morphine and the limit of detection is 1 ng/ml, a 20 mg intravenous (IV) dose of morphine is detectable for 12–24 hours. A limit of detection of 0.6 ng/ml had similar results.[69]

## Natural occurrence [edit]

*See also: Opium*

A freshly-scored opium poppy seedpod bleeding latex.

Morphine is the most abundant opiate found in opium, the dried latex extracted by shallowly scoring the unripe seedpods of the *Papaver somniferum* poppy. Morphine is generally 8–14% of the dry weight of opium,[70] although specially bred cultivars reach 26% or produce little morphine at all (under 1%, perhaps down to 0.04%). The latter varieties, including the 'Przemko' and 'Norman' cultivars of the opium poppy, are used to produce two other alkaloids, thebaine and oripavine, which are used in the manufacture of semi-synthetic and synthetic opioids like oxycodone and etorphine and some other types of drugs. *P. bracteatum* does not contain morphine or codeine, or other narcotic phenanthrene-type, alkaloids. This species is rather a source of thebaine.[71] Occurrence of morphine in other Papaverales and Papaveraceae, as well as in some species of hops and mulberry trees has not been confirmed. Morphine is produced most predominantly early in the life cycle of the plant. Past the optimum point for extraction, various processes in the plant produce codeine, thebaine, and in some cases negligible amounts of hydromorphone, dihydromorphine, dihydrocodeine, tetrahydro-thebaine, and hydrocodone (these compounds are rather synthesized from thebaine and oripavine).

In the brain of mammals, morphine is detectable in trace steady-state concentrations.[7] The human body also produces endorphins, which are chemically related endogenous opioid peptides that function as neuropeptides and have similar effects as morphine.[72]

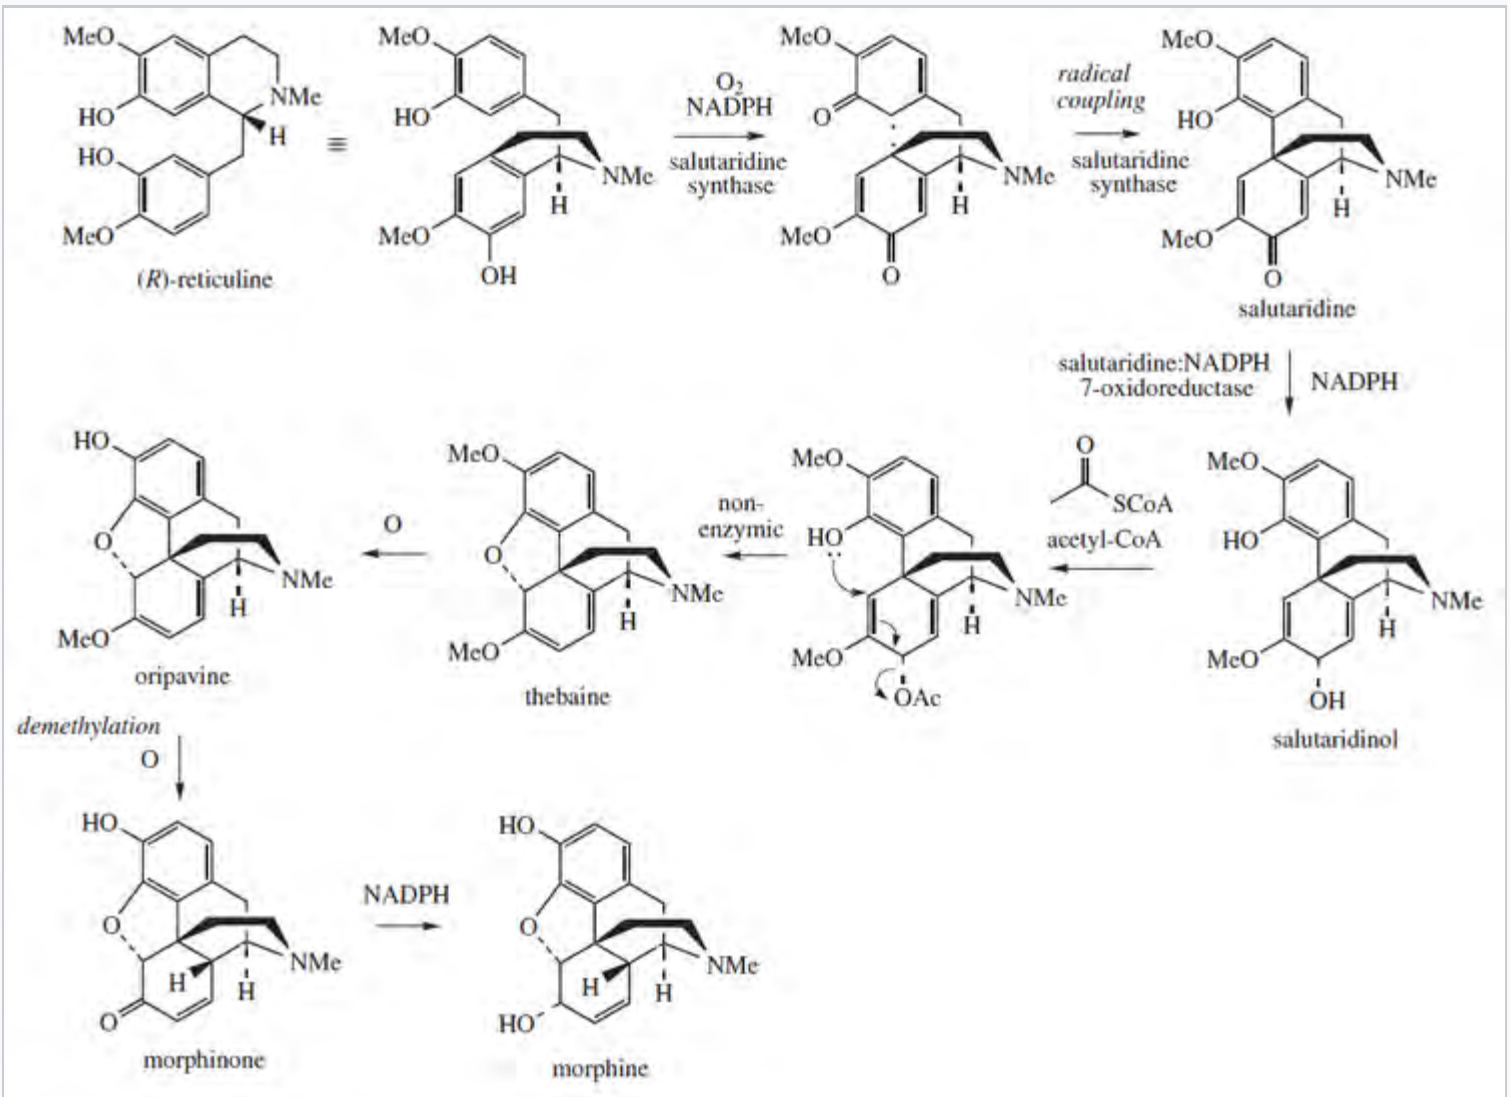
### Human biosynthesis [edit]

**This section needs expansion**. You can help by adding to it. *(October 2016)*

[7]

Morphine is an endogenous opioid in humans that can be synthesized and released by white blood cells. CYP2D6, a cytochrome P450 isoenzyme, catalyzes the biosynthesis of morphine from codeine and dopamine from tyramine along the biosynthetic pathway of morphine in humans.[7][73] The morphine biosynthetic pathway in humans occurs as follows:[7]
L-tyrosine → *para*-tyramine or L-DOPA → dopamine → (*S*)-norlaudanosoline → (*S*)-reticuline → 1,2-dehydroretinulinium → (*R*)-reticuline → salutaridine → salutaridinol → thebaine → neopinone → codeinone → codeine → morphine
(*S*)-Norlaudanosoline (also known as tetrahydropapaveroline) can also be synthesized from 3,4-dihydroxyphenylacetaldehyde (DOPAL), a metabolite of L-DOPA and dopamine.[7] Urinary concentrations of endogenous codeine and morphine have been found to significantly increase in individuals taking L-DOPA for the treatment of Parkinson's disease.[7]

## Biosynthesis in the opium poppy [edit]



Morphine biosynthesis in the opium poppy

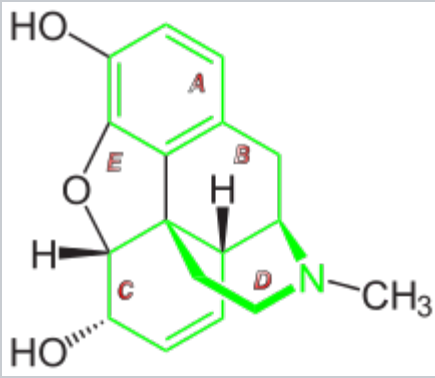
Morphine is biosynthesized in the opium poppy from the tetrahydroisoquinoline reticuline. It is converted into salutaridine, thebaine, and oripavine. The enzymes involved in this process are the salutaridine synthase, salutaridine:NADPH 7-oxidoreductase and the codeinone reductase.[74] Researchers are attempting to reproduce the biosynthetic pathway that produces morphine in genetically engineered yeast.[75] In June 2015 the *S*-reticuline could be produced from sugar and *R*-reticuline could be converted to morphine, but the intermediate reaction could not be performed.[76] In August 2015 the first complete synthesis of thebaine and hydrocodone in yeast were reported, but the process would need to be 100,000

times more productive to be suitable for commercial use.[77][78]

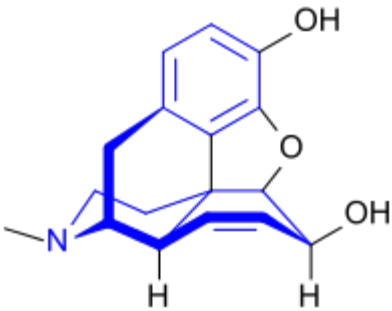
## Chemistry [edit]

Morphine is a benzylisoquinoline alkaloid with two additional ring closures. It has:

- A rigid pentacyclic structure consisting of a benzene ring (A), two partially unsaturated cyclohexane rings (B and C), a piperidine ring (D) and a tetrahydrofuran ring (E). Rings A, B and C are the phenanthrene ring system. This ring system has little conformational flexibility.
- Two hydroxyl functional groups: a C3-phenolic OH ($pK_a$ 9.9) and a C6-allylic OH,
- An ether linkage between C4 and C5,
- Unsaturation between C7 and C8,
- A basic, tertiary amine function at position 17,
- 5 centers of chirality (C5, C6, C9, C13 and C14) with morphine exhibiting a high degree of stereoselectivity of analgesic action.[79]



Chemical structure of morphine. The benzylisoquinoline backbone is shown in green.



Same structure with correct 3D configuration; backbone in blue.

Most of the licit morphine produced is used to make codeine by methylation. It is also a precursor for many drugs including heroin (3,6-diacetylmorphine), hydromorphone (dihydromorphinone), and oxymorphone (14-hydroxydihydromorphinone); many morphine derivatives can also be manufactured using thebaine or codeine as a starting material. Replacement of the *N*-methyl group of morphine with an *N*-phenylethyl group results in a product that is 18 times more powerful than morphine in its opiate agonist potency. Combining this modification with the replacement of the 6-hydroxyl with a 6-methylene group produces a compound some 1,443 times more potent than morphine, stronger than the Bentley compounds such as etorphine (M99, the Immobilon tranquilliser dart) by some measures.

The structure-activity relationship of morphine has been extensively studied. As a result of the extensive study and use of this molecule, more than 250 morphine derivatives (also counting codeine and related drugs) have been developed since the last quarter of the 19th century. These drugs range from 25% the analgesic strength of codeine (or slightly more than 2% of the strength of morphine) to several thousand times the strength of morphine, to powerful opioid antagonists, including naloxone (Narcan), naltrexone (Trexan), diprenorphine (M5050, the reversing agent for the Immobilon dart) and nalorphine (Nalline). Some opioid agonist-antagonists, partial agonists, and inverse agonists are also derived from morphine. The receptor-activation profile of the semi-synthetic morphine derivatives varies widely and some, like apomorphine are devoid of narcotic effects.

Morphine and most of its derivatives do not exhibit optical isomerism, although some more distant relatives like the morphinan series (levorphanol, dextorphan and the racemic parent chemical dromoran) do, and as noted above stereoselectivity in vivo is an important issue.

Morphine-derived agonist–antagonist drugs have also been developed. Elements of the morphine structure have been used to create completely synthetic drugs such as the morphinan family (levorphanol, dextromethorphan and others) and other groups that have many members with morphine-like qualities. The modification of morphine and the aforementioned synthetics has also given rise to non-narcotic drugs with other uses such as emetics, stimulants, antitussives, anticholinergics, muscle relaxants, local anaesthetics, general anaesthetics, and others.

Most semi-synthetic opioids, both of the morphine and codeine subgroups, are created by modifying one or more of the following:

- Halogenating or making other modifications at positions 1 or 2 on the morphine carbon skeleton.

- The methyl group that makes morphine into codeine can be removed or added back, or replaced with another functional group like ethyl and others to make codeine analogues of morphine-derived drugs and vice versa. Codeine analogues of morphine-based drugs often serve as prodrugs of the stronger drug, as in codeine and morphine, hydrocodone and hydromorphone, oxycodone and oxymorphone, nicocodeine and nicomorphine, dihydrocodeine and dihydromorphine, etc.
- Saturating, opening, or other changes to the bond between positions 7 and 8, as well as adding, removing, or modifying functional groups to these positions; saturating, reducing, eliminating, or otherwise modifying the 7–8 bond and attaching a functional group at 14 yields hydromorphinol; the oxidation of the hydroxyl group to a carbonyl and changing the 7–8 bond to single from double changes codeine into oxycodone.
- Attachment, removal or modification of functional groups to positions 3 or 6 (dihydrocodeine and related, hydrocodone, nicomorphine); in the case of moving the methyl functional group from position 3 to 6, codeine becomes heterocodeine, which is 72 times stronger, and therefore six times stronger than morphine
- Attachment of functional groups or other modification at position 14 (oxymorphone, oxycodone, naloxone)
- Modifications at positions 2, 4, 5 or 17, usually along with other changes to the molecule elsewhere on the morphine skeleton. Often this is done with drugs produced by catalytic reduction, hydrogenation, oxidation, or the like, producing strong derivatives of morphine and codeine.

Both morphine and its hydrated form, $C_{17}H_{19}NO_3H_2O$, are sparingly soluble in water. In five liters of water, only one gram of the hydrate will dissolve. For this reason, pharmaceutical companies produce sulfate and hydrochloride salts of the drug, both of which are over 300 times more water-soluble than their parent molecule. Whereas the pH of a saturated morphine hydrate solution is 8.5, the salts are acidic. Since they derive from a strong acid but weak base, they are both at about pH = 5; as a consequence, the morphine salts are mixed with small amounts of NaOH to make them suitable for injection.[81]

A number of salts of morphine are used, with the most common in current clinical use being the hydrochloride, sulfate, tartrate, and citrate; less commonly methobromide, hydrobromide, hydroiodide, lactate, chloride, and bitartrate and the others listed below. Morphine diacetate, which is another name for heroin, is a Schedule I controlled substance, so it is not used clinically in the United States; it is a sanctioned medication in the United Kingdom and in Canada and some countries in Continental Europe, its use being particularly common (nearly to the degree of the hydrochloride salt) in the United Kingdom. Morphine meconate is a major form of the alkaloid in the poppy, as is morphine pectinate, nitrate, sulphate, and some others. Like codeine, dihydrocodeine and other (especially older) opiates, morphine has been used as the salicylate salt by some suppliers and can be easily compounded, imparting the therapeutic advantage of both the opioid and the NSAID; multiple barbiturate salts of morphine were also used in the past, as was/is morphine valerate, the salt of the acid being the active principle of valerian. Calcium morphenate is the intermediate in various latex and poppy-straw methods of morphine production, more rarely sodium morphenate takes its place. Morphine ascorbate and other salts such as the tannate, citrate, and acetate, phosphate, valerate and others may be present in poppy tea depending on the method of preparation. Morphine valerate produced industrially was one ingredient of a medication available for both oral and parenteral administration popular many years ago in Europe and elsewhere called Trivalin (not to be confused with the current, unrelated herbal preparation of the same name), which also included the valerates of caffeine and cocaine, with a version containing codeine valerate as a fourth ingredient being distributed under the name Tetravalin.

Closely related to morphine are the opioids morphine-*N*-oxide (genomorphine), which is a pharmaceutical that is no longer in common use; and pseudomorphine, an alkaloid that exists in opium, form as degradation products of morphine.

The salts listed by the United States Drug Enforcement Administration for reporting purposes, in addition to a few others, are as follows:

**Select forms of morphine as 'morphiniums' or *N*-protonated cations of morphine, i.e. ionic salts & chemical form with freebase conversion ratios:**

| Salt or drug | CSA schedule | ACSCN | Free base conversion ratio |
|---|---|---|---|
| Morphine (base) | II | 9300 | 1 |

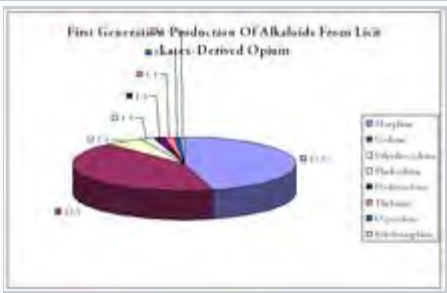
## Synthesis [edit]

*Main article: Morphine total synthesis*

The first morphine total synthesis, devised by Marshall D. Gates, Jr. in 1952, remains a widely used example of total synthesis.[82] Several other syntheses were reported, notably by the research groups of Rice,[83] Evans,[84] Fuchs,[85] Parker,[86] Overman,[87] Mulzer-Trauner,[88] White,[89] Taber,[90] Trost,[91] Fukuyama,[92] Guillou,[93] and Stork.[94] It is "highly unlikely" that a chemical synthesis will ever be able to compete with the cost of producing morphine from the opium poppy.[95]

## Production [edit]



First generation production of Alkaloids from licit latex-derived opium

In the opium poppy, the alkaloids are bound to meconic acid. The method is to extract from the crushed plant with diluted sulfuric acid, which is a stronger acid than meconic acid, but not so strong to react with alkaloid molecules. The extraction is performed in many steps (one amount of crushed plant is extracted at least six to ten times, so practically every alkaloid goes into the solution). From the solution obtained at the last extraction step, the alkaloids are precipitated by either ammonium hydroxide or sodium carbonate. The last step is purifying and separating morphine from other opium alkaloids. The somewhat similar Gregory process was developed in the United Kingdom during the Second World War, which begins with stewing the entire plant, in most cases save the roots and leaves, in plain or mildly acidified water, then proceeding through steps of concentration, extraction, and purification of alkaloids.[*citation needed*] Other methods of processing "poppy straw" (i.e., dried pods and stalks) use steam, one or more of several types of alcohol, or other organic solvents.

The poppy straw methods predominate in Continental Europe and the British Commonwealth, with the latex method in most common use in India. The latex method can involve either vertical or horizontal slicing of the unripe pods with a two-to five-bladed knife with a guard developed specifically for this purpose to the depth of a fraction of a millimetre and scoring of the pods can be done up to five times. An alternative latex method sometimes used in China in the past is to cut off the poppy heads, run a large needle through them, and collect the dried latex 24 to 48 hours later.[*citation needed*]

In India, opium harvested by licensed poppy farmers is dehydrated to uniform levels of hydration at government processing centers, and then sold to pharmaceutical companies that extract morphine from the opium. However, in Turkey and Tasmania, morphine is obtained by harvesting and processing the fully mature dry seed pods with attached stalks, called *poppy straw*. In Turkey, a water extraction process is used, while in Tasmania, a solvent extraction process is used.[*citation needed*]

Opium poppy contains at least 50 different alkaloids, but most of them are of very low concentration. Morphine is the principal alkaloid in raw opium and constitutes roughly 8–19% of opium by dry weight (depending on growing conditions).[62] Some purpose-developed strains of poppy now produce opium that is up to 26% morphine by weight.[*citation needed*] A rough rule of thumb to determine the morphine content of pulverised dried poppy straw is to divide the percentage expected for the strain or crop via the latex method by eight or an empirically determined factor, which is often in the range of 5 to 15.[*citation needed*] The Norman strain of *P. Somniferum*, also developed in Tasmania, produces down to 0.04% morphine but with much higher amounts of thebaine and oripavine, which can be used to synthesise semi-synthetic

opioids as well as other drugs like stimulants, emetics, opioid antagonists, anticholinergics, and smooth-muscle agents.[*citation needed*]

In the 1950s and 1960s, Hungary supplied nearly 60% of Europe's total medication-purpose morphine production. To this day, poppy farming is legal in Hungary, but poppy farms are limited by law to 2 acres (8,100 $m^2$). It is also legal to sell dried poppy in flower shops for use in floral arrangements.

It was announced in 1973 that a team at the National Institutes of Health in the United States had developed a method for total synthesis of morphine, codeine, and thebaine using coal tar as a starting material. A shortage in codeine-hydrocodone class cough suppressants (all of which can be made from morphine in one or more steps, as well as from codeine or thebaine) was the initial reason for the research.

Most morphine produced for pharmaceutical use around the world is actually converted into codeine as the concentration of the latter in both raw opium and poppy straw is much lower than that of morphine; in most countries, the usage of codeine (both as end-product and precursor) is at least equal or greater than that of morphine on a weight basis.

## Precursor to other opioids [edit]

### Pharmaceutical [edit]

Morphine is a precursor in the manufacture in a large number of opioids such as dihydromorphine, hydromorphone, hydrocodone, and oxycodone as well as codeine, which itself has a large family of semi-synthetic derivatives. Morphine is commonly treated with acetic anhydride and ignited to yield heroin.[96] Throughout Europe there is growing acceptance within the medical community of the use of slow release oral morphine as a substitution treatment alternative to methadone and buprenorphine for patients not able to tolerate the side-effects of buprenorphine and methadone. Slow-release oral morphine has been in widespread use for opiate maintenance therapy in Austria, Bulgaria, and Slovakia for many years and it is available on a small scale in many other countries including the UK. The long-acting nature of slow-release morphine mimics that of buprenorphine because the sustained blood levels are relatively flat so there is no "high" per se that a patient would feel but rather a sustained feeling of wellness and avoidance of withdrawal symptoms. For patients sensitive to the side-effects that in part may be a result of the unnatural pharmacological actions of buprenorphine and methadone, slow-release oral morphine formulations offer a promising future for use managing opiate addiction. The pharmacology of heroin and morphine is identical except the two acetyl groups increase the lipid solubility of the heroin molecule, causing heroin to cross the blood–brain barrier and enter the brain more rapidly in injection. Once in the brain, these acetyl groups are removed to yield morphine, which causes the subjective effects of heroin. Thus, heroin may be thought of as a more rapidly acting form of morphine.[97]

### Illicit [edit]

Illicit morphine is rarely produced from codeine found in over-the-counter cough and pain medicines. This demethylation reaction is often performed using pyridine and hydrochloric acid.[98]

Another source of illicit morphine comes from the extraction of morphine from extended-release morphine products, such as MS-Contin. Morphine can be extracted from these products with simple extraction techniques to yield a morphine solution that can be injected.[99] As an alternative, the tablets can be crushed and snorted, injected or swallowed, although this provides much less euphoria but retains some of the extended-release effect, and the extended-release property is why MS-Contin is used in some countries alongside methadone, dihydrocodeine, buprenorphine, dihydroetorphine, piritramide, levo-alpha-acetylmethadol (LAAM), and special 24-hour formulations of hydromorphone for maintenance and detoxification of those physically dependent on opioids.

Another means of using or misusing morphine is to use chemical reactions to turn it into heroin or another stronger opioid. Morphine can, using a technique reported in New Zealand (where the initial precursor is codeine) and elsewhere known as home-bake, be turned into what is usually a mixture of morphine, heroin, 3-monoacetylmorphine, 6-monoacetylmorphine, and codeine derivatives like acetylcodeine if the

process is using morphine made from demethylating codeine.

Since heroin is one of a series of 3,6 diesters of morphine, it is possible to convert morphine to nicomorphine (Vilan) using nicotinic anhydride, dipropanoylmorphine with propionic anhydride, dibutanoylmorphine and disalicyloylmorphine with the respective acid anhydrides. Glacial acetic acid can be used to obtain a mixture high in 6-monoacetylmorphine, niacin (vitamin $B_3$) in some form would be precursor to 6-nicotinylmorphine, salicylic acid may yield the salicyoyl analogue of 6-MAM, and so on.

The clandestine conversion of morphine to ketones of the hydromorphone class or other derivatives like dihydromorphine (Paramorfan), desomorphine (Permonid), metopon, etc. and codeine to hydrocodone (Dicodid), dihydrocodeine (Paracodin), etc. is more involved, time-consuming, requires lab equipment of various types, and usually requires expensive catalysts and large amounts of morphine at the outset and is less common but still has been discovered by authorities in various ways during the last 20 years or so. Dihydromorphine can be acetylated into another 3,6 morphine diester, namely diacetyldihydromorphine (Paralaudin), and hydrocodone into thebacon.

## History [edit]

Friedrich Sertürner

An opium-based elixir has been ascribed to alchemists of Byzantine times, but the specific formula was lost during the Ottoman conquest of Constantinople (Istanbul).[100] Around 1522, Paracelsus made reference to an opium-based elixir that he called *laudanum* from the Latin word *laudare*, meaning "to praise" He described it as a potent painkiller, but recommended that it be used sparingly. In the late eighteenth century, when the East India Company gained a direct interest in the opium trade through India, another opiate recipe called laudanum became very popular among physicians and their patients.

Morphine was discovered as the first active alkaloid extracted from the opium poppy plant in December 1804 in Paderborn, Germany, by Friedrich Sertürner.[9][101] In 1817 Sertürner reported experiments in which he administered morphine to himself, three young boys, three dogs, and a mouse; all four people almost died.[102] Sertürner originally named the substance *morphium* after the Greek god of dreams, Morpheus as it has a tendency to cause sleep.[10][103]

The drug was first marketed to the general public by Sertürner and Company in 1817 as an pain medication, and also as a treatment for opium and alcohol addiction. It was first used as a poison in 1822 when Dr. Edme Castaing of France was convicted of murdering a patient.[104] Commercial production began in Darmstadt, Germany in 1827 by the pharmacy that became the pharmaceutical company Merck, with morphine sales being a large part of their early growth.[*citation needed*] In the 1850s Alexander Wood reported that he had injected morphine into his wife as an experiment; his wife died from respiratory depression.[102]

Later it was found that morphine was more addictive than either alcohol or opium, and its extensive use during the American Civil War allegedly resulted in over 400,000[105] sufferers from the "soldier's disease" of morphine addiction.[106] This idea has been a subject of controversy, as there have been suggestions that such a disease was in fact a fabrication; the first documented use of the phrase "soldier's disease" was in 1915.[107][108]

Diacetylmorphine (better known as heroin) was synthesized from morphine in 1874 and brought to market by Bayer in 1898. Heroin is approximately 1.5 to 2 times more potent than morphine weight for weight. Due to the lipid solubility of diacetylmorphine, it can cross the blood–brain barrier faster than morphine, subsequently increasing the reinforcing component of addiction.[109] Using a variety of subjective and objective measures, one study estimated the relative potency of heroin to morphine administered intravenously to post-addicts to be 1.80–2.66 mg of morphine sulfate to 1 mg of diamorphine hydrochloride (heroin).[37]

An ampoule of morphine with integral needle for immediate use. Also known as a "syrette". From WWII. On display at the Army Medical Services Museum.

Advertisement for curing morphine addiction, ca. 1900[110]

Morphine became a controlled substance in the US under the Harrison Narcotics Tax Act of 1914, and possession without a prescription in the US is a criminal offense. Morphine was the most commonly abused narcotic analgesic in the world until heroin was synthesized and came into use. In general, until the synthesis of dihydromorphine (ca. 1900), the dihydromorphinone class of opioids (1920s), and oxycodone (1916) and similar drugs, there were no other drugs in the same efficacy range as opium, morphine, and heroin, with synthetics still several years away (pethidine was invented in Germany in 1937) and opioid agonists among the semi-synthetics were analogues and derivatives of codeine such as dihydrocodeine (Paracodin), ethylmorphine (Dionine), and benzylmorphine (Peronine). Even today, morphine is the most sought after prescription narcotic by heroin addicts when heroin is scarce, all other things being equal; local conditions and user preference may cause hydromorphone, oxymorphone, high-dose oxycodone, or methadone as well as dextromoramide in specific instances such as 1970s Australia, to top that particular list. The stop-gap drugs used by the largest absolute number of heroin addicts is probably codeine, with significant use also of dihydrocodeine, poppy straw derivatives like poppy pod and poppy seed tea, propoxyphene, and tramadol.

The structural formula of morphine was determined by 1925 by Robert Robinson. At least three methods of total synthesis of morphine from starting materials such as coal tar and petroleum distillates have been patented, the first of which was announced in 1952, by Dr. Marshall D. Gates, Jr. at the University of Rochester.[111] Still, the vast majority of morphine is derived from the opium poppy by either the traditional method of gathering latex from the scored, unripe pods of the poppy, or processes using poppy straw, the dried pods and stems of the plant, the most widespread of which was invented in Hungary in 1925 and announced in 1930 by the chemist János Kabay.

In 2003, there was discovery of endogenous morphine occurring naturally in the human body. Thirty years of speculation were made on this subject because there was a receptor that, it appeared, reacted only to morphine: the $\mu_3$-opioid receptor in human tissue.[112] Human cells that form in reaction to cancerous neuroblastoma cells have been found to contain trace amounts of endogenous morphine.[113]

## Society and culture [edit]

### Legal status [edit]

- In Australia, morphine is classified as a Schedule 8 drug under the variously titled State and Territory Poisons Acts.
- In Canada, morphine is classified as a Schedule I drug under the Controlled Drugs and Substances Act.
- In France, morphine is in the strictest schedule of controlled substances, based upon the December 1970 French controlled substances law.
- In Germany, morphine is a *verkehrsfähiges und verschreibungsfähiges Betäubungsmittel* listed under *Anlage III* (the equivalent of CSA Schedule II) of the Betäubungsmittelgesetz.[114]
  In Switzerland, morphine is similarly scheduled to Germany's legal classification of the drug.
- In Japan, morphine is classified as a narcotic under the Narcotics and Psychotropics Control Act (麻薬及び向精神薬取締法, *mayaku oyobi kōseishinyaku torishimarihō*).
- In the Netherlands, morphine is classified as a List 1 drug under the Opium Law.
- In the United Kingdom, morphine is listed as a Class A drug under the Misuse of Drugs Act 1971 and a Schedule 2 Controlled Drug under the Misuse of Drugs Regulations 2001.
- In the United States, morphine is classified as a Schedule II controlled substance under the Controlled

Substances Act with a main Administrative Controlled Substances Code Number (ACSCN) of ACSCN 9300. Morphine pharmaceuticals in the US are subject to annual manufacturing quotas; morphine production for use in extremely dilute formulations and its production as an intermediate, or chemical precursor, for conversion into other drugs is excluded from the US manufacturing quota.

- Internationally (UN), morphine is a Schedule I drug under the Single Convention on Narcotic Drugs.[115]

## Non-medical use [edit]

The euphoria, comprehensive alleviation of distress and therefore all aspects of suffering, promotion of sociability and empathy, "body high", and anxiolysis provided by narcotic drugs including the opioids can cause the use of high doses in the absence of pain for a protracted period, which can impart a morbid craving for the drug in the user. Being the prototype of the entire opioid class of drugs means that morphine has properties that may lend it to misuse. Morphine addiction is the model upon which the current perception of addiction is based.[*medical citation needed*]

Example of different morphine tablets

Animal and human studies and clinical experience back up the contention that morphine is one of the most euphoric of drugs on earth, and via all but the IV route heroin and morphine cannot be distinguished according to studies because heroin is a prodrug for the delivery of systemic morphine. Chemical changes to the morphine molecule yield other euphorigenics such as dihydromorphine, hydromorphone (Dilaudid, Hydal), and oxymorphone (Numorphan, Opana), as well as the latter three's methylated equivalents dihydrocodeine, hydrocodone, and oxycodone, respectively; in addition to heroin, there are dipropanoylmorphine, diacetyldihydromorphine, and other members of the 3,6 morphine diester category like nicomorphine and other similar semi-synthetic opiates like desomorphine, hydromorphinol, etc. used clinically in many countries of the world but in many cases also produced illicitly in rare instances.[*medical citation needed*]

In general, non-medical use of morphine entails taking more than prescribed or outside of medical supervision, injecting oral formulations, mixing it with unapproved potentiators such as alcohol, cocaine, and the like, or defeating the extended-release mechanism by chewing the tablets or turning into a powder for snorting or preparing injectables. The latter method can be as time-consuming and involved as traditional methods of smoking opium. This and the fact that the liver destroys a large percentage of the drug on the first pass impacts the demand side of the equation for clandestine re-sellers, as many customers are not needle users and may have been disappointed with ingesting the drug orally. As morphine is generally as hard or harder to divert than oxycodone in a lot of cases, morphine in any form is uncommon on the street, although ampoules and phials of morphine injection, pure pharmaceutical morphine powder, and soluble multi-purpose tablets are very popular where available.[*medical citation needed*]

Morphine is also available in a paste that is used in the production of heroin, which can be smoked by itself or turned to a soluble salt and injected; the same goes for the penultimate products of the Kompot (Polish Heroin) and black tar processes. Poppy straw as well as opium can yield morphine of purity levels ranging from poppy tea to near-pharmaceutical-grade morphine by itself or with all of the more than 50 other alkaloids. It also is the active narcotic ingredient in opium and all of its forms, derivatives, and analogues as well as forming from breakdown of heroin and otherwise present in many batches of illicit heroin as the result of incomplete acetylation.[*medical citation needed*]

## Slang terms [edit]

Informal names for morphine include: Cube Juice, Dope, Dreamer, Emsel, First Line, God's Drug, Hard Stuff, Hocus, Hows, Lydia, Lydic, M, Miss Emma, Mister Blue, Monkey, Morf, Morph, Morphide, Morphie, Morpho,

Mother, MS, Ms. Emma, Mud, New Jack Swing (if mixed with heroin), Sister, Tab, Unkie, Unkie White, and Stuff.[116]

MS Contin tablets are known as misties, and the 100 mg extended-release tablets as greys and blockbusters. The "speedball" can use morphine as the opioid component, which is combined with cocaine, amphetamines, methylphenidate, or similar drugs. "Blue Velvet" is a combination of morphine with the antihistamine tripelennamine (Pyrabenzamine, PBZ, Pelamine) taken by injection, or less commonly the mixture when swallowed or used as a retention enema; the name is also known to refer to a combination of tripelennamine and dihydrocodeine or codeine tablets or syrups taken by mouth. "Morphia" is an older official term for morphine also used as a slang term. "Driving Miss Emma" is intravenous administration of morphine. Multi-purpose tablets (readily soluble hypodermic tablets that can also be swallowed or dissolved under the tongue or betwixt the cheek and jaw) are known, as are some brands of hydromorphone, as Shake & Bake or Shake & Shoot.

Morphine can be smoked, especially diacetylmorphine (heroin), the most common method being the "Chasing The Dragon" method. To perform a relatively crude acetylation to turn the morphine into heroin and related drugs immediately prior to use is known as AAing (for Acetic Anhydride) or home-bake, and the output of the procedure also known as home-bake or, Blue Heroin (not to be confused with Blue Magic heroin, or the linctus known as Blue Morphine or Blue Morphone, or the Blue Velvet mixture described above).

## Trade names [edit]

Morphine is marketed under many different brand names in various parts of the world.[1]

## Access in developing countries [edit]

Although morphine is cheap, people in poorer countries often do not have access to it. According to a 2005 estimate by the International Narcotics Control Board, six countries (Australia, Canada, France, Germany, the United Kingdom, and the United States) consume 79% of the world's morphine. The less affluent countries, accounting for 80% of the world's population, consumed only about 6% of the global morphine supply. Some countries import virtually no morphine, and in others the drug is rarely available even for relieving severe pain while dying.

Experts in pain management attribute the under-distribution of morphine to an unwarranted fear of the drug's potential for addiction and abuse. While morphine is clearly addictive, Western doctors believe it is worthwhile to use the drug and then wean the patient off when the treatment is over.[117]

# Nystatin

From Wikipedia, the free encyclopedia

**Nystatin**, sold under the brandname **Mycostatin** among others, is an antifungal medication.[1] It is used to treat *Candida* infections of the skin including diaper rash, thrush, esophageal candidiasis, and vaginal yeast infections. It may also be used to prevent candidiasis in those who are at high risk. Nystatin may be used by mouth, in the vagina, or applied to the skin.[1]

Common side effects when applied to the skin include burning, itching, and a rash. Common side effects when taken by mouth include vomiting and diarrhea. During pregnancy use in the vagina is safe while other formulations have not been studied in this group. It works by disrupting the cell membrane of the fungal cells.[1]

Nystatin was discovered in 1950 by Rachel Fuller Brown and Elizabeth Lee Hazen.[2] It is on the World Health Organization's List of Essential Medicines, the most important medications needed in a basic health system.[3] It is available as a generic medication.[1] The wholesale price of the cream in the developing world is about 0.70 USD per 30 gram tube.[4] In the United States it is less than 25 USD for a course of treatment.[5] It is made from the bacterium, *Streptomyces noursei*.[2]

Contents

## Medical uses [edit]

Skin, vaginal, mouth, and esophageal *Candida* infections usually respond well to treatment with nystatin. It is available in many forms.

Oral nystatin is often used as a preventive treatment in people

who are at risk for fungal infections, such as AIDS patients with a low CD4+ count and people receiving chemotherapy. It has been investigated for use in patients after liver transplantation, but fluconazole was found to be much more effective for preventing colonization, invasive infection, and death.[6]

It is also used in very low birth-weight (less than 1500 g or 3lb 5oz 0) infants to prevent invasive fungal infections, although fluconazole is the preferred treatment. It has been found to reduce the rate of invasive fungal infections and also reduce deaths when used in these babies.[7]

Liposomal nystatin is not commercially available, but investigational use has shown greater *in vitro* activity than colloidal formulations of amphotericin B, and demonstrated effectiveness against some amphotericin B-resistant forms of fungi.[8] It offers an intriguing possibility for difficult-to-treat systemic infections, such as invasive aspergillosis, or infections that demonstrate resistance to amphotericin B. *Cryptococcus* is also sensitive to nystatin. Additionally, liposomal nystatin appears to cause fewer cases of and less severe nephrotoxicity than observed with amphotericin B.[8]

In the UK, its license for treating neonatal oral thrush is restricted to those over the age of one month.[*citation needed*]

It is prescribed in 'units', with doses varying from 100,000 units (for oral infections) to 1 million (for intestinal ones). As it is not absorbed from the gut, it is fairly safe for oral use and does not have problems of drug interactions. On occasion, serum levels of the drug can be identified from oral, vaginal, or cutaneous administration, and lead to toxicity.

## Adverse effects [edit]

The oral suspension form produces a number of adverse effects including but not limited to:[9]

1. Diarrhea
2. Abdominal pain
3. Rarely, tachycardia, bronchospasm, facial swelling, muscle aches

Both the oral suspension and the topical form can cause:

1. Hypersensitivity reactions, including Stevens-Johnson syndrome in some cases [10]
2. Rash, itching, burning and acute generalized exanthematous pustulosis[11]

## Mechanism of action [edit]

Like amphotericin B and natamycin, nystatin binds to ergosterol, a major component of the fungal cell membrane. When present in sufficient concentrations, it forms pores in the membrane that lead to $K^+$ leakage, acidification, and death of the fungus.[12] Ergosterol is a sterol

unique to fungi, so the drug does not have such catastrophic effects on animals or plants. However, many of the systemic/toxic effects of nystatin in humans are attributable to its binding to mammalian sterols, namely cholesterol. This is the effect that accounts for the nephrotoxicity observed when high serum levels of nystatin are achieved.

## Biosynthesis [edit]

Nystatin $A_1$ (or referred to as nystatin) is biosynthesized by a bacterial strain, *Streptomyces noursei*.[13] The structure of this active compound is characterized as a polyene macrolide with a deoxysugar D-mycosamine, an aminoglycoside.[13] The genomic sequence of nystatin reveals the presence of the polyketide loading module (nysA), six polyketide synthases modules (nysB, nysC, nysI, nysJ, and nysK) and two thioesterase modules (nysK and nysE).[13] It is evident that the biosynthesis of the macrolide functionality follows the polyketide synthase I pathway.[14]

Following the biosynthesis of the macrolide, the compound undergoes post-synthetic modifications, which are aided by the following enzymes: GDP-mannose dehydratase (nysIII), P450 monooxygenase (nysL and nysN), aminotransferase (nysDII), and glycosyltransferase (nysDI).[13] The biosynthetic pathway is thought to proceed as shown to yield nystatin.

## History [edit]

Like many other antifungals and antibiotics, nystatin is of bacterial origin. It was isolated from *Streptomyces noursei* in 1950 by Elizabeth Lee Hazen and Rachel Fuller Brown, who were doing research for the Division of Laboratories and Research of the New York State Department of Health. Hazen found a promising micro-organism in the soil of a friend's dairy farm. She named it *Streptomyces noursei*, after Jessie Nourse, the wife of the farm's owner.[15] Hazen and Brown named nystatin after the New York State Health Department in 1954.[16] The two discoverers patented the drug, and then donated the $13 million in profits to a foundation to fund similar research.[17][18]

Elizabeth Lee Hazen (left) and Rachel Fuller Brown in 1955.

## Other uses [edit]

It is also used in cellular biology as an inhibitor of the lipid raft-caveolae endocytosis pathway on mammalian cells, at concentrations around 3 µg/ml.

In certain cases, nystatin has been used to prevent the spread of mold on objects such as works of art. For example, it was applied to wood panel paintings damaged as a result of the Arno River Flood of 1966 in Florence, Italy.

*Penicillium*-infected tangerine: The spot absent of growth had nystatin applied to it before the fungus covered the fruit.

Nystatin is also used as a tool by scientists performing "perforated" patch-clamp electrophysiologic recordings of cells. When loaded in the recording pipette, it allows for measurement of electrical currents without washing out the intracellular contents, because it forms pores in the cell membrane that are permeable to only monovalent ions.[19]

## Formulations [edit]

- An oral suspension form is used for the prophylaxis or treatment of oropharyngeal thrush, a superficial candidal infection of the mouth and pharynx.
- A tablet form is preferred for candidal infections in the intestines.
- Nystatin is available as a topical cream and can be used for superficial candidal infections of the skin.
- Additionally, a liposomal formulation of nystatin was investigated in the 1980s and into the early 21st century. The liposomal form was intended to resolve problems arising from the poor solubility of the parent molecule and the associated systemic toxicity of the free drug.

Due to its toxicity profile when high levels in the serum are obtained, no injectable formulations of this drug are currently on the US market. However, injectable formulations have been investigated in the past.[8]

## Brand names [edit]

The original brandname was Fungicidin

- Nyamyc
- Pedi-Dri
- Pediaderm AF Complete
- Candistatin
- Nyaderm
- Bio-Statin
- PMS-Nystatin
- Nystan (oral tablets, topical ointment, and pessaries, formerly from Bristol-Myers Squibb)
- Infestat
- Nystalocal from Medinova AG
- Nystamont
- Nystop (topical powder, Paddock)
- Nystex
- Mykinac
- Nysert (vaginal suppositories, Procter & Gamble)
- Nystaform (topical cream, and ointment and cream combined with iodochlorhydroxyquine and hydrocortisone; formerly Bayer now Typharm Ltd)
- Nilstat (vaginal tablet, oral drops, Lederle)
- Korostatin (vaginal tablets, Holland Rantos)
- Mycostatin (vaginal tablets, topical powder, suspension Bristol-Myers Squibb)
- Mycolog-II (topical ointment, combined with triamcinolone; Apothecon)
- Mytrex (topical ointment, combined with triamcinolone)
- Mykacet (topical ointment, combined with triamcinolone)
- Myco-Triacet II (topical ointment, combined with triamcinolone)

Flagystatin II (cream, combined with metronidazole)
- Timodine (cream, combined with hydrocortisone and dimethicone)
- Nistatina (oral tablets, Antibiotice Iaşi)
- Nidoflor (cream, combined with neomycin sulfate and triamcinolone acetonide)
- Stamicin (oral tablets, Antibiotice Iaşi)
- Lystin
- Animax (veterinary topical ointment or cream; combined with neomycin sulfate, thiostrepton and triamcinolone acetonide)

# Paracetamol

From Wikipedia, the free encyclopedia

**Paracetamol**, also known as **acetaminophen** or **APAP**, is a medication used to treat pain and fever.[10] It is typically used for mild to moderate pain.[10] There is poor evidence for fever relief in children.[11] It is often sold in combination with other ingredients such as in many cold medications.[10] In combination with opioid pain medication, paracetamol is used for more severe pain such as cancer pain and after surgery.[12] It is typically used either by mouth or rectally but is also available intravenously.[10][13] Effects last between two and four hours.[13]

Paracetamol is generally safe at recommended doses.[14] Serious skin rashes may rarely occur, and too high a dose can result in liver failure.[10] It appears to be safe during pregnancy and when breastfeeding.[10] In those with liver disease, it may still be used, but lower doses should be taken.[15] Paracetamol is classified as a mild analgesic.[13] It does not have significant anti-inflammatory activity and how it works is not entirely clear.[16]

Paracetamol was discovered in 1877.[17] It is the most commonly used medication for pain and fever in both the United States and Europe.[18] It is on the WHO Model List of Essential Medicines, the most important medications needed in a basic health system.[19] Paracetamol is available as a generic medication with trade names including *Tylenol* and *Panadol* among others.[20] The wholesale price in the developing world is less than 0.01 USD per dose.[21] In the United States it costs about 0.04 USD per dose.[22]

# Medical uses [edit]

## Fever [edit]

Paracetamol is used for reducing fever in people of all ages.[23] The World Health Organization (WHO) recommends that paracetamol be used to treat fever in children only if their temperature is greater than 38.5 °C (101.3 °F).[24] The efficacy of paracetamol by itself in children with fevers has been questioned[25] and a meta-analysis showed that it is less effective than ibuprofen.[26]

## Pain [edit]

Paracetamol is used for the relief of mild to moderate pain. The use of the intravenous form for pain of sudden onset in people in the emergency department is supported by limited evidence.[27]

## Osteoarthritis [edit]

The American College of Rheumatology recommends paracetamol as one of several treatment options for people with arthritis pain of the hip, hand, or knee that does not improve with exercise and weight loss.[28] A 2015 review, however, found it provided only a small benefit in osteoarthritis.[29]

Paracetamol has relatively little anti-inflammatory activity, unlike other common analgesics such as the NSAIDs aspirin and ibuprofen, but ibuprofen and paracetamol have similar effects in the treatment of headache. Paracetamol can relieve pain in mild arthritis, but has no effect on the underlying inflammation, redness, and swelling of the joint.[30] It has analgesic properties comparable to those of aspirin, while its anti-inflammatory effects are weaker. It is better tolerated than aspirin due to concerns about bleeding with aspirin.

## Low back pain [edit]

Based on a systematic review, paracetamol is recommended by the American College of Physicians and the American Pain Society as a first-line treatment for low back pain.[31][32] However, other systematic reviews concluded that evidence for its efficacy is lacking.[29][33]

## Headaches [edit]

A joint statement of the German, Austrian, and Swiss headache societies and the German Society of Neurology recommends the use of paracetamol in combination with caffeine as one of several first line therapies for treatment of tension or migraine headache.[34] In the treatment of acute migraine, it is superior to placebo, with 39% of people experiencing pain relief at 1 hour compared to 20% in the control group.[35]

## Postoperative pain [edit]

Paracetamol combined with NSAIDs may be more effective for treating postoperative pain than either paracetamol alone or NSAIDs alone.[36]

## Dental use [edit]

NSAIDs such as ibuprofen, naproxen, diclofenac are more effective than paracetamol for controlling dental pain or pain arising from dental procedures; combinations of NSAIDs and paracetamol are more effective than either alone.[37] Paracetamol is particularly useful when NSAIDs are contraindicated due to hypersensitivity or history of gastrointestinal ulceration or bleeding.[38] It can also be used in combination with NSAIDs when these are ineffective in controlling dental pain alone.[39] The Cochrane review of preoperative analgesics for additional pain relief in children and adolescents shows no evidence of benefit in taking paracetamol before dental treatment to help reduce pain after treatment for procedures under local anaesthetic, however the quality of evidence is low.[40]

## Other [edit]

The efficacy of paracetamol when used in combination with weak opioids (such as codeine) improved for approximately 50% of people but with increases in the number experiencing side effects.[41][42] Combination drugs of paracetamol and strong opioids like morphine improve analgesic effect.[43]

The combination of paracetamol with caffeine is superior to paracetamol alone for the treatment of common pain conditions including dental pain, postpartum pain, and headache.[44]

# Adverse effects [edit]

Healthy adults taking regular doses of up to 4,000 mg a day show little evidence of toxicity (although some researchers disagree). They are more likely to have abnormal liver function tests, but the significance of this is uncertain.[29]

## Liver damage [edit]

Acute overdoses of paracetamol can cause potentially fatal liver damage. In 2011 the US Food and Drug Administration launched a public education program to help consumers avoid overdose, warning: "Acetaminophen can cause serious liver damage if more than directed is used."[45][46][47] In a 2011 Safety

Warning the FDA immediately required manufacturers to update labels of all prescription combination acetaminophen products to warn of the potential risk for severe liver injury and required that such combinations contain no more than 325 mg of acetaminophen.[48][49] FDA has likewise requested prescribers to limit combination opioids to 325 mg of acetaminophen. Such overdoses are frequently related to high-dose recreational use of prescription opioids, as these opioids are most often combined with acetaminophen.[50] The overdose risk may be heightened by frequent consumption of alcohol.

Paracetamol toxicity is the foremost cause of acute liver failure in the Western world and accounts for most drug overdoses in the United States, the United Kingdom, Australia, and New Zealand.[51][52][53][54] According to the FDA, in the United States there were "56,000 emergency room visits, 26,000 hospitalizations, and 458 deaths per year related to acetaminophen-associated overdoses during the 1990s. Within these estimates, unintentional acetaminophen overdose accounted for nearly 25 percent of the emergency department visits, 10 percent of the hospitalizations, and 25 percent of the deaths."[55]

Paracetamol is metabolised by the liver and is hepatotoxic; side effects are multiplied when combined with alcoholic drinks, and are very likely in chronic alcoholics or patients with liver damage.[56][57] Some studies have suggested the possibility of a moderately increased risk of upper gastrointestinal complications such as stomach bleeding when high doses are taken chronically.[58] Kidney damage is seen in rare cases, most commonly in overdose.[59]

## Skin reactions [edit]

On August 2, 2013, the U.S. Food and Drug Administration (FDA) issued a new warning about paracetamol. It stated that the drug could cause rare and possibly fatal skin reactions such as Stevens–Johnson syndrome and toxic epidermal necrolysis. Prescription-strength products will be required to carry a warning label about skin reactions, and the FDA has urged manufacturers to do the same with over-the-counter products.[60]

## Asthma [edit]

There is an association between paracetamol use and asthma, but the evidence suggests that this likely reflects confounders[61] rather than a causal role.[62] A 2014 review found that among children the association disappeared when respiratory infections were taken into account.[63]

As of 2014, the American Academy of Pediatrics and the National Institute for Health and Care Excellence (NICE) continue to recommend paracetamol for pain and discomfort in children,[64][65][66][67][68][69] but some experts have recommended that paracetamol use by children with asthma or at risk for asthma should be avoided.[70][71]

## Other factors [edit]

In contrast to aspirin, paracetamol does not prevent blood from clotting (it is not an antiplatelet), and thus may be used in patients where failure of blood coagulation is a concern; and it does not cause gastric irritation.[72] However, paracetamol does not help reduce inflammation, while aspirin does.[73] Compared to ibuprofen—whose side effects may include diarrhea, vomiting and abdominal pain—paracetamol has fewer adverse gastrointestinal effects.[74] Unlike aspirin, paracetamol is generally considered safe for children, as it is not associated with a risk of Reye's syndrome in children with viral illnesses.[75] If taken recreationally with opioids, there is weak evidence suggesting that it may cause hearing loss.[76]

## Overdose [edit]

*Main article: Paracetamol toxicity*

Untreated paracetamol overdose results in a lengthy, painful illness. Signs and symptoms of paracetamol toxicity may initially be absent or non-specific symptoms. The first symptoms of overdose usually begin several hours after ingestion, with nausea, vomiting, sweating, and pain as acute liver failure starts.[77]

People who take overdoses of paracetamol do not fall asleep or lose consciousness, although most people who attempt suicide with paracetamol wrongly believe that they will be rendered unconscious by the drug.[78] The process of dying from an overdose takes from 3–5 days to 4–6 weeks.

Paracetamol hepatotoxicity is by far the most common cause of acute liver failure in both the United States and the United Kingdom.[54][79] Paracetamol overdose results in more calls to poison control centers in the US than overdose of any other pharmacological substance.[80] Toxicity of paracetamol is believed to be due to its quinone metabolite.[81]

Untreated overdose can lead to liver failure and death within days. Treatment is aimed at removing the paracetamol from the body and replacing glutathione.[81] Activated charcoal can be used to decrease absorption of paracetamol if the patient presents for treatment soon after the overdose. While the antidote, acetylcysteine (also called N-acetylcysteine or NAC), acts as a precursor for glutathione, helping the body regenerate enough to prevent or at least decrease the possible damage to the liver, a liver transplant is often required if damage to the liver becomes severe.[51][82] NAC was usually given following a treatment nomogram (one for patients with risk factors, and one for those without) but the use of the nomogram is no longer recommended as evidence to support the use of risk factors was poor and inconsistent, and many of the risk factors are imprecise and difficult to determine with sufficient certainty in clinical practice.[83] NAC also helps in neutralizing the imidoquinone metabolite of paracetamol.[81] Kidney failure is also a possible side effect.

Until 2004, tablets were available (brand-name in the UK Paradote) that combined paracetamol with an antidote (methionine) to protect the liver in case of an overdose. One theoretical, but rarely if ever used, option in the United States is to request a compounding pharmacy to make a similar drug mix for at-risk patients.

In June 2009, a U.S. Food and Drug Administration (FDA) advisory committee recommended that new restrictions be placed on paracetamol usage in the United States to help protect people from the potential toxic effects. The maximum dosage at any given time would be decreased from 1000 mg to 650 mg, while combinations of paracetamol and opioid analgesics would be prohibited. Committee members were particularly concerned by the fact that the present maximum dosages of paracetamol had been shown to produce alterations in hepatic function.[84]

In January 2011, the FDA asked manufacturers of prescription combination products containing paracetamol to limit the amount of paracetamol to no more than 325 mg per tablet or capsule and began requiring manufacturers to update the labels of all prescription combination paracetamol products to warn of the potential risk of severe liver damage.[85][86][87][88] Manufacturers had three years to limit the amount of paracetamol in their prescription drug products to 325 mg per dosage unit.[86][88] In November 2011, the Medicines and Healthcare products Regulatory Agency revised UK dosing of liquid paracetamol for children.[89]

## Pregnancy [edit]

Experimental studies in animals and cohort studies in humans indicate no detectable increase in congenital malformations associated with paracetamol use during pregnancy.[90] Additionally, paracetamol does not affect the closure of the fetal ductus arteriosus as NSAIDs can.[91]

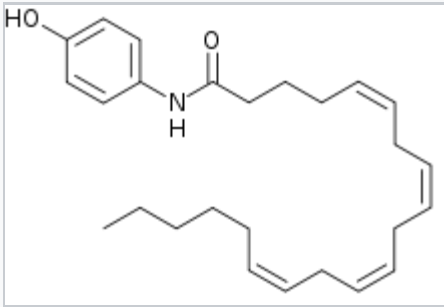
Paracetamol use by the mother during pregnancy is associated with an increased risk of childhood asthma.[92] It is also associated with an increase in ADHD but it is unclear whether the relationship is causal.[93] A 2015 review states that paracetamol remains a first-line recommended medication for pain and fever during pregnancy, despite these concerns.[94]

## Cancer [edit]

Some studies have found an association between paracetamol and a slight increase in kidney cancer,[95] but no effect on bladder cancer risk.[96]

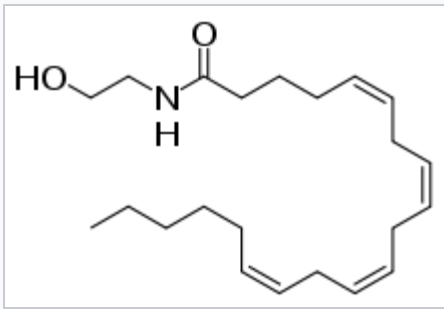
## Mechanism of action [edit]

To date, the mechanism of action of paracetamol is not completely understood. The main mechanism proposed is the inhibition of cyclooxygenase (COX), and recent findings suggest that it is highly selective for COX-2.[97] Because of its selectivity for COX-2, it does not significantly inhibit the production of the pro-clotting thromboxanes.[97] While it has analgesic and antipyretic properties comparable to those of aspirin or other NSAIDs, its peripheral anti-inflammatory activity is usually limited by several factors, one of which is the high level of peroxides present in inflammatory lesions.



AM404 – Metabolite of paracetamol

An article[98] in Nature Communications from researchers in London, UK and Lund, Sweden in November 2011 has found a hint to the analgesic mechanism of paracetamol, being that the metabolites of paracetamol (e.g., NAPQI), act on TRPA1-receptors in the spinal cord to suppress the signal transduction from the superficial layers of the dorsal horn, to alleviate pain.



Anandamide – Endogenous cannabinoid

This conclusion has been contested in a new hypothesis paper[99] on how paracetamol might act. The author concedes that NAPQI is the active metabolite but that this reactive compound should react not only with the thiol in TRPA1 but also with any other suitably available nucleophile that it happens to encounter. It is suggested that thiol groups in cysteine proteases, e.g. the proteases that take part in the processing of procytokines, such as those generating IL-1β and IL-6, might be the targets giving rise to overall analgesic effects.

The COX family of enzymes are responsible for the metabolism of arachidonic acid to prostaglandin $H_2$, an unstable molecule that is, in turn, converted to numerous other pro-inflammatory compounds. Classical anti-inflammatories such as the NSAIDs block this step. Only when appropriately oxidised is the COX enzyme highly active.[100][101] Paracetamol reduces the oxidised form of the COX enzyme, preventing it from forming pro-inflammatory chemicals.[102][103] This leads to a reduced amount of *prostaglandin E2* in the CNS, thus lowering the hypothalamic set-point in the thermoregulatory centre.

Aspirin is known to inhibit the cyclooxygenase (COX) family of enzymes and, because paracetamol's action is partially similar to aspirin's,[*clarification needed*] much research has focused on whether paracetamol also inhibits COX. It is now clear that paracetamol acts via at least two pathways.[102][104][105][106]

The exact mechanisms by which COX is inhibited in various circumstances are still a subject of discussion. Because of differences in the activity of paracetamol, aspirin, and other NSAIDs, it has been postulated that further COX variants may exist. One theory holds that paracetamol works by inhibiting the COX-3 isoform—a COX-1 splice variant—of the COX family of enzymes.[97] When expressed in dogs, this enzyme shares a strong similarity to the other COX enzymes, produces pro-inflammatory chemicals, and is selectively inhibited by paracetamol.[107] However, some research has suggested that, in humans and mice, the COX-3 enzyme is without inflammatory action and paracetamol's blockage of it is not significant in its functioning in humans.[97][105]

Another possibility is that paracetamol blocks cyclooxygenase (as in aspirin), but that, in an inflammatory environment where the concentration of peroxides is high, the high oxidation state of paracetamol prevents its actions. This idea would mean that paracetamol has no direct effect at the site of inflammation, but instead acts in the CNS where the environment is not oxidative, to reduce temperature, etc.[107]

Paracetamol also modulates the endogenous cannabinoid system.[108] Paracetamol is metabolised to AM404, a compound with several actions; what is most important is that it inhibits the reuptake of the endogenous cannabinoid/vanilloid anandamide by neurons. Anandamide reuptake lowers synaptic levels of

anandamide and results in more activation of the main pain receptor (nociceptor) of the body, the TRPV1 (older name: vanilloid receptor). By inhibiting anandamide reuptake, levels in the synapse remain high and are able to desensitise the TRPV1 receptor much like capsaicin. Furthermore, AM404 inhibits sodium channels, as do the anesthetics lidocaine and procaine.[109] Both of these actions by themselves have been shown to reduce pain, and are a possible mechanism for paracetamol. It has been demonstrated that when cannabinoid receptors are blocked with synthetic antagonists, paracetamol's analgesic effects are prevented, suggesting its pain-relieving action involves the endogenous cannabinoid system.[110] Spinal TRPA1 receptors have also been demonstrated to mediate antinociceptive effects of paracetamol and Δ9-tetrahydrocannabinol in mice.[111]

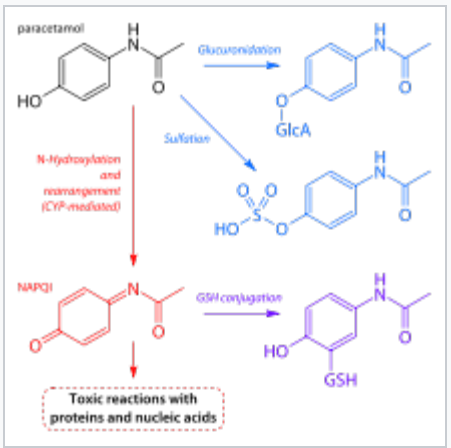
Increase of social behavior in mice dosed with paracetamol (which corresponds to a reduction of social rejection response in humans) does not appear to be due to cannabinoid receptor type 1 activity. It may result from serotonin receptor agonism.[112]

## Pharmacokinetics [edit]

After being taken by mouth it is rapidly absorbed by the GI tract (although absorption through the stomach is negligible);[113] its volume of distribution is roughly 50 L.[114] The concentration in serum after a typical dose of paracetamol usually peaks below 30 µg/ml, which equals 200 µmol/L.[115] After 4 hours the concentration is usually less than 10 µg/mL, which equals 66 µmol/L.[115]

Paracetamol is metabolised primarily in the liver, into toxic and non-toxic products. Three metabolic pathways are notable:[81]

- Glucuronidation (45-55%),[4] by UGT1A1 and UGT1A6;[96]
- Sulfation (sulfate conjugation) (20–30%)[4] by SULT1A1;[96]
- *N*-hydroxylation and dehydration, then glutathione conjugation, (less than 15%). The hepatic cytochrome P450 enzyme system metabolises paracetamol, forming a minor yet significant alkylating metabolite known as NAPQI (*N*-acetyl-*p*-benzoquinone imine) (also known as *N*-acetylimidoquinone).[81][116] NAPQI is then irreversibly conjugated with the sulfhydryl groups of glutathione.[116]



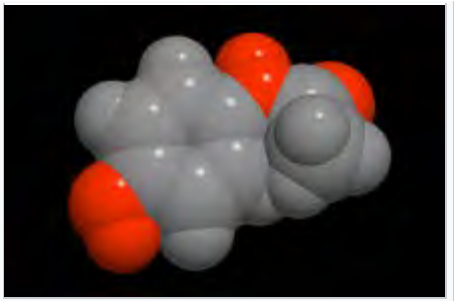
Main pathways of paracetamol metabolism *(click to enlarge)*. Pathways shown in blue and purple lead to non-toxic metabolites; the pathway in red leads to toxic NAPQI.

All three pathways yield final products that are inactive, non-toxic, and eventually excreted by the kidneys. In the third pathway, however, the intermediate product NAPQI is toxic. NAPQI is primarily responsible for the toxic effects of paracetamol; this constitutes an example of toxication.[117] Production of NAPQI is due primarily to two isoenzymes of cytochrome P450: CYP2E1[96] and CYP3A4.[117] At usual doses, NAPQI is quickly detoxified by conjugation with glutathione.[81][116]

## Chemistry [edit]

### Chemical properties [edit]

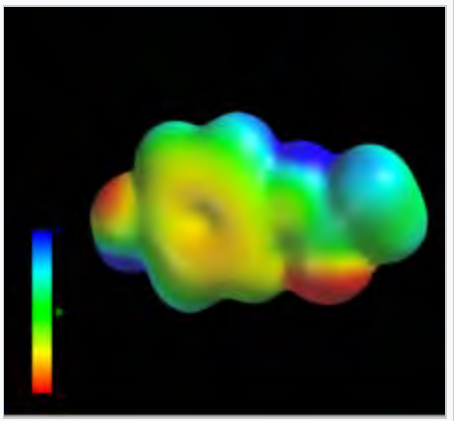
Paracetamol consists of a benzene ring core, substituted by one hydroxyl group and the nitrogen atom of an amide group in the *para* (1,4) pattern.[118] The amide group is acetamide (ethanamide). It is an extensively conjugated system, as the lone pair on the hydroxyl oxygen, the benzene pi cloud, the nitrogen lone pair, the p orbital on the carbonyl carbon, and the lone pair on the carbonyl oxygen are all conjugated. The presence of two activating groups also make the benzene ring highly reactive toward electrophilic aromatic substitution.



Paracetamol molecule polar surface area

As the substituents are *ortho, para*-directing and *para* with respect to each other, all positions on the ring are more or less equally activated. The conjugation also greatly reduces the basicity of the oxygens and the nitrogen, while making the hydroxyl acidic through delocalisation of charge developed on the phenoxide anion.

Paracetamol is part of the class of drugs known as "aniline analgesics"; it is the only such drug still in use today.[104] It is not considered an NSAID because it does not exhibit significant anti-inflammatory activity (it is a weak COX inhibitor).[119][120] This is despite the evidence that paracetamol and NSAIDs have some similar pharmacological activity.[121]

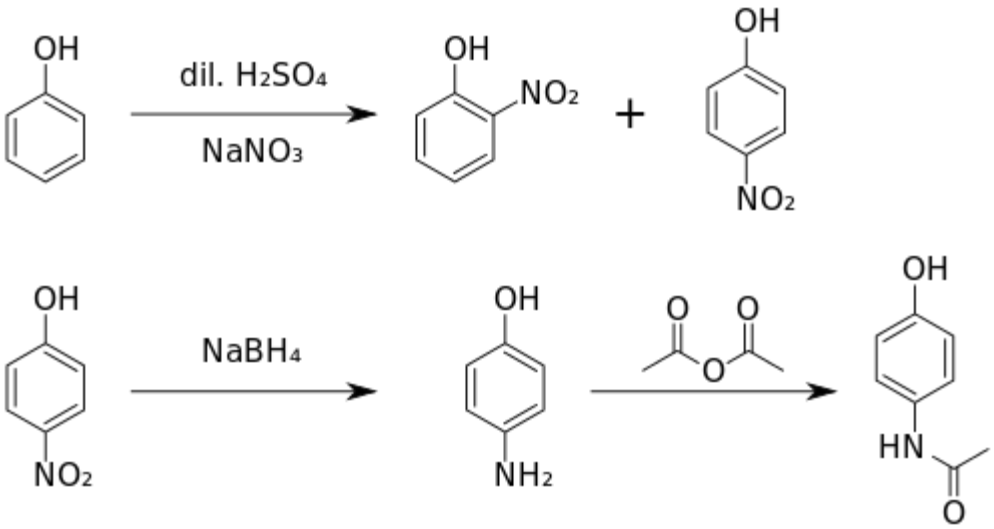


Paracetamol electron map electrostatic surface area[*citation needed*]

## Synthesis [edit]

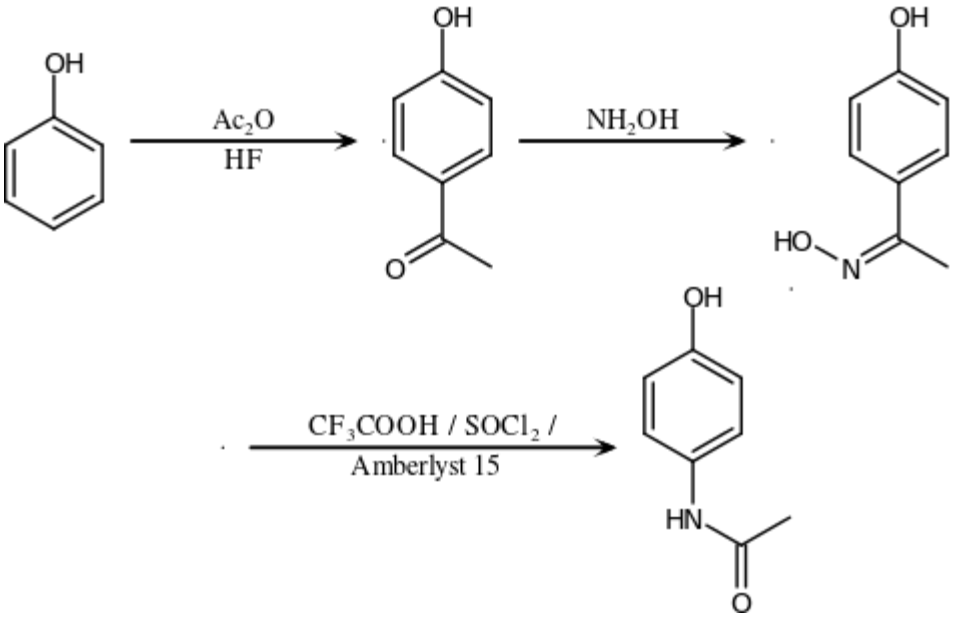
### Original (Boots) method [edit]

The original method for production involves the nitration of phenol with sodium nitrate gives a mixture of two isomers, from which the wanted 4-nitrophenol (bp 279 °C) can easily be separated by steam distillation. In this electrophilic aromatic substitution reaction, phenol's oxygen is strongly activating, thus the reaction requires only mild conditions as compared to nitration of benzene itself. The nitro group is then reduced to an amine, giving 4-aminophenol. Finally, the amine is acetylated with acetic anhydride.[122] Industrially direct hydrogenation is used, but in the laboratory scale sodium borohydride serves.[123][124]



### Green(er) synthesis [edit]

An alternative industrial synthesis developed by Hoechst–Celanese involves direct acylation of phenol with acetic anhydride catalyzed by HF, conversion of the ketone to a ketoxime with hydroxylamine, followed by the acid-catalyzed Beckmann rearrangement to give the amide.[124][125]



## Direct synthesis [edit]

More recently (2014) a "one-pot" synthesis from hydroquinone has been described before the Royal Society of Chemistry.[126][127] The process may be summarized as follows:

> Hydroquinone, ammonium acetate, and acetic acid were mixed in an argon atmosphere and heated slowly to 230 °C. The mixture was stirred at this temperature for 15 hours. After cooling the acetic acid was evaporated and the precipitate was filtered, washed with water and dried to give paracetamol as a white solid.

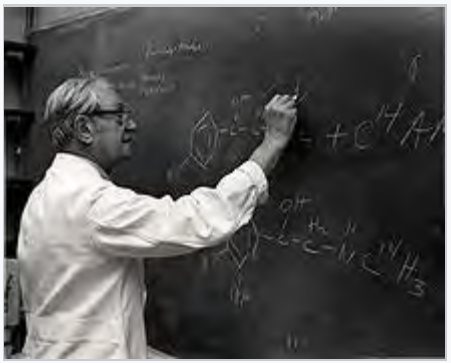
The authors go on to claim an 88% yield and 99% purity.

## Reactions [edit]

*4*-Aminophenol may be obtained by the amide hydrolysis of paracetamol. *4*-Aminophenol prepared this way, and related to the commercially available Metol, has been used as a developer in photography by hobbyists.[128] This reaction is also used to determine paracetamol in urine samples: After hydrolysis with hydrochloric acid, *4*-aminophenol reacts in ammonia solution with a phenol derivate, e.g. salicylic acid, to form an indophenol dye under oxidization by air.[129]

# History [edit]

Acetanilide was the first aniline derivative serendipitously found to possess analgesic as well as antipyretic properties, and was quickly introduced into medical practice under the name of Antifebrin by A. Cahn and P. Hepp in 1886.[130] But its unacceptable toxic effects, the most alarming being cyanosis due to methemoglobinemia, prompted the search for less toxic aniline derivatives.[104] Harmon Northrop Morse had already synthesised paracetamol at Johns Hopkins University via the reduction of *p*-nitrophenol with tin in glacial acetic acid in 1877,[131][132] but it was not until 1887 that clinical pharmacologist Joseph von Mering tried paracetamol on patients.[104] In 1893, von Mering published a paper reporting on the clinical results of paracetamol with phenacetin, another aniline derivative.[133] Von Mering claimed that, unlike phenacetin, paracetamol had a slight tendency to produce methemoglobinemia. Paracetamol was then quickly discarded in favor of phenacetin. The sales of phenacetin established Bayer as a leading



Julius Axelrod *(pictured)* and Bernard Brodie demonstrated that acetanilide and phenacetin are both metabolised to paracetamol,

which is a better tolerated analgesic.

pharmaceutical company.[134] Overshadowed in part by aspirin, introduced into medicine by Heinrich Dreser in 1899, phenacetin was popular for many decades, particularly in widely advertised over-the-counter "headache mixtures", usually containing phenacetin, an aminopyrine derivative of aspirin, caffeine, and sometimes a barbiturate.[104]

Paracetamol is the active metabolite of phenacetin and acetanilide, both once popular as analgesics and antipyretics in their own right.[114][135] However, unlike phenacetin, acetanilide and their combinations, paracetamol is not considered carcinogenic at therapeutic doses.[136]

Von Mering's claims remained essentially unchallenged for half a century, until two teams of researchers from the United States analyzed the metabolism of acetanilide and paracetamol.[134] In 1947 David Lester and Leon Greenberg found strong evidence that paracetamol was a major metabolite of acetanilide in human blood, and in a subsequent study they reported that large doses of paracetamol given to albino rats did not cause methemoglobinemia.[137] In three papers published in the September 1948 issue of the *Journal of Pharmacology and Experimental Therapeutics*, Bernard Brodie, Julius Axelrod and Frederick Flinn confirmed using more specific methods that paracetamol was the major metabolite of acetanilide in human blood, and established that it was just as efficacious an analgesic as its precursor.[138][139][140] They also suggested that methemoglobinemia is produced in humans mainly by another metabolite, phenylhydroxylamine. A follow-up paper by Brodie and Axelrod in 1949 established that phenacetin was also metabolised to paracetamol.[141] This led to a "rediscovery" of paracetamol.[104] It has been suggested that contamination of paracetamol with 4-aminophenol, the substance von Mering synthesised it from, may be the cause for his spurious findings.[134]

Paracetamol was first marketed in the United States in 1950 under the name Triagesic, a combination of paracetamol, aspirin, and caffeine.[132] Reports in 1951 of three users stricken with the blood disease agranulocytosis led to its removal from the marketplace, and it took several years until it became clear that the disease was unconnected.[132] Paracetamol was marketed in 1953 by Sterling-Winthrop Co. as Panadol, available only by prescription, and promoted as preferable to aspirin since it was safe for children and people with ulcers.[132][134][142] In 1955, paracetamol was marketed as Children's Tylenol Elixir by McNeil Laboratories.[143] In 1956, 500 mg tablets of paracetamol went on sale in the United Kingdom under the trade name Panadol, produced by Frederick Stearns & Co, a subsidiary of Sterling Drug Inc. In 1963, paracetamol was added to the *British Pharmacopoeia*, and has gained popularity since then as an analgesic agent with few side-effects and little interaction with other pharmaceutical agents.[132] Concerns about paracetamol's safety delayed its widespread acceptance until the 1970s, but in the 1980s paracetamol sales exceeded those of aspirin in many countries, including the United Kingdom. This was accompanied by the commercial demise of phenacetin, blamed as the cause of analgesic nephropathy and hematological toxicity.[104] In 1988 Sterling Winthrop was acquired by Eastman Kodak which sold the over the counter drug rights to SmithKline Beecham in 1994.[144]

Available without a prescription since 1959,[145] it has since become a common household drug.[146] Patents on paracetamol have long expired, and generic versions of the drug are widely available.[1][147]

## Society and culture [edit]

### Naming [edit]

Acetaminophen is the name generally used in the United States (USAN), Japan (JAN), Canada[148] Venezuela, Colombia.,[149] and Iran; paracetamol is used in international venues (INN, AAN, BAN).[148][149][150] In some contexts, such as on prescription bottles of painkillers that incorporate this medicine, it is simply abbreviated as APAP, for **a**cetyl-**p**ara-**a**mino**p**henol.

Both acetaminophen and paracetamol come from a chemical name for the compound: *para*-**acet**yl**aminophen**ol and *para*-**acet**yl**am**inophen**ol**.

## Available forms [edit]

*See also: Paracetamol brand names*

Paracetamol is available in a tablet, capsule, liquid suspension, suppository, intravenous, intramuscular and effervescent form. The common adult dose is 500 mg to 1000 mg. The recommended maximum daily dose for adults is 4000 mg. In recommended doses, paracetamol is generally safe for children and infants as well as for adults,[151] although rare cases of acute liver injury have been linked to amounts lower than 2500 mg per day.[152]

In some formulations, paracetamol is combined with the opioid codeine, sometimes referred to as co-codamol (BAN) and Panadeine in Australia. In the U.S., this combination is available only by prescription, while the lowest-strength preparation is over the counter in Canada, and in other countries other strengths may be available over the counter.[*citation needed*] Paracetamol is also combined with other opioids such as dihydrocodeine, referred to as co-dydramol (BAN), oxycodone or hydrocodone. Another very commonly used analgesic combination includes paracetamol in combination with propoxyphene napsylate. A combination of paracetamol, codeine, and the calmative doxylamine succinate is also available. The efficacy of paracetamol/codeine combinations has been questioned by recent research.[43]

Paracetamol is commonly used in multi-ingredient preparations for migraine headache, typically including butalbital and paracetamol with or without caffeine, and sometimes containing codeine.

Paracetamol is sometimes combined with phenylephrine hydrochloride.[153] Sometimes a third active ingredient, such as ascorbic acid,[153][154] caffeine,[155][156] chlorpheniramine maleate,[157] or guaifenesin[158][159][160] is added to this combination.

When marketed in combination with diphenhydramine hydrochloride, it is frequently given the label "PM" and is meant as a sleep aid. Diphenhydramine hydrochloride is known to have hypnotic effects and is non-habit forming. Unfortunately it has been implicated in the occasional development of restless leg syndrome.[161]

Tylenol 500 mg capsules

## Controversy [edit]

In September 2013, an episode of *This American Life* entitled "Use Only as Directed"[162] highlighted deaths from paracetamol overdose. This report was followed by two reports by ProPublica[163][164] alleging that the "FDA has long been aware of studies showing the risks of acetaminophen. So has the maker of Tylenol, McNeil Consumer Healthcare, a division of Johnson & Johnson" and "McNeil, the maker of Tylenol, ... has repeatedly opposed safety warnings, dosage restrictions and other measures meant to safeguard users of the drug."

A report prepared by an internal FDA working group describes a history of FDA initiatives designed to educate consumers about the risk of paracetamol overdose and notes that one challenge to the Agency has been "identifying the appropriate message about the relative safety of acetaminophen, especially compared to other OTC pain relievers (e.g., aspirin and other NSAIDs)". The report notes that "Chronic use of NSAIDs is also associated with significant morbidity and mortality. NSAID gastrointestinal risk is substantial, with deaths and hospitalization estimated in one publication as 3200 and 32,000 per year respectively. Possible cardiovascular toxicity with chronic NSAID use has been a major discussion recently", finally noting that "The goal of the educational efforts is not to decrease appropriate acetaminophen use or encourage substitution of NSAID use, but rather to educate consumers so that they can avoid unnecessary health risks."[165]

# Veterinary use [edit]

## Cats [edit]

Paracetamol is extremely toxic to cats, which lack the necessary glucuronyl transferase enzymes to break it down safely. Initial symptoms include vomiting, salivation, and discoloration of the tongue and gums.

Unlike an overdose in humans, liver damage is rarely the cause of death; instead, methemoglobin formation and the production of Heinz bodies in red blood cells inhibit oxygen transport by the blood, causing asphyxiation (methemoglobemia and hemolytic anemia).[166]

Treatment with N-acetylcysteine,[167] methylene blue or both is sometimes effective after the ingestion of small doses of paracetamol.

## Dogs [edit]

Although paracetamol is believed to have no significant anti-inflammatory activity, it has been reported as effective as aspirin in the treatment of musculoskeletal pain in dogs.[168]

A paracetamol-codeine product (trade name Pardale-V)[169] licensed for use in dogs is available on veterinary prescription in the UK.[169] It should be administered to dogs only on veterinary advice and with extreme caution.[169]

The main effect of toxicity in dogs is liver damage, and GI ulceration has been reported.[167][170][171][172] N-acetylcysteine treatment is efficacious in dogs when administered within 2 hours of paracetamol ingestion.[167][168]

## Snakes [edit]

Paracetamol is also lethal to snakes, and has been suggested as a chemical control program for the invasive brown tree snake (*Boiga irregularis*) in Guam.[173][174] Doses of 80 mg are inserted into dead mice scattered by helicopter.[175]

# Propofol

From Wikipedia, the free encyclopedia

*Not to be confused with Profadol, Propanol, or Propranolol.*

**Propofol**, marketed as **Diprivan** among others, is a short-acting medication that results in a decreased level of consciousness and lack of memory for events.[2] Its uses include the starting and maintenance of general anesthesia, sedation for mechanically ventilated adults, and procedural sedation. It is also used for status epilepticus if other medications have not worked. It is given intravenously. Maximum effect takes about two minutes to occur and it typically lasts five to ten minutes.[2]

Common side effects include an irregular heart rate, low blood pressure, burning sensation at the site of injection, and the stopping of breathing. Other serious side effects may include seizures, infections with improper use, addiction, and propofol infusion syndrome with long-term use. It appears to be safe for using during pregnancy but has not been well studied in this group. However, it is not recommended during cesarean section.[2] Propofol is not a pain medication, so opioids such as morphine may also be used.[3] Whether or not they are always needed is unclear.[4] Propofol is believed to work at least partly via the receptor for GABA.[2]

Propofol was discovered in 1977.[5] It is on the WHO Model List of Essential Medicines, the most important medications needed in a health system.[6] It is available as a generic medication.[2] The wholesale price in the developing world is between 0.61 and 8.50 USD per vial.[7] It has been referred to as **milk of amnesia** because of the milk-like appearance of the intravenous preparation.[8] Propofol is also used in veterinary medicine.[9]

# Medical uses [edit]

## Anesthesia [edit]

Propofol is used for induction and maintenance (in some cases) of anesthesia, having largely replaced sodium thiopental.[3] It can also be administered as part of an anaesthesia maintenance technique called total intravenous anesthesia using either manually-programmed infusion pumps or computer-controlled infusion pumps in a process called target controlled infusion or TCI. Propofol is also used to sedate individuals who are receiving mechanical ventilation but are not undergoing surgery, such as patients in the intensive care unit. In critically ill patients, propofol has been found to be superior to lorazepam both in effectiveness and overall cost.[10]

Propofol is often used instead of sodium thiopental for starting anesthesia because recovery from propofol is more rapid and "clear."

## Procedural sedation [edit]

Propofol is also used for procedural sedation. Its use in these settings results in a faster recovery compared to midazolam.[11] It can also be combined with opioids or benzodiazepines.[12][13][14] Because of its fast induction and recovery time, propofol is also widely used for sedation of infants and children undergoing MRI.[15] It is also often used in combination with ketamine as the two together have lower rates of side effects.[16]

# Other uses [edit]

## Executions [edit]

The Missouri Supreme Court decided to allow the use of propofol to execute prisoners condemned to death. However, the first execution by administration of a lethal dose of propofol was halted on 11 October 2013 by governor Jay Nixon following threats from the European Union to limit the drug's export if it were used for that purpose.[17][18] The United Kingdom had already banned the export of medicines or veterinary medicines containing propofol to the United States.[19]

## Recreational use [edit]

Recreational use of the drug via self-administration has been reported[20][21] (including among medical professionals, see below), but is relatively rare due to its potency and the level of monitoring required for safe use.[*citation needed*] Critically, the steep dose-response curve of the drug makes potential misuse very dangerous without proper monitoring, and deaths from self-administration continue to be reported.[22][23]

The short-term effects sought via recreational use include mild euphoria, hallucinations, and disinhibition.[24][25] The euphoria caused by propofol has been reported to be unlike that caused by other sedation agents; as one anesthetist reported, "I... remember my first experience using [administering] propofol: a young woman... emerging from a MAC anesthesia looked at me as though I were a masked Brad Pitt and told me that she felt simply wonderful."[26]

Recreational use of the drug has been described among medical staff, such as anesthetists who have access to the drug,[27] and is reportedly more common among anesthetists on rotations with short rest periods (as rousing is to a well-rested state).[28] Long-term use has been reported to result in addiction.[27][29]

Attention to the risks of off-label use of propofol increased in August 2009 due to the Los Angeles County coroner's conclusion that music icon Michael Jackson died from a mixture of propofol and the benzodiazepine drugs lorazepam and diazepam on June 25, 2009, the propofol sometimes administered orally.[30][31][32][33] According to a 22 July 2009 search warrant affidavit unsealed by the district court of Harris County, Texas, Jackson's personal physician, Conrad Murray, administered 25 milligrams of propofol diluted with lidocaine shortly before Jackson's death.[31][32][34] Even so, as of 2016 propofol was not on a U.S Drug Enforcement Administration schedule.[28][35]

## Side effects [edit]

One of propofol's most frequent side effects is pain on injection, especially in smaller veins. This pain arises from activation of the pain receptor, TRPA1,[36] found on sensory nerves and can be mitigated by pretreatment with lidocaine.[37] Less pain is experienced when infused at a slower rate in a large vein (antecubital fossa). Patients show great variability in their response to propofol, at times showing profound sedation with small doses.

Additional side effects include low blood pressure related to vasodilation, transient apnea following induction doses, and cerebrovascular effects. Propofol has more pronounced hemodynamic effects relative to many intravenous anesthetic agents.[38] Reports of blood pressure drops of 30% or more are thought to be at least partially due to inhibition of sympathetic nerve activity.[39] This effect is related to dose and rate of propofol administration. It may also be potentiated by opioid analgesics.[40] Propofol can also cause decreased systemic vascular resistance, myocardial blood flow, and oxygen consumption, possibly through direct vasodilation.[41] There are also reports that it may cause green discolouration of the urine.[42]

As a respiratory depressant, propofol frequently produces apnea. The persistence of apnea can depend on factors such as premedication, dose administered, and rate of administration, and may sometimes persist for longer than 60 seconds.[43] Possibly as the result of depression of the central inspiratory drive, propofol may produce significant decreases in respiratory rate, minute volume, tidal volume, mean inspiratory flow rate, and functional residual capacity.[38]

Diminishing cerebral blood flow, cerebral metabolic oxygen consumption, and intracranial pressure are also characteristics of propofol administration.[44] In addition, propofol may decrease intraocular pressure by as much as 50% in patients with normal intraocular pressure.[45]

A more serious but rare side effect is dystonia.[46] Mild myoclonic movements are common, as with other intravenous hypnotic agents. Propofol appears to be safe for use in porphyria, and has not been known to trigger malignant hyperpyrexia.[*citation needed*]

Propofol is also reported to induce priapism in some individuals,[47][48] and has been observed to suppress REM sleep stage and to worsen the poor sleep quality in some patients.[49]

As with any other general anesthetic agent, propofol should be administered only where appropriately trained staff and facilities for monitoring are available, as well as proper airway management, a supply of supplemental oxygen, artificial ventilation, and cardiovascular resuscitation.[50]

### Propofol infusion syndrome [edit]

*Main article: Propofol infusion syndrome*

Another recently described rare, but serious, side effect is propofol infusion syndrome. This potentially lethal metabolic derangement has been reported in critically ill patients after a prolonged infusion of high-dose substance in combination with catecholamines and/or corticosteroids.[51]

### CBS genetic defects [edit]

People with this gene have trouble processing sulphites (one of the potential ingredients), and should discuss use of this drug with their specialist.

## Interactions [edit]

The respiratory effects of propofol are increased if given with other respiratory depressants, including benzodiazepines.[52]

## Mechanism of action [edit]

Propofol has been proposed to have several mechanisms of action,[53][54][55] both through potentiation of $GABA_A$ receptor activity, thereby slowing the channel-closing time,[56][57][58] and also acting as a sodium channel blocker.[59][60] Recent research has also suggested that the endocannabinoid system may contribute significantly to propofol's anesthetic action and to its unique properties.[61] EEG research upon those undergoing general anesthesia with propofol finds that it causes a prominent reduction in the brain's information integration capacity at gamma wave band frequencies.[62]

Researchers have identified the site where propofol binds to $GABA_A$ receptors in the brain, on the second transmembrane domain of the beta subunit of the GABA $_A$ receptor.[63]

## Pharmacokinetics [edit]

Propofol is highly protein-bound *in vivo* and is metabolised by conjugation in the liver.[64] The half-life of elimination of propofol has been estimated to be between 2 and 24 hours. However, its duration of clinical effect is much shorter, because propofol is rapidly distributed into peripheral tissues. When used for IV sedation, a single dose of propofol typically wears off within minutes. Propofol is versatile; the drug can be given for short or prolonged sedation, as well as for general anesthesia. Its use is not associated with nausea as is often seen with opioid medications. These characteristics of rapid onset and recovery along with its amnestic effects[65] have led to its widespread use for sedation and anesthesia.

## Chemistry [edit]

Propofol was originally developed in the UK by Imperial Chemical Industries as ICI 35868. Clinical trials followed in 1977, using a form solubilised in cremophor EL. However, due to anaphylactic reactions to cremophor, this formulation was withdrawn from the market and subsequently reformulated as an emulsion of a soya oil/propofol mixture in water. The emulsified formulation was relaunched in 1986 by ICI

A 20-ml ampoule of 1% propofol emulsion, as sold in Australia by Sandoz

(now AstraZeneca) under the brand name Diprivan. The currently available preparation is 1% propofol, 10% soybean oil, and 1.2% purified egg phospholipid as an emulsifier, with 2.25% glycerol as a tonicity-adjusting agent, and sodium hydroxide to adjust the pH. Diprivan contains EDTA, a common chelation agent, that also acts alone (bacteriostatically against some bacteria) and synergistically with some other antimicrobial agents. Newer generic formulations contain sodium metabisulfite or benzyl alcohol as antimicrobial agents. Propofol emulsion is a highly opaque white fluid due to the scattering of light from the tiny (about 150-nm) oil droplets it contains.

A water-soluble prodrug form, fospropofol, has recently been developed and tested with positive results. Fospropofol is rapidly broken down by the enzyme alkaline phosphatase to form propofol. Marketed as Lusedra, this new formulation may not produce the pain at injection site that often occurs with the traditional form of the drug. The US Food and Drug Administration approved the product in 2008.[66] However fospropofol is a Schedule IV controlled substance with the DEA ACSCN of 2138 in the United States unlike propofol.[67]

## Society and culture [edit]

### Supply issues [edit]

On 4 June 2010, Teva Pharmaceutical Industries Ltd., an Israel-based pharmaceutical firm and a major supplier of the drug, announced the firm would no longer manufacture it. This aggravates an already existing shortage, caused by manufacturing difficulties at Teva and Hospira. A Teva spokesperson attributed the halt to ongoing process difficulties, and a number of pending lawsuits related to the drug.[68] In Switzerland, various preparations of the drug are supplied by Fresenius-Kabi, a German company.

## Recent developments [edit]

By incorporation of an azobenzene unit, a photoswitchable version of propofol (AP2) was developed in 2012 that allows for optical control of $GABA_A$ receptors with light.[69] In 2013, a propofol binding site on mammalian $GABA_A$ receptors has been identified by photolabeling using a Diazirine derivative.[70] Additionally, it was shown that the hyaluronan polymer present in the synovia can be protected from free-radical synovia by propofol.[71]

Propofol is one of the chemicals used in the manufacture of Avasamibe (ACAT inhibitor).

# Salbutamol

From Wikipedia, the free encyclopedia

**Salbutamol**, also known as **albuterol** and marketed as **Ventolin** among other names,[1] is a medication that opens up the medium and large airways in the lungs.[3] It is used to treat asthma, exercise-induced bronchospasm, and chronic obstructive pulmonary disease (COPD).[3] It may also be used to treat high blood potassium levels.[4] It is usually used by inhaler or nebulizer but is also available as a pill and intravenous solution.[3][5] Onset of action of the inhaled version is typically within 15 minutes and lasts for two to six hours.[3]

Common side effects include shakiness, headache, fast heart rate, dizziness, and feeling anxious. Serious side effects may include worsening bronchospasm, irregular heartbeat, and low blood potassium levels.[3] It can be used during pregnancy and breastfeeding, but safety is not entirely clear.[3][6] Salbutamol is a short-acting $\beta_2$ adrenergic receptor agonist which works by causing airway smooth muscles to relax.[3]

Salbutamol was first made in 1967 in Britain.[7] It was approved for medical use in the United States in 1982.[3] It is on the World Health Organization's List of Essential Medicines, the most important medication needed in a basic health system.[8] It is available as a generic medication.[3] The wholesale cost in the developing world of an inhaler which contains 200 doses is between $1.12 and $2.64 (USD) as of 2014.[9] In the United States it is between $25 and $50 for a typical month supply.[10]

# Medical uses [edit]

Salbutamol is typically used to treat bronchospasm (due to any cause, allergen asthma or exercise-induced), as well as chronic obstructive pulmonary disease.[11]

As a $\beta_2$ agonist, salbutamol also finds use in obstetrics. Intravenous salbutamol can be used as a tocolytic to relax the uterine smooth muscle to delay premature labor. While preferred over agents such as atosiban and ritodrine, its role has largely been replaced by the calcium channel blocker nifedipine, which is more effective, better tolerated and orally administered.[12]

Salbutamol has been used to treat acute hyperkalemia, as it stimulates potassium flow into cells thus lowering the level in the blood.[4]

# Adverse effects [edit]

The most common side effects are fine tremor, anxiety, headache, muscle cramps, dry mouth, and palpitation.[13] Other symptoms may include tachycardia, arrhythmia, flushing, myocardial ischemia (rare), and disturbances of sleep and behaviour.[13] Rarely occurring, but of importance, are allergic reactions of paradoxical bronchospasm, urticaria, angioedema, hypotension, and collapse. High doses or prolonged use may cause hypokalaemia, which is of concern especially in patients with renal failure and those on certain diuretics and xanthine derivatives.[13]

# Chemistry [edit]

## Structure and activity [edit]

This drug is sold as a racemic mixture. The (*R*)-(−)-enantiomer (CIP nomenclature) is shown in the image at right (top), and is responsible for the pharmacologic activity; the (*S*)-(+)-enantiomer (bottom) blocks metabolic pathways associated with elimination of itself and of the pharmacologically active enantiomer (*R*).[14]

With regard to structure-activity relationships, the tertiary butyl group in salbutamol makes it more selective for $\beta_2$ receptors.[*citation needed*]

## Detection after dosing [edit]

Salbutamol may be quantified in blood or plasma; practical needs for this include to confirm a diagnosis of poisoning in hospitalized patients, or to aid in a forensic investigation.[*citation needed*] As well, urinary salbutamol concentrations are frequently measured in competitive sports programs, for which a level in excess of 1000 μg/L is considered to represent abuse.[*citation needed*]

The window of detection for urine testing is on the order of just 24 hours,

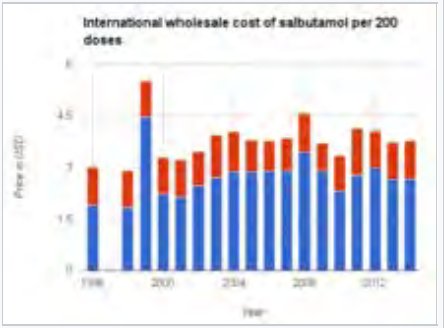
given the relatively short elimination half-life of the drug,[15][16][17] estimated at between 5 and 6 hours following oral administration of 4 mg.[18]

## Society and culture [edit]

### Cost [edit]

The wholesale cost of an inhaler which contains 200 doses is between $1.12 and $2.64 (USD) in the developing world as of 2014.[9] In the United Kingdom the wholesale price of an inhaler which contains 200 doses is GB£1.50 as of 2015.[19] In the United States a typical month supply is between $25 and $50.[10]



International wholesale price of 200 doses of salbutamol[9]

In some countries compliance with the Montreal Protocol, which requires the banning of the use of ozone-layer depleting CFCs, has caused the price of inhalers to increase as much as ten-fold, as generics have been forced off the market from 2009 to 2013 by new patents obtained by pharmaceutical companies for non-CFC delivery systems.[*citation needed*]

### Names [edit]

Salbutamol is the INN while albuterol is the USAN. The drug is usually manufactured and distributed as the sulfate salt (salbutamol sulfate).

It was first sold by Allen & Hanburys (UK) under the brand name Ventolin, and has been used for the treatment of asthma ever since.[20] The drug is marketed under many names worldwide.[1]

Ventolin 2 mg tablets made by GSK (Turkey)

### Doping [edit]

There is no compelling evidence that salbutamol and other $\beta_2$ agonists can increase performance in healthy athletes.[21] In spite of this, salbutamol required "a declaration of Use in accordance with the International Standard for Therapeutic Use Exemptions" under the 2010 WADA prohibited list. This requirement was relaxed when the 2011 list was published to permit the use of "salbutamol (maximum 1600 micrograms over 24 hours) and salmeterol when taken by inhalation in accordance with the manufacturers' recommended therapeutic regimen."[22][23]

According to two small and limited studies, performed on eight and 16 subjects, respectively, salbutamol increases performance on endurance exercise even for a person without asthma.[24][25][26]

Another study contradicts the above findings, however. The double blind, randomised test conducted on 12 non-asthmatic athletes concluded that salbutamol had a negligible effect on endurance performance. Nevertheless, the study also showed that the drug's bronchodilating effect may have improved respiratory adaptation at the beginning of exercise.[27]

Salbutamol has been shown to improve muscle weight in rats[28] and anecdotal reports hypothesise that it

might be an alternative to clenbuterol for purposes of fat burning and muscle gain, with multiple studies supporting this claim.[29][30][31][32][33] Abuse of the drug may be confirmed by detection of its presence in plasma or urine, typically exceeding 1000 µg/L.[15]

## History [edit]

Salbutamol was discovered in 1966 by a team led by David Jack at the Allen and Hanburys laboratory (a subsidiary of Glaxo) in Ware, Hertfordshire, England, and was launched as Ventolin in 1969.[34]

## Research [edit]

Salbutamol has also been tested in a trial aimed at treatment of spinal muscular atrophy; it is speculated to modulate the alternative splicing of the *SMN2* gene, increasing the amount of the SMN protein whose deficiency is regarded as a cause of the disease.[35][36]

It has been studied in subtypes of congenital myasthenic syndrome associated with mutations in *Dok-7*.[37]

# Brain tumor

From Wikipedia, the free encyclopedia

A **brain tumor** or **intracranial neoplasm** occurs when abnormal cells form within the brain.[1] There are two main types of tumors: malignant or cancerous tumors and benign tumors.[1] Cancerous tumors can be divided into primary tumors that start within the brain, and secondary tumors that have spread from somewhere else, known as brain metastasis tumors.[2] All types of brain tumors may produce symptoms that vary depending on the part of the brain involved.[1] These symptoms may include headaches, seizures, problem with vision, vomiting, and mental changes.[2][3][1] The headache is classically worse in the morning and goes away with vomiting.[1] More specific problems may include difficulty in walking, speaking, and with sensation.[2][4] As the disease progresses unconsciousness may occur.[4]

The cause of most brain tumors is unknown.[1] Uncommon risk factors include inherited neurofibromatosis, exposure to vinyl chloride, Epstein–Barr virus, and ionizing radiation.[1][2][4] The evidence for mobile phones is not clear.[1] The most common types of primary tumors in adults are meningiomas (usually benign), and astrocytomas such as glioblastomas.[2] In children, the most common type is a malignant medulloblastoma.[4] Diagnosis is usually by medical examination along with computed tomography or magnetic resonance imaging.[1] This is then often confirmed by a biopsy.[2] Based on the findings, the tumors are divided into different grades of severity.[2]

Treatment may include some combination of surgery, radiation therapy and chemotherapy.[2] Anticonvulsant medication may be needed if seizures occur.[2] Dexamethasone and furosemide may be used to decrease swelling around the tumor.[2] Some tumors grow gradually, requiring only monitoring and possibly needing no further intervention.[2] Treatments that use a person's immune system are being studied.[1] Outcome varies considerably depending on the type of tumor and how far it has spread at diagnosis.[4] Glioblastomas usually have poor outcomes while meningiomas usually have good outcomes.[4] The average five-year survival rate for brain cancer in the United States is 33%.[5]

Secondary or metastatic brain tumors are more common than primary brain tumors,[1] with about half of

## Variants

**Brain tumor**

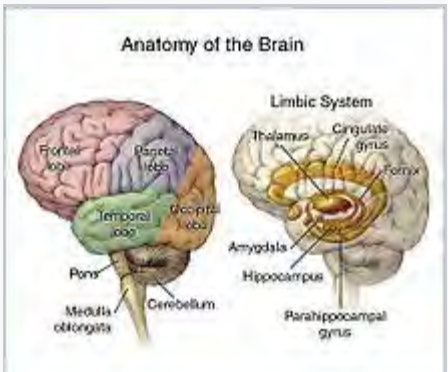
[edit on Wikidata]

metastases coming from lung cancer.[1] Primary brain tumors occur in around 250,000 people a year globally, making up less than 2% of cancers.[4] In children younger than 15, brain tumors are second only to acute lymphoblastic leukemia as a cause of cancer.[6] In Australia the average economic cost of a case of brain cancer is $1.9 million, the greatest of any type of cancer.[7]

## Signs and symptoms [edit]

The signs and symptoms of brain tumors are broad. People with brain tumors will experience them no matter if the tumor is benign (not cancerous) or cancerous.[8] Primary and secondary brain tumors present with similar symptoms, with symptoms depend on the location, size, and rate of growth of the tumor.[9] For example, larger tumors in the frontal lobe can cause changes in the ability to think. However, a smaller tumor in an area such as Wernicke's area (small area responsible for language comprehension) can result in a greater loss of function.[10]



The main areas of the brain and limbic system.

Intracranial pressure is usually the first sign of a brain tumor and it can cause persistent headaches.[11][12] These headaches may not respond to headache remedies and they may be accompanied by vomiting.[11]

The brain is divided into 4 lobes and each lobe or area has its own function.[13][14] A tumor in any of these lobes may affect the area's

performance. The location of the tumor is often linked to the symptoms experienced but each person may experience something different.[15]

Frontal lobe tumors may contribute to poor reasoning, inappropriate social behavior, personality changes, poor planning, lower inhibition,[15] and decreased production of speech (Broca's area)

Temporal lobe: Tumors in this lobe may contribute to poor memory, loss of hearing,[14] difficulty in language comprehension (Wernicke's area)

Parietal lobe: Tumors here may result in poor interpretation of languages, decreased sense of touch and pain, and poor spatial and visual perception[16]

Occipital lobe: Damage to this lobe may result in poor or loss of vision[16]

Cerebellum: Tumors in this area may cause poor balance, muscle movement, and posture[16]

Brain stem: Tumors on this can affect blood pressure, swallowing, and heartbeat[14]

### Behavior changes [edit]

Despite the personality and behavior changes occur in people with brain tumors, little research on such changes has been done.[13] A person's personality may be altered due to the tumor damaging lobes of the brain. Since the frontal, temporal, and parietal lobes[9] control inhibition, emotions, mood, judgement, reasoning, and behavior, a primary or secondary tumor in that region can cause inappropriate social behavior,[12] temper tantrums,[12] laughing at things which merit no laughter,[12] and even psychological symptoms such as depression and anxiety.[15]

Personality changes can have damaging effects such as unemployment, unstable relationships, and a lack of control.[13]

## Cause [edit]

Epidemiological studies are required to determine risk factors.[17] Aside from exposure to vinyl chloride or ionizing radiation, there are no known environmental factors associated with brain tumors. Mutations and deletions of so-called tumor suppressor genes, such as P53, are thought to be the cause of some forms of brain tumor.[18] Inherited conditions, such as Von Hippel–Lindau disease, multiple endocrine neoplasia, and neurofibromatosis type 2 carry a high risk for the development of brain tumors.

Although studies have not shown any link between cell phone or mobile phone radiation and the occurrence of brain tumors,[19] the World Health Organization has classified mobile phone radiation on the IARC scale into Group 2B – possibly carcinogenic.[20] Discounting claims that current cell phone usage may cause brain cancer, modern, third-generation (3G) phones emit, on average, about 1% of the energy emitted by the GSM (2G) phones that were in use when epidemiological studies that observed a slight increase in the risk for glioma – a malignant type of brain cancer –among heavy users of wireless and cordless telephones were conducted.[4]

## Pathophysiology [edit]

### Meninges [edit]

Human brains are surrounded by a system of connective tissue membranes called meninges that separate the brain from the skull. This three-layered covering is composed of (from the outside in) the dura mater ("hard mother"), arachnoid mater ("spidery mother"), and pia mater ("tender mother"). The arachnoid and pia are physically connected and thus often considered as a single layer, the pia-

Brain cancer regions.

arachnoid. Between the arachnoid mater and the pia mater is the subarachnoid space which contains cerebrospinal fluid (CSF). This fluid circulates in the narrow spaces between cells and through the cavities in the brain called ventricles, to nourish, support, and protect the brain tissue. Blood vessels enter the central nervous system through the perivascular space above the pia mater. The cells in the blood vessel walls are joined tightly, forming the blood–brain barrier which protects the brain from toxins that might enter through the blood. Tumors of the meninges are meningiomas and are often benign.

### Brain matter [edit]

The brains of humans and other vertebrates are composed of very soft tissue and a gelatin-like texture. Living brain tissue has a pink tint in color on the outside (grey matter), and nearly complete white on the inside (white matter), with subtle variations in color. Three separate brain areas make up most of the brain's volume:

- telencephalon (cerebral hemispheres or cerebrum)
- mesencephalon (midbrain)
- cerebellum

These areas are composed of two broad classes of cells: neurons and glia. These two types are equally numerous in the brain as a whole, although glial cells outnumber neurons roughly 4 to 1 in the cerebral cortex. Glia come in several types, which perform a number of critical functions, including structural support, metabolic support, insulation, and guidance of development.

Primary tumors of the glial cells are called gliomas and often are malignant by the time they are diagnosed.

### Spinal cord and other tissues [edit]

The pons in the brainstem is a specific region that consists of myelinated axons much like the spinal cord. The thalamus and hypothalamus of the diencephalon also consist of neuron and glial cell tissue with the hypophysis (pituitary gland) and pineal gland (which is glandular tissue) attached at the bottom; tumors of the pituitary and pineal gland are often benign. The medulla oblongata is at the start of the spinal cord and is composed mainly of neuron tissue enveloped in Schwann cells and meninges tissue. The spinal cord is made up of bundles of these axons. Glial cells such as Schwann cells in the periphery or, within the cord itself, oligodendrocytes, wrap themselves around the axon, thus promoting faster transmission of electrical signals and also providing for general maintenance of the environment surrounding the cord, in part by shuttling different compounds around in response to injury or other stimulus.

## Diagnosis [edit]

Most of the brain is separated from the blood by the blood-brain barrier (BBB), which exerts a restrictive control as to which substances are allowed to pass. Therefore, many tracers that reach tumors in the body very easily would only reach brain tumors once there is a disruption of the BBB. Thus the disruption of the BBB, which can be detected by a MRI and CT, is regarded as the main diagnostic indicator for malignant gliomas, meningiomas, and brain metastases.[21]

Although there is no specific or singular clinical symptom or sign for any

A posterior fossa tumor leading to mass effect and midline shift

brain tumors, the presence of a combination of symptoms and the lack of corresponding clinical indications of infections or other causes can be an indicator to redirect diagnostic investigation towards the possibility of an intracranial neoplasm. Brain tumors have similar characteristics and obstacles when it comes to diagnosis and therapy with tumors located elsewhere in the body. However, they create specific issues that follow closely to the properties of the organ they are in.[21]

The diagnosis will often start by taking a medical history noting medical antecedents, and current symptoms. Clinical and laboratory investigations will serve to exclude infections as the cause of the symptoms. Examinations in this stage may include the eyes, otolaryngological (or ENT) and electrophysiological exams. The use of electroencephalography (EEG) often plays a role in the diagnosis of brain tumors.

Swelling, or obstruction of the passage of cerebrospinal fluid (CSF) from the brain may cause (early) signs of increased intracranial pressure which translates clinically into headaches, vomiting, or an altered state of consciousness, and in children changes to the diameter of the skull and bulging of the fontanelles. More complex symptoms such as endocrine dysfunctions should alarm doctors not to exclude brain tumors.

A bilateral temporal visual field defect (due to compression of the optic chiasm) or dilation of the pupil, and the occurrence of either slowly evolving or the sudden onset of focal neurologic symptoms, such as cognitive and behavioral impairment (including impaired judgment, memory loss, lack of recognition, spatial orientation disorders), personality or emotional changes, hemiparesis, hypoesthesia, aphasia, ataxia, visual field impairment, impaired sense of smell, impaired hearing, facial paralysis, double vision, or more severe symptoms such as tremors, paralysis on one side of the body hemiplegia, or (epileptic) seizures in a patient with a negative history for epilepsy, should raise the possibility of a brain tumor.

## Imaging [edit]

Medical imaging plays a central role in the diagnosis of brain tumors. Early imaging methods—invasive and sometimes dangerous— such as pneumoencephalography and cerebral angiography have been abandoned in favor of non-invasive, high-resolution techniques, especially magnetic resonance imaging (MRI) and computed tomography (CT) scans. Neoplasms will often show as differently colored masses (also referred to as processes) in CT or MRI results.

- Benign brain tumors often show up as hypodense (darker than brain tissue) mass lesions on CT scans. On MRI, they appear either hypodense or isointense (same intensity as brain tissue) on T1-weighted scans, or hyperintense (brighter than brain tissue) on T2-weighted MRI, although the appearance is variable.
- Contrast agent uptake, sometimes in characteristic patterns, can be demonstrated on either CT or MRI scans in most malignant primary and metastatic brain tumors.
- Pressure areas where the brain tissue has been compressed by a tumor also appear hyperintense on T2-weighted scans and might indicate the presence a diffuse neoplasm due to an unclear outline. Swelling around the tumor known as *peritumoral edema* can also show a similar result.

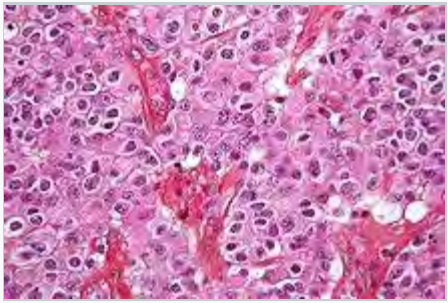
This is because these tumors disrupt the normal functioning of the BBB and lead to an increase in its permeability. However, it is not possible to diagnose high- versus low-grade gliomas based on enhancement pattern alone.

The definitive diagnosis of brain tumor can only be confirmed by histological examination of tumor tissue samples obtained either by means of brain biopsy or open surgery. The histological examination is essential

for determining the appropriate treatment and the correct prognosis. This examination, performed by a pathologist, typically has three stages: interoperative examination of fresh tissue, preliminary microscopic examination of prepared tissues, and follow-up examination of prepared tissues after immunohistochemical staining or genetic analysis.

## Pathology [edit]

Tumors have characteristics that allow determination of malignacy and how they will evolve, and determining these characteristics will allow the medical team to determine the management plan.



Micrograph of an oligodendroglioma, a type of brain cancer. Brain biopsy. H&E stain.

Anaplasia or dedifferentiation: loss of differentiation of cells and of their orientation to one another and blood vessels, a characteristic of anaplastic tumor tissue. Anaplastic cells have lost total control of their normal functions and many have deteriorated cell structures. Anaplastic cells often have abnormally high nuclear-to-cytoplasmic ratios, and many are multinucleated. Additionally, the nuclei of anaplastic cells are usually unnaturally shaped or oversized. Cells can become anaplastic in two ways: neoplastic tumor cells can dedifferentiate to become anaplasias (the dedifferentiation causes the cells to lose all of their normal structure/function), or cancer stem cells can increase in their capacity to multiply (i.e., uncontrollable growth due to failure of differentiation).

Atypia: an indication of abnormality of a cell (which may be indicative for malignancy). Significance of the abnormality is highly dependent on context.

Neoplasia: the (uncontrolled) division of cells. As such, neoplasia is not problematic but its consequences are: the uncontrolled division of cells means that the mass of a neoplasm increases in size, and in a confined space such as the intracranial cavity this quickly becomes problematic because the mass invades the space of the brain pushing it aside, leading to compression of the brain tissue and increased intracranial pressure and destruction of brain parenchyma. Increased intracranial pressure (ICP) may be attributable to the direct mass effect of the tumor, increased blood volume, or increased cerebrospinal fluid (CSF) volume, which may in turn have secondary symptoms.

Necrosis: the (premature) death of cells, caused by external factors such as infection, toxin or trauma. Necrotic cells send the wrong chemical signals which prevents phagocytes from disposing of the dead cells, leading to a buildup of dead tissue, cell debris and toxins at or near the site of the necrotic cells[22]

Arterial and venous hypoxia, or the deprivation of adequate oxygen supply to certain areas of the brain, occurs when a tumor makes use of nearby blood vessels for its supply of blood and the neoplasm enters into competition for nutrients with the surrounding brain tissue.

More generally a neoplasm may cause release of metabolic end products (e.g., free radicals, altered electrolytes, neurotransmitters), and release and recruitment of cellular mediators (e.g., cytokines) that disrupt normal parenchymal function.

## Classification [edit]

## Secondary brain tumors [edit]

Secondary tumors of the brain are metastatic and have invaded the brain from cancers originating in other organs. This means that a cancerous neoplasm has developed in another organ elsewhere in the body and that cancer cells have leaked from that primary tumor and then entered the lymphatic system and blood vessels. They then circulate through the bloodstream, and are deposited in the brain. There, these cells continue growing and dividing, becoming another invasive neoplasm of the primary cancer's tissue. Secondary tumors of the brain are very common in the terminal phases of patients with an incurable metastasized cancer; the most common types of cancers that bring about secondary tumors of the brain are lung cancer, breast cancer, malignant melanoma, kidney cancer, and colon cancer (in decreasing order

of frequency).

Secondary brain tumors are more common than primary ones; in the United States there are about 170,000 new cases every year. Secondary brain tumors are the most common cause of tumors in the intracranial cavity. The skull bone structure can also be subject to a neoplasm that by its very nature reduces the volume of the intracranial cavity, and can damage the brain.[23]

## By behavior [edit]

Brain tumors or intracranial neoplasms can be cancerous (malignant) or non-cancerous (benign). However, the definitions of malignant or benign neoplasms differs from those commonly used in other types of cancerous or non-cancerous neoplasms in the body. In cancers elsewhere in the body, three malignant properties differentiate benign tumors from malignant forms of cancer: benign tumors are self-limited and do not invade or metastasize. Characteristics of malignant tumors include:

- uncontrolled mitosis (growth by division beyond the normal limits)
- anaplasia: the cells in the neoplasm have an obviously different form (in size and shape). Anaplastic cells display marked pleomorphism. The cell nuclei are characteristically extremely hyperchromatic (darkly stained) and enlarged; the nucleus might have the same size as the cytoplasm of the cell (nuclear-cytoplasmic ratio may approach 1:1, instead of the normal 1:4 or 1:6 ratio). Giant cells – considerably larger than their neighbors – may form and possess either one enormous nucleus or several nuclei (syncytia). Anaplastic nuclei are variable and bizarre in size and shape.
- invasion or infiltration (medical literature uses these terms as synonymous equivalents. However, for clarity, the articles that follow adhere to a convention that they mean slightly different things; this convention is not followed outside these articles):
  - Invasion or invasiveness is the spatial expansion of the tumor through uncontrolled mitosis, in the sense that the neoplasm invades the space occupied by adjacent tissue, thereby pushing the other tissue aside and eventually compressing the tissue. Often these tumors are associated with clearly outlined tumors in imaging.
  - Infiltration is the behavior of the tumor either to grow (microscopic) tentacles that push into the surrounding tissue (often making the outline of the tumor undefined or diffuse) or to have tumor cells "seeded" into the tissue beyond the circumference of the tumorous mass; this does not mean that an infiltrative tumor does not take up space or does not compress the surrounding tissue as it grows, but an infiltrating neoplasm makes it difficult to say where the tumor ends and the healthy tissue starts.
- metastasis (spread to other locations in the body via lymph or blood).

Of the above malignant characteristics, some elements do not apply to primary neoplasms of the brain:

- Primary brain tumors rarely metastasize to other organs; some forms of primary brain tumors can metastasize but will not spread outside the intracranial cavity or the central spinal canal. Due to the BBB, cancerous cells of a primary neoplasm cannot enter the bloodstream and get carried to another location in the body. (Occasional isolated case reports suggest spread of certain brain tumors outside the central nervous system, e.g. bone metastasis of glioblastoma multiforme.[24])
- Primary brain tumors generally are invasive (i.e. they will expand spatially and intrude into the space occupied by other brain tissue and compress those brain tissues); however, some of the more malignant primary brain tumors will infiltrate the surrounding tissue.

Of numerous grading systems in use for the classification of tumor of the central nervous system, the World Health Organization (WHO) grading system is commonly used for astrocytoma. Established in 1993 in an effort to eliminate confusion regarding diagnoses, the WHO system established a four-tiered histologic grading guideline for astrocytomas that assigns a grade from 1 to 4, with 1 being the least aggressive and 4 being the most aggressive.

## Types [edit]

Tumors can be benign or malignant, can occur in different parts of the brain, and may be primary or secondary. A primary tumor is one that has started in the brain, as opposed to a metastatic tumor, which is something that has spread to the brain from another part of the body.[25] The incidence of metastatic

tumors are more prevalent than primary tumors by 4:1.[26] Tumors may or may not be symptomatic: some tumors are discovered because the patient has symptoms, others show up incidentally on an imaging scan, or at an autopsy.

The most common primary brain tumors are:[27]

- Gliomas (50.4%)
- Meningiomas (20.8%)
- Pituitary adenomas (15%)
- Nerve sheath tumors (8%)

These common tumors can also be organized according to tissue of origin as shown below:[28][*verification needed*]

| Tissue of origin | Children | Adults |
|---|---|---|
| Astrocytes | Pilocytic Astrocytoma (PCA) | Glioblastoma Multiforme (GBM) |
| Oligodendrocytes | | Oligodendroglioma |
| Ependyma | Ependymoma | |
| Neurons | Medulloblastoma | |
| Meninges | | Meningioma |

### Specific types [edit]

*Main article: WHO classification of the tumors of the central nervous system*

Anaplastic astrocytoma, Astrocytoma, Central neurocytoma, Choroid plexus carcinoma, Choroid plexus papilloma, Choroid plexus tumor, Dysembryoplastic neuroepithelial tumour, Ependymal tumor, Fibrillary astrocytoma, Giant-cell glioblastoma, Glioblastoma multiforme, Gliomatosis cerebri, Gliosarcoma, Hemangiopericytoma, Medulloblastoma, Medulloepithelioma, Meningeal carcinomatosis, Neuroblastoma, Neurocytoma, Oligoastrocytoma, Oligodendroglioma, Optic nerve sheath meningioma, Pediatric ependymoma, Pilocytic astrocytoma, Pinealoblastoma, Pineocytoma, Pleomorphic anaplastic neuroblastoma, Pleomorphic xanthoastrocytoma, Primary central nervous system lymphoma, Sphenoid wing meningioma, Subependymal giant cell astrocytoma, Subependymoma, Trilateral retinoblastoma.

## Treatment [edit]

When a brain tumor is diagnosed, a medical team will be formed to assess the treatment options presented by the leading surgeon to the patient and his/her family. Given the location of primary solid neoplasms of the brain in most cases a "do-nothing" option is usually not presented. Neurosurgeons take the time to observe the evolution of the neoplasm before proposing a management plan to the patient and his/her relatives. These various types of treatment are available depending on neoplasm type and location and may be combined to give the best chances of survival:

- Surgery: complete or partial resection of the tumor with the objective of removing as many tumor cells as possible.
- Radiotherapy: the most commonly used treatment for brain tumors; the tumor is irradiated with beta, x rays or gamma rays.
- Chemotherapy: is a treatment option for cancer, however it is not always used to treat brain tumors as the blood-brain barrier can prevent some drugs from reaching the cancerous cells.
- A variety of experimental therapies are available through clinical trials.

Survival rates in primary brain tumors depend on the type of tumor, age, functional status of the patient, the extent of surgical tumor removal and other factors specific to each case.[29]

## Surgery [edit]

The primary and most desired course of action described in medical literature is surgical removal (resection) via craniotomy. Minimally invasive techniques are becoming the dominant trend in neurosurgical oncology.[30] The prime remediating objective of surgery is to remove as many tumor cells as possible, with complete removal being the best outcome and cytoreduction ("debulking") of the tumor otherwise. In some cases access to the tumor is impossible and impedes or prohibits surgery.

Many meningiomas, with the exception of some tumors located at the skull base, can be successfully removed surgically. Most pituitary adenomas can be removed surgically, often using a minimally invasive approach through the nasal cavity and skull base (trans-nasal, trans-sphenoidal approach). Large pituitary adenomas require a craniotomy (opening of the skull) for their removal. Radiotherapy, including stereotactic approaches, is reserved for inoperable cases.

Several current research studies aim to improve the surgical removal of brain tumors by labeling tumor cells with 5-aminolevulinic acid that causes them to fluoresce.[31] Postoperative radiotherapy and chemotherapy are integral parts of the therapeutic standard for malignant tumors. Radiotherapy may also be administered in cases of "low-grade" gliomas, when a significant tumor burden reduction could not be achieved surgically.

Any person undergoing brain surgery may suffer from epileptic seizures. These can take the form of either absence seizures or tonic-clonic seizures. Medication can lessen and sometimes prevent these attacks.

Multiple metastatic tumors are generally treated with radiotherapy and chemotherapy rather than surgery and the prognosis in such cases is determined by the primary tumor, and is generally poor.

## Radiation therapy [edit]

The goal of radiation therapy is to kill tumor cells while leaving normal brain tissue unharmed. In standard external beam radiation therapy, multiple treatments of standard-dose "fractions" of radiation are applied to the brain. This process is repeated for a total of 10 to 30 treatments, depending on the type of tumor. This additional treatment provides some patients with improved outcomes and longer survival rates.

Radiosurgery is a treatment method that uses computerized calculations to focus radiation at the site of the tumor while minimizing the radiation dose to the surrounding brain. Radiosurgery may be an adjunct to other treatments, or it may represent the primary treatment technique for some tumors. Forms used include stereotactic radiosurgery, such as Gamma knife, Cyberknife or Novalis Tx radiosurgery.[32][*unreliable medical source?*]

Radiotherapy may be used following, or in some cases in place of, resection of the tumor. Forms of radiotherapy used for brain cancer include external beam radiation therapy, the most common, and brachytherapy and proton therapy, the last especially used for children.

Radiotherapy is the most common treatment for secondary brain tumors. The amount of radiotherapy depends on the size of the area of the brain affected by cancer. Conventional external beam "whole-brain radiotherapy treatment" (WBRT) or "whole-brain irradiation" may be suggested if there is a risk that other secondary tumors will develop in the future.[33] Stereotactic radiotherapy is usually recommended in cases involving fewer than three small secondary brain tumors.

People who receive stereotactic radiosurgery (SRS) and whole-brain radiation therapy (WBRT) for the treatment of metastatic brain tumors have more than twice the risk of developing learning and memory problems than those treated with SRS alone.[34][35]

## Chemotherapy [edit]

Patients undergoing chemotherapy are administered drugs designed to kill tumor cells. Although chemotherapy may improve overall survival in patients with the most malignant primary brain tumors, it does so in only about 20 percent of patients. Chemotherapy is often used in young children instead of radiation, as radiation may have negative effects on the developing brain. The decision to prescribe this treatment is based on a patient's overall health, type of tumor, and extent of the cancer. The toxicity and

many side effects of the drugs, and the uncertain outcome of chemotherapy in brain tumors puts this treatment further down the line of treatment options with surgery and radiation therapy preferred.

UCLA Neuro-Oncology publishes real-time survival data for patients with a diagnosis of glioblastoma multiforme. They are the only institution in the United States that displays how brain tumor patients are performing on current therapies. They also show a listing of chemotherapy agents used to treat high-grade glioma tumors.[36]

### Other [edit]

A shunt may be used to relieve symptoms caused by intracranial pressure, by reducing the build-up of fluid (hydrocephalus) caused by the blockage of the free flow of cerebrospinal fluid.[37]

## Prognosis [edit]

The prognosis of brain cancer depends on the type of cancer diagnosed. Medulloblastoma has a good prognosis with chemotherapy, radiotherapy, and surgical resection while glioblastoma multiforme has a median survival of only 12 months even with aggressive chemoradiotherapy and surgery. Brainstem gliomas have the poorest prognosis of any form of brain cancer, with most patients dying within one year, even with therapy that typically consists of radiation to the tumor along with corticosteroids. However, one type, focal brainstem gliomas in children, seems open to exceptional prognosis and long-term survival has frequently been reported.[38]

### Glioblastoma multiforme [edit]

*Main article: Glioblastoma multiforme*

Glioblastoma multiforme is the most aggressive (grade IV) and most common form of a malignant brain tumor. Even when aggressive multimodality therapy consisting of radiotherapy, chemotherapy, and surgical excision is used, median survival is only 12–17 months. Standard therapy for glioblastoma multiforme consists of maximal surgical resection of the tumor, followed by radiotherapy between two and four weeks after the surgical procedure to remove the cancer, then by chemotherapy. Most patients with glioblastoma take a corticosteroid, typically dexamethasone, during their illness to relieve symptoms. Experimental treatments include gamma knife radiosurgery,[39] boron neutron capture therapy and gene therapy.[40][41]

### Oligodendrogliomas [edit]

*Main article: Oligodendroglioma*

Oligodendrogliomas are incurable but slowly progressive malignant brain tumors. They can be treated with surgical resection, chemotherapy, radiotherapy or a combination. For some suspected low-grade (grade II) tumors, only a course of watchful waiting and symptomatic therapy is opted for. These tumors show a high frequency of co-deletions of the p and q arms of chromosome 1 and chromosome 19 respectively (1p19q co-deletion) and have been found to be especially chemosensitive with one report claiming them to be one of the most chemosensitive tumors.[42] A median survival of up to 16.7 years has been reported for grade II oligodendrogliomas.[43]

## Epidemiology [edit]

Figures for incidences of cancers of the brain show a significant difference between more- and less-developed countries (the less-developed countries have lower incidences of tumors of the brain),[44]— this could be explained by undiagnosed tumor-related deaths (patients in extreme poor situations do not get diagnosed, simply because they do not have access to the modern diagnostic facilities required to diagnose a brain tumor) and by deaths caused by other poverty-related causes that preempt a patient's life before tumors develop or tumors become life-threatening. Nevertheless, studies[*which?*] suggest that certain forms

of primary brain tumors are more prevalent among certain groups of the population.

The incidence of low-grade astrocytoma has not been shown to vary significantly with nationality. However, studies examining the incidence of malignant central nervous system (CNS) tumors have shown some variation with national origin. Since some high-grade lesions arise from low-grade tumors, these trends are worth mentioning. Specifically, the incidence of CNS tumors in the United States, Israel, and the Nordic countries is relatively high, while Japan and Asian countries have a lower incidence. These differences probably reflect some biological differences as well as differences in pathologic diagnosis and reporting.[45] Worldwide data on incidence of cancer can be found at the WHO (World Health Organisation) and is handled by the IARC (International Agency for Research on Cancer) located in France.[46]

### United States [edit]

For the United States in the year 2005, it was projected that there would be 43,800 new cases of brain tumors[47][48] which accounted for less than 1 percent of all cancers, 2.4 percent of all cancer deaths,[49] and 20–25 percent of pediatric cancers.[49][50] Ultimately, it is estimated there are 13,000 deaths per year in the United States alone as a result of brain tumors.[48]

### UK [edit]

Brain, other CNS or intracranial tumors are the ninth most common cancer in the UK (around 10,600 people were diagnosed in 2013), and it is the eighth most common cause of cancer death (around 5,200 people died in 2012).[51]

## Research [edit]

### Immunotherapy [edit]

Cancer immunotherapy is being actively studied. For malignant gliomas no therapy has been shown to improve life expectancy as of 2015.[52]

### Vesicular stomatitis virus [edit]

*See also: Oncolytic virus*

In 2000, researchers used the vesicular stomatitis virus, or VSV, to infect and kill cancer cells without affecting healthy cells.[53][54]

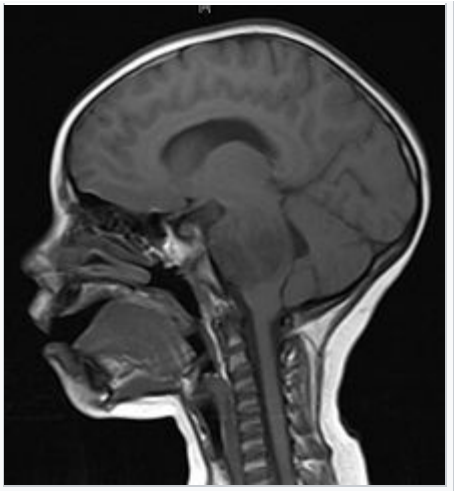
The initial discovery of the virus' oncolytic properties were limited to only a few types of cancer. Several independent studies have identified many more types susceptible to the virus, including glioblastoma multiforme cancer cells, which account for the majority of brain tumors.

In 2008, researchers artificially engineered strains of VSV that were less cytotoxic to normal cells. This advance allows administration of the virus without coadministration with interferon. Consequently, administration of the virus can be given intravenously or through the olfactory nerve. In the research, a human brain tumor was implanted into mice brains.

Research on virus treatment like this has been conducted for some years, but no other viruses have been shown to be as efficient or specific as the VSV mutant strains.

### Retroviral replicating vectors [edit]

Led by Prof. Nori Kasahara, researchers from USC, who are now at UCLA, reported in 2001 the first successful example of applying the use of retroviral replicating vectors towards transducing cell lines derived from solid tumors.[55] Building on this initial work, the researchers applied the technology to *in vivo* models of cancer and in 2005 reported



A brainstem glioma in four-year-old. MRI, sagittal, without contrast

a long-term survival benefit in an experimental brain tumor animal model.[56][*unreliable medical source?*] Subsequently, in preparation for human clinical trials, this technology was further developed by Tocagen (a pharmaceutical company primarily focused on brain cancer treatments) as a combination treatment (Toca 511 & Toca FC). This has been under investigation since 2010 in a Phase I/II clinical trial for the potential treatment of recurrent high-grade glioma including glioblastoma multiforme (GBM) and anaplastic astrocytoma. No results have yet been published.[57]

## Children [edit]

This section needs to be **updated**. Please update this article to reflect recent events or newly available information.
Last update: PMID 23436013 *(July 2014)*

In the USA, about 2,000 children and adolescents younger than 20 years of age are diagnosed with malignant brain tumors each year. Higher incidence rates were reported in 1985–1994 than in 1975–1983. There is some debate as to the reasons; one theory is that the trend is the result of improved diagnosis and reporting, since the jump occurred at the same time that MRIs became available widely, and there was no coincident jump in mortality. The central nervous system cancer survival rate in children is approximately 60%. The rate varies with the type of cancer and the age of onset: younger patients have higher mortality.[58]

In children under 2, about 70% of brain tumors are medulloblastomas, ependymomas, and low-grade gliomas. Less commonly, and seen usually in infants, are teratomas and atypical teratoid rhabdoid tumors.[59] Germ cell tumors, including teratomas, make up just 3% of pediatric primary brain tumors, but the worldwide incidence varies significantly.[60]

In the UK, 429 children aged 14 and under are diagnosed with a brain tumour on average each year, and 563 children and young people under the age of 19 are diagnosed.[61]

## See also [edit]

- Timeline of brain cancer
- List of notable brain tumor patients
- Pituitary adenomas ("pituitary tumours") are sometimes incorrectly referred to as a brain tumours.[62][63] This is perhaps because the pituitary gland is in the skull, however it is not part of the brain. Pituitary adenomas are rarely cancerous.

# Breast cancer

From Wikipedia, the free encyclopedia

**Breast cancer** is cancer that develops from breast tissue.[1] Signs of breast cancer may include a lump in the breast, a change in breast shape, dimpling of the skin, fluid coming from the nipple, or a red scaly patch of skin.[2] In those with distant spread of the disease, there may be bone pain, swollen lymph nodes, shortness of breath, or yellow skin.[3]

Risk factors for developing breast cancer include being female, obesity, lack of physical exercise, drinking alcohol, hormone replacement therapy during menopause, ionizing radiation, early age at first menstruation, having children late or not at all, older age, and family history.[2][4] About 5–10% of cases are due to genes inherited from a person's parents, including BRCA1 and BRCA2 among others. Breast cancer most commonly develops in cells from the lining of milk ducts and the lobules that supply the ducts with milk. Cancers developing from the ducts are known as ductal carcinomas, while those developing from lobules are known as lobular carcinomas.[2] In addition, there are more than 18 other sub-types of breast cancer. Some cancers, such as ductal carcinoma in situ, develop from pre-invasive lesions.[4] The diagnosis of breast cancer is confirmed by taking a biopsy of the concerning lump. Once the diagnosis is made, further tests are done to determine if the cancer has spread beyond the breast and which treatments it may respond to.[2]

The balance of benefits versus harms of breast cancer screening is controversial. A 2013 Cochrane review stated that it is unclear if mammographic screening does more good or harm.[5] A 2009 review for the US Preventive Services Task Force found evidence of benefit in those 40 to 70 years of age,[6] and the organization recommends screening every two years in women 50 to 74 years old.[7] The medications tamoxifen or raloxifene may be used in an effort to prevent breast cancer in those who are at high risk of developing it.[4] Surgical removal of both breasts is another preventative measure in some high risk women.[4] In those who have been diagnosed with cancer, a number of treatments may be used, including surgery, radiation therapy, chemotherapy, hormonal therapy and targeted therapy.[2] Types of surgery vary from breast-conserving surgery to mastectomy.[8][9] Breast reconstruction may take place at the time of surgery or at a later date. In those in whom the cancer has spread to other parts of the body, treatments are mostly aimed at improving quality of life and comfort.[9]

Outcomes for breast cancer vary depending on the cancer type, extent of disease, and person's age.[9] Survival rates in the developed world are high,[10] with between 80% and 90% of those in England and the United States alive for at least 5 years.[11][12] In developing countries survival rates are poorer.[4] Worldwide, breast cancer is the leading type of cancer in women, accounting for 25% of all cases.[13] In 2012 it resulted in 1.68 million cases and 522,000 deaths.[13] It is more common in developed countries[4] and is more than 100 times more common in women than in men.[10][14]

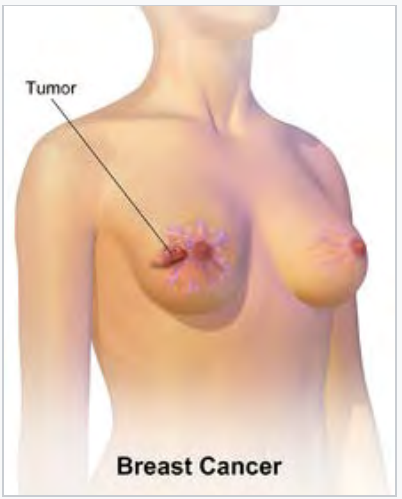
## Signs and symptoms [edit]

The first noticeable symptom of breast cancer is typically a lump that feels different from the rest of the breast tissue. More than 80% of breast cancer cases are discovered when the woman feels a lump.[15] The earliest breast cancers are detected by a mammogram.[16] Lumps found in lymph nodes located in the armpits[15] can also indicate breast cancer.

Indications of breast cancer other than a lump may include thickening different from the other breast tissue, one breast becoming larger or lower, a nipple changing position or shape or becoming inverted, skin puckering or dimpling, a rash on or around a nipple, discharge from nipple/s, constant pain in part of the breast or armpit, and swelling beneath the armpit or around the collarbone.[17] Pain ("mastodynia") is an unreliable tool in determining the presence or absence of breast cancer, but may be indicative of other breast health issues.[15][16][18]

Inflammatory breast cancer is a particular type of breast cancer which can pose a substantial diagnostic challenge. Symptoms may resemble a breast inflammation and may include itching, pain, swelling, nipple inversion, warmth and redness throughout the breast, as well as an orange-peel texture to the skin referred to as *peau d'orange*.[15] As inflammatory breast cancer does not present as a lump there can sometimes be a delay in diagnosis.

Another reported symptom complex of breast cancer is Paget's disease of the



Breast cancer

Breast cancer showing an inverted nipple, lump, and skin dimpling.

breast. This syndrome presents as skin changes resembling eczema, such as redness, discoloration, or mild flaking of the nipple skin. As Paget's disease of the breast advances, symptoms may include tingling, itching, increased sensitivity, burning, and pain. There may also be discharge from the nipple. Approximately half of women diagnosed with Paget's disease of the breast also have a lump in the breast.[19]

In rare cases, what initially appears as a fibroadenoma (hard, movable non-cancerous lump) could in fact be a phyllodes tumor. Phyllodes tumors are formed within the stroma (connective tissue) of the breast and contain glandular as well as stromal tissue. Phyllodes tumors are not staged in the usual sense; they are classified on the basis of their appearance under the microscope as benign, borderline, or malignant.[20]

Occasionally, breast cancer presents as metastatic disease—that is, cancer that has spread beyond the original organ. The symptoms caused by metastatic breast cancer will depend on the location of metastasis. Common sites of metastasis include bone, liver, lung and brain.[21] Unexplained weight loss can occasionally signal breast cancer, as can symptoms of fevers or chills. Bone or joint pains can sometimes be manifestations of metastatic breast cancer, as can jaundice or neurological symptoms. These symptoms are called *non-specific*, meaning they could be manifestations of many other illnesses.[22]

Most symptoms of breast disorders, including most lumps, do not turn out to represent underlying breast cancer. Fewer than 20% of lumps, for example, are cancerous,[23] and benign breast diseases such as mastitis and fibroadenoma of the breast are more common causes of breast disorder symptoms. Nevertheless, the appearance of a new symptom should be taken seriously by both patients and their doctors, because of the possibility of an underlying breast cancer at almost any age.[24]

## Risk factors [edit]

*Main article: Risk factors of breast cancer*

Risk factors can be divided into two categories:

- *modifiable* risk factors (things that people can change themselves, such as consumption of alcoholic beverages), and
- *fixed* risk factors (things that cannot be changed, such as age and biological sex).[25]

The primary risk factors for breast cancer are being female and older age.[26] Other potential risk factors include genetics,[27] lack of childbearing or lack of breastfeeding,[28] higher levels of certain hormones,[29][30] certain dietary patterns, and obesity. Recent studies have indicated that exposure to light pollution is a risk factor for the development of breast cancer.[31]

### Lifestyle [edit]

*See also: List of breast carcinogenic substances*

Smoking tobacco appears to increase the risk of breast cancer, with the greater the amount smoked and the earlier in life that smoking began, the higher the risk.[32] In those who are long-term smokers, the risk is increased 35% to 50%.[32] A lack of physical activity has been linked to about 10% of cases.[33] Sitting regularly for prolonged periods is associated with higher mortality from breast cancer. The risk is not negated by regular exercise, though it is lowered.[34]

There is an association between use of hormonal birth control and the development of premenopausal breast cancer,[25][35] but whether oral contraceptives use may actually cause premenopausal breast cancer is a matter of debate.[36] If there is indeed a link, the absolute effect is small.[36][37] Additionally, it is not clear if the association exists with newer hormonal birth controls.[37] In those with mutations in the breast cancer susceptibility genes *BRCA1* or *BRCA2*, or who have a family history of breast cancer, use of modern oral contraceptives does not appear to affect the risk of breast cancer.[38][39]

The association between breast feeding and breast cancer has not been clearly determined; some studies have found support for an association while others have not.[40] In the 1980s, the abortion–breast cancer hypothesis posited that induced abortion increased the risk of developing breast cancer.[41] This hypothesis was the subject of

extensive scientific inquiry, which concluded that neither miscarriages nor abortions are associated with a heightened risk for breast cancer.[42]

A number of dietary factors have been linked to the risk for breast cancer. Dietary factors which may increase risk include a high fat diet,[43] high alcohol intake,[44] and obesity-related high cholesterol levels.[45][46] Dietary iodine deficiency may also play a role.[47] Evidence for fiber is unclear. A 2015 review found that studies trying to link fiber intake with breast cancer produced mixed results.[48] In 2016 a tentative association between low fiber intake during adolescence and breast cancer was observed.[49]

Other risk factors include radiation[50] and shift-work.[51] A number of chemicals have also been linked, including polychlorinated biphenyls, polycyclic aromatic hydrocarbons, organic solvents[52] Although the radiation from mammography is a low dose, it is estimated that yearly screening from 40 to 80 years of age will cause approximately 225 cases of fatal breast cancer per million women screened.[53]

### Genetics [edit]

Some genetic susceptibility may play a minor role in most cases.[54] Overall, however, genetics is believed to be the primary cause of 5–10% of all cases.[55] Women whose mother was diagnosed before 50 have an increased risk of 1.7 and those whose mother was diagnosed at age 50 or after has an increased risk of 1.4.[56] In those with zero, one or two affected relatives, the risk of breast cancer before the age of 80 is 7.8%, 13.3%, and 21.1% with a subsequent mortality from the disease of 2.3%, 4.2%, and 7.6% respectively.[57] In those with a first degree relative with the disease the risk of breast cancer between the age of 40 and 50 is double that of the general population.[58]

In less than 5% of cases, genetics plays a more significant role by causing a hereditary breast–ovarian cancer syndrome.[54] This includes those who carry the *BRCA1* and *BRCA2* gene mutation.[54] These mutations account for up to 90% of the total genetic influence with a risk of breast cancer of 60–80% in those affected.[55] Other significant mutations include *p53* (Li–Fraumeni syndrome), *PTEN* (Cowden syndrome), and *STK11* (Peutz–Jeghers syndrome), *CHEK2*, *ATM*, *BRIP1*, and *PALB2*.[55] In 2012, researchers said that there are four genetically distinct types of the breast cancer and that in each type, hallmark genetic changes lead to many cancers.[59]

### Medical conditions [edit]

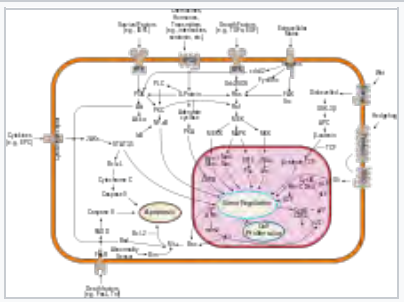
Breast changes like atypical ductal hyperplasia[60] and lobular carcinoma *in situ*,[61][62][63] found in benign breast conditions such as fibrocystic breast changes, are correlated with an increased breast cancer risk. Diabetes mellitus might also increase the risk of breast cancer.[64] Autoimmune diseases such as lupus erythematosus seem also to increase the risk for the acquisition of breast cancer.[65]

## Pathophysiology [edit]

*Main article: Carcinogenesis*

Breast cancer, like other cancers, occurs because of an interaction between an environmental (external) factor and a genetically susceptible host. Normal cells divide as many times as needed and stop. They attach to other cells and stay in place in tissues. Cells become cancerous when they lose their ability to stop dividing, to attach to other cells, to stay where they belong, and to die at the proper time.

Normal cells will commit cell suicide (programmed cell death) when they are no longer needed. Until then, they are protected from cell suicide by several protein clusters and pathways. One of the protective pathways is the PI3K/AKT pathway; another is the RAS/MEK/ERK pathway. Sometimes the genes along these protective pathways are mutated in a way that turns them permanently "on", rendering the cell incapable of committing suicide when it is no longer needed. This is one of the steps that causes cancer in combination with other mutations. Normally, the PTEN protein turns off the PI3K/AKT pathway when the cell is ready for programmed cell death. In some breast cancers, the gene for the PTEN protein is mutated, so the PI3K/AKT pathway is stuck in the "on" position, and the cancer cell does not commit suicide.[66]



Overview of signal transduction pathways involved in programmed cell death. Mutations leading to loss of this ability can lead to cancer formation.

Mutations that can lead to breast cancer have been experimentally linked to estrogen exposure.[67]

Abnormal growth factor signaling in the interaction between stromal cells and epithelial cells can facilitate malignant cell growth.[68][69] In breast adipose tissue, overexpression of leptin leads to increased cell proliferation and cancer.[70]

In the United States, 10 to 20 percent of people with breast cancer and people with ovarian cancer have a first- or second-degree relative with one of these diseases. The familial tendency to develop these cancers is called hereditary breast–ovarian cancer syndrome. The best known of these, the *BRCA* mutations, confer a lifetime risk of breast cancer of between 60 and 85 percent and a lifetime risk of ovarian cancer of between 15 and 40 percent. Some mutations associated with cancer, such as *p53*, *BRCA1* and *BRCA2*, occur in mechanisms to correct errors in DNA. These mutations are either inherited or acquired after birth. Presumably, they allow further mutations, which allow uncontrolled division, lack of attachment, and metastasis to distant organs.[50][71] However, there is strong evidence of residual risk variation that goes well beyond hereditary *BRCA* gene mutations between carrier families. This is caused by unobserved risk factors.[72] This implicates environmental and other causes as triggers for breast cancers. The inherited mutation in *BRCA1* or *BRCA2* genes can interfere with repair of DNA cross links and DNA double strand breaks (known functions of the encoded protein).[73] These carcinogens cause DNA damage such as DNA cross links and double strand breaks that often require repairs by pathways containing BRCA1 and BRCA2.[74][75] However, mutations in *BRCA* genes account for only 2 to 3 percent of all breast cancers.[76] Levin *et al.* say that cancer may not be inevitable for all carriers of *BRCA1* and *BRCA2* mutations.[77] About half of hereditary breast–ovarian cancer syndromes involve unknown genes.

GATA-3 directly controls the expression of estrogen receptor (ER) and other genes associated with epithelial differentiation, and the loss of GATA-3 leads to loss of differentiation and poor prognosis due to cancer cell invasion and metastasis.[78]

## Diagnosis [edit]

Most types of breast cancer are easy to diagnose by microscopic analysis of a sample—or biopsy—of the affected area of the breast. Also, there are types of breast cancer that require specialized lab exams.

The two most commonly used screening methods, physical examination of the breasts by a healthcare provider and mammography, can offer an approximate likelihood that a lump is cancer, and may also detect some other lesions, such as a simple cyst.[79] When these examinations are inconclusive, a healthcare provider can remove a sample of the fluid in the lump for microscopic analysis (a procedure known as fine needle aspiration, or fine needle aspiration and cytology—FNAC) to help establish the diagnosis. The needle aspiration may be performed in a healthcare provider's office or clinic using local anaesthetic if required.[*clarification needed*] A finding of clear fluid makes the lump highly unlikely to be cancerous, but bloody fluid may be sent off for inspection under a microscope for cancerous cells. Together, physical examination of the breasts, mammography, and FNAC can be used to diagnose breast cancer with a good degree of accuracy.

Other options for biopsy include a core biopsy or vacuum-assisted breast biopsy,[80] which are procedures in which a section of the breast lump is removed; or an excisional biopsy, in which the entire lump is removed. Very often the results of physical examination by a healthcare provider, mammography, and additional tests that may be performed in special circumstances (such as imaging by ultrasound or MRI) are sufficient to warrant excisional biopsy as the definitive diagnostic and primary treatment method.

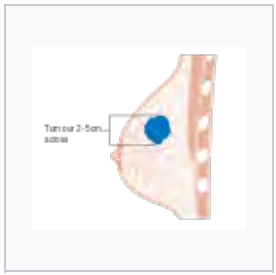
## Classification [edit]

*Main article: Breast cancer classification*

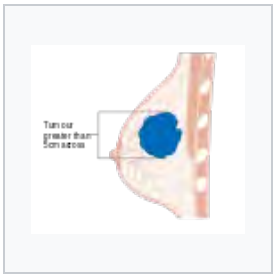
Breast cancers are classified by several grading systems. Each of these influences the prognosis and can affect treatment response. Description of a breast cancer optimally includes all of these factors.

- **Histopathology**. Breast cancer is usually classified primarily by its histological appearance. Most breast cancers are derived from the epithelium lining the ducts or lobules, and these cancers are classified as ductal or lobular carcinoma. *Carcinoma in situ* is growth of low-grade cancerous or precancerous cells within a particular tissue compartment such as the mammary duct without invasion of the surrounding tissue. In contrast, *invasive carcinoma* does not confine itself to the initial tissue compartment.[81]
- **Grade**. Grading compares the appearance of the breast cancer cells to the appearance of normal breast tissue. Normal cells in an organ like the breast become differentiated, meaning that they take on specific shapes and forms that reflect their function as part of that organ. Cancerous cells lose that differentiation. In cancer, the cells that would normally line up in an orderly way to make up the milk ducts become disorganized. Cell division becomes uncontrolled. Cell nuclei become less uniform. Pathologists describe cells as well differentiated (low grade), moderately differentiated (intermediate grade), and poorly differentiated (high grade) as the cells progressively lose the features seen in normal breast cells. Poorly differentiated cancers (the ones whose tissue is least like normal breast tissue) have a worse prognosis.
- **Stage**. Breast cancer staging using the TNM system is based on the size of the tumor (**T**), whether or not the tumor has spread to the lymph nodes (**N**) in the armpits, and whether the tumor has metastasized (**M**) (i.e. spread to a more distant part of the body). Larger size, nodal spread, and metastasis have a larger stage number and a worse prognosis.
  The main stages are:
  - Stage 0 is a pre-cancerous or marker condition, either ductal carcinoma in situ (DCIS) or lobular carcinoma in situ (LCIS).
  - Stages 1–3 are within the breast or regional lymph nodes.
  - Stage 4 is 'metastatic' cancer that has a less favorable prognosis since it has spread beyond the breast and regional lymph nodes.

Stage T1 breast cancer



Stage T2 breast cancer



Stage T3 breast cancer

Where available, imaging studies may be employed as part of the staging process in select cases to look for signs of metastatic cancer. However, in cases of breast cancer with low risk for metastasis, the risks associated

with PET scans, CT scans, or bone scans outweigh the possible benefits, as these procedures expose the patient to a substantial amount of potentially dangerous ionizing radiation.[82][83]

- **Receptor status**. Breast cancer cells have receptors on their surface and in their cytoplasm and nucleus. Chemical messengers such as hormones bind to receptors, and this causes changes in the cell. Breast cancer cells may or may not have three important receptors: estrogen receptor (ER), progesterone receptor (PR), and HER2.
  ER+ cancer cells (that is, cancer cells that have estrogen receptors) depend on estrogen for their growth, so they can be treated with drugs to block estrogen effects (e.g. tamoxifen), and generally have a better prognosis. Untreated, HER2+ breast cancers are generally more aggressive than HER2- breast cancers,[84][85] but HER2+ cancer cells respond to drugs such as the monoclonal antibody trastuzumab (in combination with conventional chemotherapy), and this has improved the prognosis significantly.[86] Cells that do not have any of these three receptor types (estrogen receptors, progesterone receptors, or HER2) are called triple-negative, although they frequently do express receptors for other hormones, such as androgen receptor and prolactin receptor.
- **DNA assays**. DNA testing of various types including DNA microarrays have compared normal cells to breast cancer cells. The specific changes in a particular breast cancer can be used to classify the cancer in several ways, and may assist in choosing the most effective treatment for that DNA type.

Stage 1A breast cancer

Stage 1B breast cancer

Stage 3B breast cancer

Stage 4 breast cancer

## Prevention [edit]

### Life-style [edit]

Women may reduce their risk of breast cancer by maintaining a healthy weight, drinking less alcohol, being physically active and breastfeeding their children.[87] These modifications might prevent 38% of breast cancers in the US, 42% in the UK, 28% in Brazil and 20% in China.[87] The benefits with moderate exercise such as brisk

walking are seen at all age groups including postmenopausal women.[87][88] High levels of physical activity reduce the risk of breast cancer by about 14%.[89] Strategies that encourage regular physical activity and reduce obesity could also have other benefits, such as reduced risks of cardiovascular disease and diabetes.[25]

High intake of citrus fruit has been associated with a 10% reduction in the risk of breast cancer.[90]

Marine omega-3 polyunsaturated fatty acids appear to reduce the risk.[91] High consumption of soy-based foods may reduce risk.[92]

### Pre-emptive surgery [edit]

Removal of both breasts before any cancer has been diagnosed or any suspicious lump or other lesion has appeared (a procedure known as prophylactic bilateral mastectomy) may be considered in people with BRCA1 and BRCA2 mutations, which are associated with a substantially heightened risk for an eventual diagnosis of breast cancer.[93][94] Evidence is not strong enough to support this procedure in anyone but those at the highest risk.[95] BRCA testing is recommended in those with a high family risk after genetic counseling. It is not recommended routinely.[96] This is because there are many forms of changes in *BRCA* genes, ranging from harmless polymorphisms to obviously dangerous frameshift mutations. The effect of most of the identifiable changes in the genes is uncertain. Testing in an average-risk person is particularly likely to return one of these indeterminate, useless results. It is unclear if removing the second breast in those who have breast cancer in one is beneficial.[95]

### Medications [edit]

The selective estrogen receptor modulators (such as tamoxifen) reduce the risk of breast cancer but increase the risk of thromboembolism and endometrial cancer.[97][97] There is no overall change in the risk of death.[97][98] They are thus not recommended for the prevention of breast cancer in women at average risk but may be offered for those at high risk.[99] The benefit of breast cancer reduction continues for at least five years after stopping a course of treatment with these medications.[100]

## Screening [edit]

*Main article: Breast cancer screening*

Breast cancer screening refers to testing otherwise-healthy women for breast cancer in an attempt to achieve an earlier diagnosis under the assumption that early detection will improve outcomes. A number of screening tests have been employed including clinical and self breast exams, mammography, genetic screening, ultrasound, and magnetic resonance imaging.

A mobile breast cancer screening unit in New Zealand

A clinical or self breast exam involves feeling the breast for lumps or other abnormalities. Clinical breast exams are performed by health care providers, while self-breast exams are performed by the person themselves.[101] Evidence does not support the effectiveness of either type of breast exam, as by the time a lump is large enough to be found it is likely to have been growing for several years and thus soon be large enough to be found without an exam.[102][103] Mammographic screening for breast cancer uses X-rays to examine the breast for any uncharacteristic masses or lumps. During a screening, the breast is compressed and a technician takes photos from multiple angles. A general mammogram takes photos of the entire breast, while a diagnostic mammogram focuses on a specific lump or area of concern.[104]

A number of national bodies recommend breast cancer screening. For the average woman, the U.S. Preventive Services Task Force recommends mammography every two years in women between the ages of 50 and 74,[7] the Council of Europe recommends mammography between 50 and 69 with most programs using a 2-year frequency,[105] and in Canada screening is recommended between the ages of 50 and 74 at a frequency of 2 to 3 years.[106] These task force reports point out that in addition to unnecessary surgery and anxiety, the risks of more frequent mammograms include a small but significant increase in breast cancer induced by radiation.[107]

The Cochrane collaboration (2013) states that the best quality evidence neither demonstrates a reduction in cancer specific, nor a reduction in all cause mortality from screening mammography.[5] When less rigorous trials are added to the analysis there is a reduction in mortality due to breast cancer of 0.05% (a decrease of 1 in 2000 deaths from breast cancer over 10 years or a relative decrease of 15% from breast cancer).[5] Screening over 10 years results in a 30% increase in rates of over-diagnosis and over-treatment (3 to 14 per 1000) and more than

half will have at least one falsely positive test.[5][108][109] This has resulted in the view that it is not clear whether mammography screening does more good or harm.[5] Cochrane states that, due to recent improvements in breast cancer treatment, and the risks of false positives from breast cancer screening leading to unnecessary treatment, "it therefore no longer seems beneficial to attend for breast cancer screening" at any age.[110] Whether MRI as a screening method has greater harms or benefits when compared to standard mammography is not known.[111]

# Management [edit]

*Main article: Breast cancer management*

The management of breast cancer depends on various factors, including the stage of the cancer and the age of the patient. Increasingly aggressive treatments are employed in accordance with the poorer the patient's prognosis and the higher the risk of recurrence of the cancer following treatment.

Breast cancer is usually treated with surgery, which may be followed by chemotherapy or radiation therapy, or both. A multidisciplinary approach is preferable.[112] Hormone receptor-positive cancers are often treated with hormone-blocking therapy over courses of several years. Monoclonal antibodies, or other immune-modulating treatments, may be administered in certain cases of metastatic and other advanced stages of breast cancer.

## Surgery [edit]

Surgery involves the physical removal of the tumor, typically along with some of the surrounding tissue. One or more lymph nodes may be biopsied during the surgery; increasingly the lymph node sampling is performed by a sentinel lymph node biopsy.

Standard surgeries include:

- Mastectomy: Removal of the whole breast.
- Quadrantectomy: Removal of one-quarter of the breast.
- Lumpectomy: Removal of a small part of the breast.

Once the tumor has been removed, if the patient desires, breast reconstruction surgery, a type of plastic surgery, may then be performed to improve the aesthetic appearance of the treated site. Alternatively, women use breast prostheses to simulate a breast under clothing, or choose a flat chest. Nipple prosthesis can be used at any time following the mastectomy.

Chest after right breast mastectomy

## Medication [edit]

Drugs used after and in addition to surgery are called adjuvant therapy. Chemotherapy or other types of therapy prior to surgery are called neoadjuvant therapy. Aspirin may reduce mortality from breast cancer.[113]

There are currently three main groups of medications used for adjuvant breast cancer treatment: hormone-blocking agents, chemotherapy, and monoclonal antibodies.

### Hormone blocking therapy

Some breast cancers require estrogen to continue growing. They can be identified by the presence of estrogen receptors (ER+) and progesterone receptors (PR+) on their surface (sometimes referred to together as hormone receptors). These ER+ cancers can be treated with drugs that either block the receptors, e.g. tamoxifen, or alternatively block the production of estrogen with an aromatase inhibitor, e.g. anastrozole[114] or letrozole. The use of tamoxifen is recommended for 10 years.[115] Letrozole is recommended for 5 years. Aromatase inhibitors are only suitable for women after menopause; however, in this group, they appear better than tamoxifen.[116] This is because the active aromatase in postmenopausal women is different from the prevalent form in premenopausal women, and therefore these agents are ineffective in inhibiting the predominant aromatase of premenopausal women.[117] Aromatase inhibitors should not be given to premenopausal women with intact ovarian function (unless they are also on treatment to stop their ovaries from working).[118]

### Chemotherapy

Chemotherapy is predominantly used for cases of breast cancer in stages 2–4, and is particularly beneficial in estrogen receptor-negative (ER-) disease. The chemotherapy medications are administered in combinations, usually for periods of 3–6 months. One of the most common regimens, known as "AC", combines cyclophosphamide with doxorubicin. Sometimes a taxane drug, such as docetaxel, is added, and the regime is

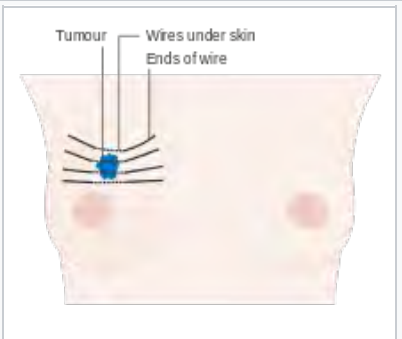
then known as "CAT". Another common treatment is cyclophosphamide, methotrexate, and fluorouracil (or "CMF"). Most chemotherapy medications work by destroying fast-growing and/or fast-replicating cancer cells, either by causing DNA damage upon replication or by other mechanisms. However, the medications also damage fast-growing normal cells, which may cause serious side effects. Damage to the heart muscle is the most dangerous complication of doxorubicin, for example.

### Monoclonal antibodies

Trastuzumab, a monoclonal antibody to HER2 (a cell receptor that is especially active in some breast cancer cells), has improved the 5-year disease free survival of stage 1–3 HER2-positive breast cancers to about 87% (overall survival 95%).[119] When stimulated by certain growth factors, HER2 causes cellular growth and division; in the absence of stimulation by the growth factor, the cell will normally stop growing. Between 25% and 30% of breast cancers overexpress the HER2 gene or its protein product,[120] and overexpression of HER2 in breast cancer is associated with increased disease recurrence and worse prognosis. When trastuzumab binds to the HER2 in breast cancer cells that overexpress the receptor, trastuzumab prevents growth factors from being able to bind to and stimulate the receptors, effectively blocking the growth of the cancer cells. Trastuzumab, however, is very expensive, and its use may cause serious side effects (approximately 2% of patients who receive it suffer significant heart damage).[121] Further, trastuzumab is only effective in patients with HER2 amplification/overexpression.

## Radiation [edit]

Radiotherapy is given after surgery to the region of the tumor bed and regional lymph nodes, to destroy microscopic tumor cells that may have escaped surgery. It may also have a beneficial effect on tumor microenvironment.[122][123] Radiation therapy can be delivered as external beam radiotherapy or as brachytherapy (internal radiotherapy). Conventionally radiotherapy is given *after* the operation for breast cancer. Radiation can also be given at the time of operation on the breast cancer. Radiation can reduce the risk of recurrence by 50–66% (1/2 – 2/3 reduction of risk) when delivered in the correct dose[124] and is considered essential when breast cancer is treated by removing only the lump (Lumpectomy or Wide local excision).



Internal radiotherapy for breast cancer

Breasts after double mastectomy followed by nipple-sparing reconstruction with implants

## Prognosis [edit]

Prognosis is usually given for the probability of progression-free survival (PFS) or disease-free survival (DFS). These predictions are based on experience with breast cancer patients with similar classification. A prognosis is an estimate, as patients with the same classification will survive a different amount of time, and classifications are not always precise. Survival is usually calculated as an average number of months (or years) that 50% of patients survive, or the percentage of patients that are alive after 1, 5, 15, and 20 years. Prognosis is important for treatment decisions because patients with a good prognosis are usually offered less invasive treatments, such as lumpectomy and radiation or hormone therapy, while patients with poor prognosis are usually offered more aggressive treatment, such as more extensive mastectomy and one or more chemotherapy drugs.

## Prognostic factors [edit]

Prognostic factors are reflected in the classification scheme for breast cancer including stage, (i.e., tumor size, location, whether disease has spread to lymph nodes and other parts of the body), grade, recurrence of the disease, and the age and health of the patient. The Nottingham Prognostic Index is a commonly used prognostic tool.

The stage of the breast cancer is the most important component of traditional classification methods of breast cancer, because it has a greater effect on the prognosis than the other considerations. Staging takes into consideration size, local involvement, lymph node status and whether metastatic disease is present. The higher the stage at diagnosis, the poorer the prognosis. The stage is raised by the invasiveness of disease to lymph nodes, chest wall, skin or beyond, and the aggressiveness of the cancer cells. The stage is lowered by the presence of cancer-free zones and close-to-normal cell behaviour

An example of an advanced recurrent breast cancer with an ulcerating axillary mass

(grading). Size is not a factor in staging unless the cancer is invasive. For example, Ductal Carcinoma In Situ (DCIS) involving the entire breast will still be stage zero and consequently an excellent prognosis with a 10-year disease free survival of about 98%.[125]

- Stage 1 cancers (and DCIS, LCIS) have an excellent prognosis and are generally treated with lumpectomy and sometimes radiation.[126] HER2+ cancers should be treated with the trastuzumab (Herceptin) regime.[127] Chemotherapy is uncommon for other types of stage 1 cancers.
- Stage 2 and 3 cancers with a progressively poorer prognosis and greater risk of recurrence are generally treated with surgery (lumpectomy or mastectomy with or without lymph node removal), chemotherapy (plus trastuzumab for HER2+ cancers) and sometimes radiation (particularly following large cancers, multiple positive nodes or lumpectomy).
- Stage 4, metastatic cancer, (i.e. spread to distant sites) has poor prognosis and is managed by various combination of all treatments from surgery, radiation, chemotherapy and targeted therapies. Ten-year survival rate is 5% without treatment and 10% with optimal treatment.[128]

The breast cancer grade is assessed by comparison of the breast cancer cells to normal breast cells. The closer to normal the cancer cells are, the slower their growth and the better the prognosis. If cells are not well differentiated, they will appear immature, will divide more rapidly, and will tend to spread. Well differentiated is given a grade of 1, moderate is grade 2, while poor or undifferentiated is given a higher grade of 3 or 4 (depending upon the scale used). The most widely used grading system is the Nottingham scheme;[129] details are provided in the discussion of breast cancer grade.

The presence of estrogen and progesterone receptors in the cancer cell is important in guiding treatment. Those who do not test positive for these specific receptors will not be able to respond to hormone therapy, and this can affect their chance of survival depending upon what treatment options remain, the exact type of cancer, and how advanced the disease is.

In addition to hormone receptors, there are other cell surface proteins that may affect prognosis and treatment. HER2 status directs the course of treatment. Patients whose cancer cells are positive for HER2 have a more aggressive disease and may be treated with the 'targeted therapy', trastuzumab (Herceptin), a monoclonal antibody that targets this protein and improves the prognosis significantly.

Younger women with an age of less than 40 years or women over 80 years tend to have a poorer prognosis than post-menopausal women due to several factors. Their breasts may change with their menstrual cycles, they may be nursing infants, and they may be unaware of changes in their breasts. Therefore, younger women are usually at a more advanced stage when diagnosed. There may also be biologic factors contributing to a higher risk of disease recurrence for younger women with breast cancer.[130][131]

High mammographic breast density, which is a marker of increased risk of developing breast cancer, may not mean an increased risk of death among breast cancer patients, according to a 2012 report of a study involving 9232 women by the National Cancer Institute (NCI).[132] On the other hand, more recent research has shown that women with extremely low mammographic densities (<10%) hold a significantly worse prognosis compared to women with other densities, irrespective of all possible confounding factors.[133]

Since breast cancer in males is usually detected at later stages, outcomes are typically worse.[134]

## Psychological aspects [edit]

The emotional impact of cancer diagnosis, symptoms, treatment, and related issues can be severe. Most larger hospitals are associated with cancer support groups which provide a supportive environment to help patients cope and gain perspective from cancer survivors.

Not all breast cancer patients experience their illness in the same manner. Factors such as age can have a significant impact on the way a patient copes with a breast cancer diagnosis. Premenopausal women with estrogen-receptor positive breast cancer must confront the issues of early menopause induced by many of the

chemotherapy regimens used to treat their breast cancer, especially those that use hormones to counteract ovarian function.[135]

On the other hand, a small 2007 study conducted by researchers at the College of Public Health of the University of Georgia suggested a need for greater attention to promoting functioning and psychological well-being among older cancer survivors, even when they may not have obvious cancer-related medical complications.[136] The study found that older breast cancer survivors showed multiple indications of decrements in their health-related quality of life, and lower psychosocial well-being than a comparison group. Survivors reported no more depressive symptoms or anxious mood than the comparison group, however, they did score lower on measures of positive psychosocial well-being and reported more depressed mood and days affected by fatigue. As the incidence of breast cancer in women over 50 rises and survival rates increase, breast cancer is increasingly becoming a geriatric issue that warrants both further research and the expansion of specialized cancer support services tailored for specific age groups.[136]

## Epidemiology [edit]

*Main article: Epidemiology of breast cancer*

Worldwide, breast cancer is the most common invasive cancer in women.[138] It affects about 12% of women worldwide.[138] (The most common form of cancer is non-invasive non-melanoma skin cancer; non-invasive cancers are generally easily cured, cause very few deaths, and are routinely excluded from cancer statistics.) Breast cancer comprises 22.9% of invasive cancers in women[139] and 16% of all female cancers.[140] In 2012, it comprised 25.2% of cancers diagnosed in women, making it the most common female cancer.[141]

Age-standardized death from breast cancer per 100,000 inhabitants in 2004.[137]

| | |
|---|---|
| no data | 12–14 |
| <2 | 14–16 |
| 2–4 | 16–18 |
| 4–6 | 18–20 |
| 6–8 | 20–22 |
| 8–10 | >22 |
| 10–12 | |

In 2008, breast cancer caused 458,503 deaths worldwide (13.7% of cancer deaths in women and 6.0% of all cancer deaths for men and women together).[139] Lung cancer, the second most common cause of cancer-related death in women, caused 12.8% of cancer deaths in women (18.2% of all cancer deaths for men and women together).[139]

The incidence of breast cancer varies greatly around the world: it is lowest in less-developed countries and greatest in the more-developed countries. In the twelve world regions, the annual age-standardized incidence rates per 100,000 women are as follows: in Eastern Asia, 18; South Central Asia, 22; sub-Saharan Africa, 22; South-Eastern Asia, 26; North Africa and Western Asia, 28; South and Central America, 42; Eastern Europe, 49; Southern Europe, 56; Northern Europe, 73; Oceania, 74; Western Europe, 78; and in North America, 90.[142]

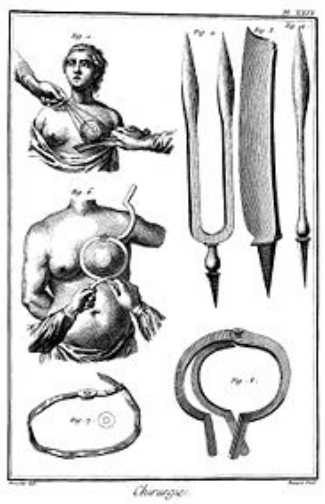
The number of cases worldwide has significantly increased since the 1970s, a phenomenon partly attributed to the modern lifestyles.[143][144] Breast cancer is strongly related to age with only 5% of all breast cancers occurring in women under 40 years old.[145] There were more than 41,000 newly diagnosed cases of breast cancer registered in England in 2011, around 80% of these cases were in women age 50 or older [146] Based on U.S. statistics in 2015 there were 2.8 million women affected by breast cancer.[138]

## History [edit]

It has been suggested that this section be split out into another article titled *History of breast cancer*. (Discuss) *(December 2015)*

Because of its visibility, breast cancer was the form of cancer most often described in ancient documents.[147] Because autopsies were rare, cancers of the internal organs were essentially invisible to ancient medicine. Breast cancer, however, could be felt through the skin, and in its advanced state often developed into fungating lesions: the tumor would become necrotic (die from the inside, causing the tumor to appear to break up) and ulcerate through the skin, weeping fetid, dark fluid.[147]

The oldest evidence of breast cancer was discovered in Egypt in 2015 and dates back to the Sixth Dynasty.[148] The study of a woman's remains from the



Breast cancer surgery in 18th century

necropolis of Qubbet el-Hawa showed the typical destructive damage due to metastatic spread.[148] The Edwin Smith Papyrus describes 8 cases of tumors or ulcers of the breast that were treated by cauterization. The writing says about the disease, "There is no treatment."[149] For centuries, physicians described similar cases in their practices, with the same conclusion. Ancient medicine, from the time of the Greeks through the 17th century, was based on humoralism, and thus believed that breast cancer was generally caused by imbalances in the fundamental fluids that controlled the body, especially an excess of black bile.[150] Alternatively, patients often saw it as divine punishment.[151] In the 18th century, a wide variety of medical explanations were proposed, including a lack of sexual activity, too much sexual activity, physical injuries to the breast, curdled breast milk, and various forms of lymphatic blockages, either internal or due to restrictive clothing.[150][152] In the 19th century, the Scottish surgeon John Rodman said that fear of cancer caused cancer, and that this anxiety, learned by example from the mother, accounted for breast cancer's tendency to run in families.[152]

Although breast cancer was known in ancient times, it was uncommon until the 19th century, when improvements in sanitation and control of deadly infectious diseases resulted in dramatic increases in lifespan. Previously, most women had died too young to have developed breast cancer.[152] Additionally, early and frequent childbearing and breastfeeding probably reduced the rate of breast cancer development in those women who did survive to middle age.[152]

Because ancient medicine believed that the cause was systemic, rather than local, and because surgery carried a high mortality rate, the preferred treatments tended to be pharmacological rather than surgical. Herbal and mineral preparations, especially involving the poison arsenic, were relatively common.

Mastectomy for breast cancer was performed at least as early as AD 548, when it was proposed by the court physician Aetios of Amida to Theodora.[147] It was not until doctors achieved greater understanding of the circulatory system in the 17th century that they could link breast cancer's spread to the lymph nodes in the armpit. The French surgeon Jean Louis Petit (1674–1750) and later the Scottish surgeon Benjamin Bell (1749–1806) were the first to remove the lymph nodes, breast tissue, and underlying chest muscle.[153]

Their successful work was carried on by William Stewart Halsted who started performing radical mastectomies in 1882, helped greatly by advances in general surgical technology, such as aseptic technique and anesthesia. The Halsted radical mastectomy often involved removing both breasts, associated lymph nodes, and the underlying chest muscles. This often led to long-term pain and disability, but was seen as necessary in order to prevent the cancer from recurring.[154] Before the advent of the Halsted radical mastectomy, 20-year survival rates were only 10%; Halsted's surgery raised that rate to 50%.[155] Extending Halsted's work, Jerome Urban promoted superradical mastectomies, taking even more tissue, until 1963, when the ten-year survival rates proved equal to the less-damaging radical mastectomy.[154]

Radical mastectomies remained the standard of care in America until the 1970s, but in Europe, breast-sparing procedures, often followed radiation therapy, were generally adopted in the 1950s.[154] One reason for this striking difference in approach may be the structure of the medical professions: European surgeons, descended from the barber surgeon, were held in less esteem than physicians; in America, the surgeon was the king of the medical profession.[154] Additionally, there were far more European women surgeons: Less than one percent of American surgical oncologists were female, but some European breast cancer wards boasted a medical staff that was half female.[154] American health insurance companies also paid surgeons more to perform radical mastectomies than they did to perform more intricate breast-sparing surgeries.[154]

Breast cancer staging systems were developed in the 1920s and 1930s.[154]

During the 1970s, a new understanding of metastasis led to perceiving cancer as a systemic illness as well as a localized one, and more sparing procedures were developed that proved equally effective. Modern chemotherapy developed after World War II.[156]

The French surgeon Bernard Peyrilhe (1737–1804) realized the first experimental transmission of cancer by injecting extracts of breast cancer into an animal.

Prominent women who died of breast cancer include Anne of Austria, the mother of Louis XIV of France; Mary Washington, mother of George, and Rachel Carson, the environmentalist.[157]

The first case-controlled study on breast cancer epidemiology was done by Janet Lane-Claypon, who published a comparative study in 1926 of 500 breast cancer cases and 500 control patients of the same background and lifestyle for the British Ministry of Health.[158]

In the 1980s and 1990s, thousands of women who had successfully completed standard treatment then demanded and received high-dose bone marrow transplants, thinking this would lead to better long-term survival. However, it proved completely ineffective, and 15–20% of women died because of the brutal treatment.[159]

The 1995 reports from the Nurses' Health Study and the 2002 conclusions of the Women's Health Initiative trial conclusively proved that hormone replacement therapy significantly increased the incidence of breast cancer.[159]

## Society and culture [edit]

*See also: Breast cancer awareness and List of people with breast cancer*

Before the 20th century, breast cancer was feared and discussed in hushed tones, as if it were shameful. As little could be safely done with primitive surgical techniques, women tended to suffer silently rather than seeking care. When surgery advanced, and long-term survival rates improved, women began raising awareness of the disease and the possibility of successful treatment. The "Women's Field Army", run by the American Society for the Control of Cancer (later the American Cancer Society) during the 1930s and 1940s was one of the first organized campaigns. In 1952, the first peer-to-peer support group, called "Reach to Recovery", began providing post-mastectomy, in-hospital visits from women who had survived breast cancer.[160]

The breast cancer movement of the 1980s and 1990s developed out of the larger feminist movements and women's health movement of the 20th century.[161] This series of political and educational campaigns, partly inspired by the politically and socially effective AIDS awareness campaigns, resulted in the widespread acceptance of second opinions before surgery, less invasive surgical procedures, support groups, and other advances in patient care.[162]

### Pink ribbon [edit]

*Main article: Pink ribbon*

A pink ribbon is the most prominent symbol of breast cancer awareness. Pink ribbons, which can be made inexpensively, are sometimes sold as fundraisers, much like poppies on Remembrance Day. They may be worn to honor those who have been diagnosed with breast cancer, or to identify products that the manufacturer would like to sell to consumers that are interested in breast cancer—usually white, middle-aged, middle-class and upper-class, educated women.[163]

The pink ribbon is a symbol to show support for breast cancer awareness

The pink ribbon is associated with individual generosity, faith in scientific progress, and a "can-do" attitude. It encourages consumers to focus on the emotionally appealing ultimate vision of a cure for breast cancer, rather than on the fraught path between current knowledge and any future cures.[164]

Wearing or displaying a pink ribbon has been criticized by the opponents of this practice as a kind of slacktivism, because it has no practical positive effect. It has also been criticized as hypocrisy, because some people wear the pink ribbon to show good will towards women with breast cancer, but then oppose these women's practical goals, like patient rights and anti-pollution legislation.[165][166] Critics say that the feel-good nature of pink ribbons and pink consumption distracts society from the lack of progress on preventing and curing breast cancer.[167] It is also criticized for reinforcing gender stereotypes and objectifying women and their breasts.[168] Breast Cancer Action launched the "Think Before You Pink" campaign, and said that businesses have co-opted the pink campaign to promote products that cause breast cancer, such as alcoholic beverages.[169]

### Breast cancer culture [edit]

This section **is written like a personal reflection or opinion essay that states a Wikipedia editor's personal feelings about a topic**. Please help improve it by rewriting it in an encyclopedic style. *(November 2015) (Learn how and when to remove this template message)*

Breast cancer culture, or pink ribbon culture, is the set of activities, attitudes, and values that surround and shape breast cancer in public. The dominant values are selflessness, cheerfulness, unity, and optimism. Appearing to have suffered bravely is the passport into the culture.

The woman with breast cancer is given a cultural template that constrains her emotional and social responses into a socially acceptable discourse: She is to use the emotional trauma of being diagnosed with breast cancer and the suffering of extended treatment to transform herself into a stronger, happier and more sensitive person who is grateful for the opportunity to become a better person. Breast cancer therapy becomes a rite of passage rather than a disease.[170] To fit into this mold, the woman with breast cancer needs to normalize and feminize her appearance, and minimize the disruption that her health issues cause anyone else. Anger, sadness, and negativity must be silenced.[170]

As with most cultural models, people who conform to the model are given social status, in this case as cancer survivors. Women who reject the model are shunned, punished and shamed.[170]

The culture is criticized for treating adult women like little girls, as evidenced by "baby" toys such as pink teddy bears given to adult women.[170]

The primary purposes or goals of breast cancer culture are to maintain breast cancer's dominance as the preëminent women's health issue, to promote the appearance that society is "doing something" effective about breast cancer, and to sustain and expand the social, political, and financial power of breast cancer activists.[171]

### Emphasis [edit]

Compared to other diseases or other cancers, breast cancer receives a proportionately greater share of resources and attention. In 2001 MP Ian Gibson, chairman of the House of Commons of the United Kingdom all party group on cancer stated "The treatment has been skewed by the lobbying, there is no doubt about that. Breast cancer sufferers get better treatment in terms of bed spaces, facilities and doctors and nurses."[172] Breast cancer also receives significantly more media coverage than other, equally prevalent cancers, with a study by Prostate Coalition showing 2.6 breast cancer stories for each one covering cancer of the prostate.[173] Ultimately there is a concern that favoring sufferers of breast cancer with disproportionate funding and research on their behalf may well be costing lives elsewhere.[172] Partly because of its relatively high prevalence and long-term survival rates, research is biased towards breast cancer. Some subjects, such as cancer-related fatigue, have been studied little except in women with breast cancer.

One result of breast cancer's high visibility is that statistical results can sometimes be misinterpreted, such as the claim that one in eight women will be diagnosed with breast cancer during their lives—a claim that depends on the unrealistic assumption that no woman will die of any other disease before the age of 95.[174] This obscures the reality, which is that about ten times as many women will die from heart disease or stroke than from breast cancer.[175]

The emphasis on breast cancer screening may be harming women by subjecting them to unnecessary radiation, biopsies, and surgery. One-third of diagnosed breast cancers might recede on their own.[176] Screening mammography efficiently finds non-life-threatening, asymptomatic breast cancers and pre-cancers, even while overlooking serious cancers. According to H. Gilbert Welch of the Dartmouth Institute for Health Policy and Clinical Practice, research on screening mammography has taken the "brain-dead approach that says the best test is the one that finds the most cancers" rather than the one that finds dangerous cancers.[176]

## Pregnancy [edit]

Breast cancers occur during pregnancy at the same rate as breast cancers in non-pregnant women of the same age. Breast cancer then becomes more common in the 5 or 10 years following pregnancy but then becomes less common than among the general population.[177] These cancers are known as postpartum breast cancer and have worse outcomes including an increased risk of distant spread of disease and mortality.[178] Other cancers found during or shortly after pregnancy appear at approximately the same rate as other cancers in women of a similar age.[179]

Diagnosing new cancer in a pregnant woman is difficult, in part because any symptoms are commonly assumed to be a normal discomfort associated with pregnancy.[179] As a result, cancer is typically discovered at a somewhat

later stage than average in many pregnant or recently pregnant women. Some imaging procedures, such as MRIs (magnetic resonance imaging), CT scans, ultrasounds, and mammograms with fetal shielding are considered safe during pregnancy; some others, such as PET scans are not.[179]

Treatment is generally the same as for non-pregnant women.[179] However, radiation is normally avoided during pregnancy, especially if the fetal dose might exceed 100 cGy. In some cases, some or all treatments are postponed until after birth if the cancer is diagnosed late in the pregnancy. Early deliveries to speed the start of treatment are not uncommon. Surgery is generally considered safe during pregnancy, but some other treatments, especially certain chemotherapy drugs given during the first trimester, increase the risk of birth defects and pregnancy loss (spontaneous abortions and stillbirths).[179] Elective abortions are not required and do not improve the likelihood of the mother surviving or being cured.[179]

Radiation treatments may interfere with the mother's ability to breastfeed her baby because it reduces the ability of that breast to produce milk and increases the risk of mastitis. Also, when chemotherapy is being given after birth, many of the drugs pass through breast milk to the baby, which could harm the baby.[179]

Regarding future pregnancy among breast cancer survivors, there is often fear of cancer recurrence.[180] On the other hand, many still regard pregnancy and parenthood to represent normalcy, happiness and life fulfillment.[180]

## Hormones [edit]

### Birth control [edit]

In breast cancer survivors, non-hormonal birth control methods should be used as first-line options. Progestogen-based methods such as depot medroxyprogesterone acetate, IUD with progestogen or progestogen only pills have a poorly investigated but possible increased risk of cancer recurrence, but may be used if positive effects outweigh this possible risk.[181]

### Menopausal hormone replacement [edit]

In breast cancer survivors, it is recommended to first consider non-hormonal options for menopausal effects, such as bisphosphonates or selective estrogen receptor modulators (SERMs) for osteoporosis, and vaginal estrogen for local symptoms. Observational studies of systemic hormone replacement therapy after breast cancer are generally reassuring. If hormone replacement is necessary after breast cancer, estrogen-only therapy or estrogen therapy with an intrauterine device with progestogen may be safer options than combined systemic therapy.[182]

## Research [edit]

It has been suggested that this section be split out into another article titled *Breast cancer research*. (Discuss) *(December 2015)*

Treatments are constantly evaluated in randomized, controlled trials, to evaluate and compare individual drugs, combinations of drugs, and surgical and radiation techniques. Investigations include new types of targeted therapy as well as cancer vaccines.

The latest research is reported annually at scientific meetings such as that of the American Society of Clinical Oncology, San Antonio Breast Cancer Symposium,[183] and the St. Gallen Oncology Conference in St. Gallen, Switzerland.[184] These studies are reviewed by professional societies and other organizations, and formulated into guidelines for specific treatment groups and risk category.

Fenretinide, a retinoid, is also being studied as a way to reduce the risk of breast cancer (retinoids are drugs related to vitamin A).[185][186]

### Cryoablation [edit]

As of 2014 cryoablation is being studied to see if it could be a substitute for a lumpectomy in small cancers.[187] There is tentative evidence in those with tumors less than 2 centimeters.[188] It may also be used in those in who surgery is not possible.[188] Another review states that cryoablation looks promising for early breast cancer of small size.[189]

### Breast cancer cell lines [edit]

*See also: List of breast cancer cell lines*

A considerable part of the current knowledge on breast carcinomas is based on in vivo and in vitro studies performed with cell lines derived from breast cancers. These provide an unlimited source of homogenous self-replicating material, free of contaminating stromal cells, and often easily cultured in simple standard media. The first breast cancer cell line described, BT-20, was established in 1958. Since then, and despite sustained work in this area, the number of permanent lines obtained has been strikingly low (about 100). Indeed, attempts to culture breast cancer cell lines from primary tumors have been largely unsuccessful. This poor efficiency was often due to technical difficulties associated with the extraction of viable tumor cells from their surrounding stroma. Most of the available breast cancer cell lines issued from metastatic tumors, mainly from pleural effusions. Effusions provided generally large numbers of dissociated, viable tumor cells with little or no contamination by fibroblasts and other tumor stroma cells. Many of the currently used BCC lines were established in the late 1970s. A very few of them, namely MCF-7, T-47D, and MDA-MB-231, account for more than two-thirds of all abstracts reporting studies on mentioned breast cancer cell lines, as concluded from a Medline-based survey.

### Molecular markers [edit]

### Transcription factors [edit]

NFAT transcription factors are implicated in breast cancer, more specifically in the process of cell motility at the basis of metastasis formation. Indeed, NFAT1 (NFATC2) and NFAT5 are pro-invasive and pro-migratory in breast carcinoma[190][191] and NFAT3 (NFATc4) is an inhibitor of cell motility.[192] NFAT1 regulates the expression of the TWEAKR and its ligand TWEAK with the Lipocalin 2 to increase breast cancer cell invasion[193] and NFAT3 inhibits Lipocalin 2 expression to blunt the cell invasion.[192]

### Metabolic markers [edit]

Clinically, the most useful metabolic markers in breast cancer are the estrogen and progesterone receptors that are used to predict response to hormone therapy. New or potentially new markers for breast cancer include BRCA1 and BRCA2[194] to identify patients at high risk of developing breast cancer, HER-2[195] and SCD1[196] for predicting response to therapeutic regimens, and urokinase plasminogen activator, PA1-1[197] and SCD1[198] for assessing prognosis.

## Other animals [edit]

- Mammary tumor for breast cancer in other animals
- Mouse models of breast cancer metastasis

The explanation for these epidemiologic findings is not known, but the parallelism between the DMBA-induced rat mammary carcinoma model and the human situation is striking. ... Abortion would interrupt this process, leaving in the gland undifferentiated structures like those observed in the rat mammary gland, which could render the gland again susceptible to carcinogenesis."

# Cancer

From Wikipedia, the free encyclopedia

*For other uses, see Cancer (disambiguation).*

**Cancer** is a group of diseases involving abnormal cell growth with the potential to invade or spread to other parts of the body.[1][2] Not all tumors are cancerous; benign tumors do not spread to other parts of the body.[2] Possible signs and symptoms include a lump, abnormal bleeding, prolonged cough, unexplained weight loss and a change in bowel movements.[3] While these symptoms may indicate cancer, they may have other causes.[3] Over 100 cancers affect humans.[2]

Tobacco use is the cause of about 22% of cancer deaths.[1] Another 10% is due to obesity, poor diet, lack of physical activity and drinking alcohol.[1][4] Other factors include certain infections, exposure to ionizing radiation and environmental pollutants.[5] In the developing world nearly 20% of cancers are due to infections such as hepatitis B, hepatitis C and human papillomavirus (HPV).[1] These factors act, at least partly, by changing the genes of a cell.[6] Typically many genetic changes are required before cancer develops.[6] Approximately 5–10% of cancers are due to inherited genetic defects from a person's parents.[7] Cancer can be detected by certain signs and symptoms or screening tests.[1] It is then typically further investigated by medical imaging and confirmed by biopsy.[8]

Many cancers can be prevented by not smoking, maintaining a healthy weight, not drinking too much alcohol, eating plenty of vegetables, fruits and whole grains, vaccination against certain infectious diseases, not eating too much processed and red meat, and avoiding too much sunlight exposure.[9][10] Early detection through screening is useful for cervical and colorectal cancer.[11] The benefits of screening in breast cancer are controversial.[11][12] Cancer is often treated with some combination of radiation therapy, surgery, chemotherapy, and targeted therapy.[1][13] Pain and symptom management are an important part of care. Palliative care is particularly important in people with advanced disease.[1] The chance of survival depends on the type of cancer and extent of disease at the start of treatment.[6] In children under 15 at diagnosis the five-year

[edit on Wikidata]

In 2012 about 14.1 million new cases of cancer occurred globally (not including skin cancer other than melanoma).[6] It caused about 8.2 million deaths or 14.6% of human deaths.[6][16] The most common types of cancer in males are lung cancer, prostate cancer, colorectal cancer and stomach cancer. In females, the most common types are breast cancer, colorectal cancer, lung cancer and cervical cancer.[6] If skin cancer other than melanoma were included in total new cancers each year it would account for around 40% of cases.[17][18] In children, acute lymphoblastic leukaemia and brain tumors are most common except in Africa where non-Hodgkin lymphoma occurs more often.[14] In 2012, about 165,000 children under 15 years of age were diagnosed with cancer. The risk of cancer increases significantly with age and many cancers occur more commonly in developed countries.[6] Rates are increasing as more people live to an old age and as lifestyle changes occur in the developing world.[19] The financial costs of cancer were estimated at $1.16 trillion US dollars per year as of 2010.[20]

**Contents**

# Definitions

Cancers are a large family of diseases that involve abnormal cell growth with the potential to invade or spread to other parts of the body.[1][2] They form a subset of neoplasms. A neoplasm or tumor is a group of cells that have undergone unregulated growth and will often form a mass or lump, but may be distributed diffusely.[21][22]

All tumor cells show the six hallmarks of cancer. These characteristics are required to produce a malignant tumor. They include:[23]

- Cell growth and division absent the proper signals
- Continuous growth and division even given contrary signals
- Avoidance of programmed cell death
- Limitless number of cell divisions
- Promoting blood vessel construction
- Invasion of tissue and formation of metastases[24]

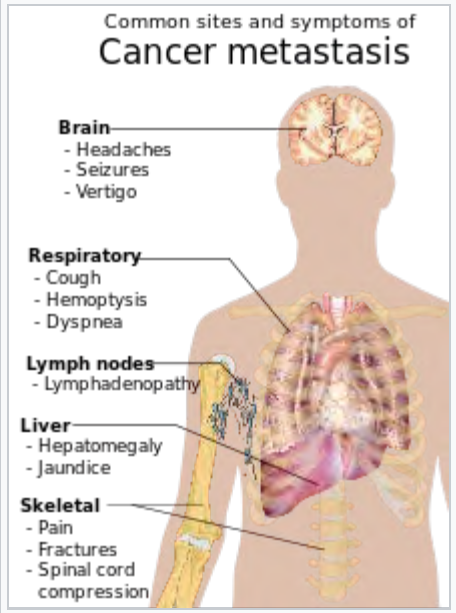
The progression from normal cells to cells that can form a detectable mass to outright cancer involves multiple steps known as malignant progression.[24][25]

# Signs and symptoms

*Main article: Cancer signs and symptoms*

When cancer begins, it produces no symptoms. Signs and symptoms appear as the mass grows or ulcerates. The findings that result depend on the cancer's type and location. Few symptoms are specific. Many frequently occur in individuals who have other conditions. Cancer is a "great imitator". Thus, it is common for people diagnosed with cancer to have been treated for other diseases, which were hypothesized to be causing their symptoms.[26]

People may become anxious or depressed post-diagnosis. The risk of suicide in people with cancer is approximately double.[27]



Symptoms of cancer metastasis depend on the location of the tumor.

## Local symptoms

Local symptoms may occur due to the mass of the tumor or its ulceration. For example, mass effects from lung cancer can block the bronchus resulting in cough or pneumonia; esophageal cancer can cause narrowing of the esophagus, making it difficult or painful to swallow; and colorectal cancer may lead to narrowing or blockages in the bowel, affecting bowel habits. Masses in breasts or testicles may produce observable lumps. Ulceration can cause bleeding that, if it occurs in the lung, will lead to coughing up blood, in the bowels to anemia or rectal bleeding, in the bladder to blood in the urine and in the uterus to vaginal bleeding. Although localized pain may occur in advanced cancer, the initial swelling is usually painless. Some cancers can cause a buildup of fluid within the chest or abdomen.[26]

## Systemic symptoms

General symptoms occur due to effects that are not related to direct or metastatic spread. These may include: unintentional weight loss, fever, excessive fatigue and changes to the skin.[28] Hodgkin disease, leukemias and cancers of the liver or kidney can cause a persistent fever.[26]

Some cancers may cause specific groups of systemic symptoms, termed paraneoplastic phenomena. Examples include the appearance of myasthenia gravis in thymoma and clubbing in lung cancer.[26]

## Metastasis

*Main article: Metastasis*

Cancer can spread from its original site by local spread, lymphatic spread to regional lymph nodes or by hematogenous spread via the blood to distant sites, known as metastasis. When cancer spreads by a hematogenous route, it usually spreads all over the body. However, cancer 'seeds' grow in certain selected site only ('soil') as hypothesized in the *soil and seed hypothesis* of cancer metastasis. The symptoms of metastatic cancers depend on the tumor location and can include enlarged lymph nodes (which can be felt or sometimes seen under the skin and are typically hard), enlarged liver or enlarged spleen, which can be felt in the abdomen, pain or fracture of affected bones and neurological symptoms.[26]

# Causes

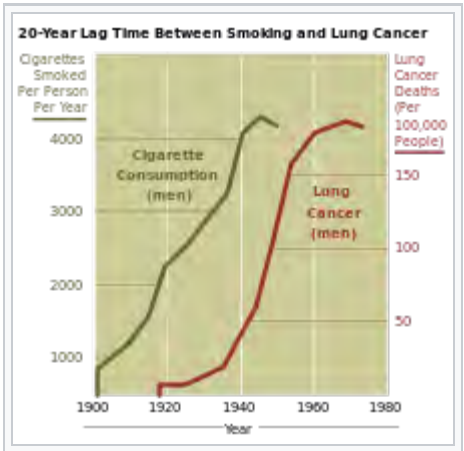
*Main article: Causes of cancer*

The majority of cancers, some 90–95% of cases, are due to environmental factors. The remaining 5–10% are due to inherited genetics.[5] *Environmental*, as used by cancer researchers, means any cause that is not inherited genetically, such as lifestyle, economic and behavioral factors and not merely pollution.[29] Common environmental factors that contribute to cancer death include tobacco (25–30%), diet and obesity (30–35%), infections (15–20%), radiation (both ionizing and non-ionizing, up to 10%), stress, lack of physical activity and environmental pollutants.[5]

It is not generally possible to prove what caused a particular cancer because the various causes do not have specific fingerprints. For example, if a person who uses tobacco heavily develops lung cancer, then it was probably caused by the tobacco use, but since everyone has a small chance of developing lung cancer as a result of air pollution or radiation, the cancer may have developed for one of those reasons. Excepting the rare transmissions that occur with pregnancies and occasional organ donors, cancer is generally not a transmissible disease.[30]

## Chemicals

*Further information: Alcohol and cancer and Smoking and cancer*

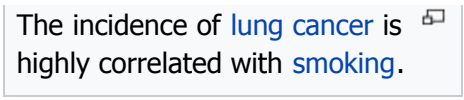


Exposure to particular substances have been linked to specific types of cancer. These substances are called *carcinogens*.

Tobacco smoke, for example, causes 90% of lung cancer.[31] It also causes cancer in the larynx, head, neck, stomach, bladder, kidney, esophagus and pancreas.[32] Tobacco smoke contains over fifty known carcinogens, including nitrosamines and polycyclic aromatic hydrocarbons.[33]

Tobacco is responsible about one in five cancer deaths worldwide[33] and about one in three in the developed world[34] Lung cancer death rates in the United States have mirrored smoking patterns, with increases in smoking followed by dramatic increases in lung cancer death rates and, more recently, decreases in smoking rates since the

1950s followed by decreases in lung cancer death rates in men since 1990.[35][36]



The incidence of lung cancer is highly correlated with smoking.

In Western Europe, 10% of cancers in males and 3% of cancers in females are attributed to alcohol exposure, especially liver and digestive tract cancers.[37] Cancer from work-related substance exposures may cause between 2 and 20% of cases,[38] causing at least 200,000 deaths.[39] Cancers such as lung cancer and mesothelioma can come from inhaling tobacco smoke or asbestos fibers, or leukemia from exposure to benzene.[39]

## Diet and exercise

*Main article: Diet and cancer*

Diet, physical inactivity and obesity are related to up to 30–35% of cancer deaths.[5][40] In the United States excess body weight is associated with the development of many types of cancer and is a factor in 14–20% of cancer deaths.[40] A UK study including data on over 5 million people showed higher body mass index to be related to at least 10 types of cancer and responsible for around 12,000 cases each year in that country.[41] Physical inactivity is believed to contribute to cancer risk, not only through its effect on body weight but also through negative effects on the immune system and endocrine system.[40] More than half of the effect from diet is due to overnutrition (eating too much), rather than from eating too few vegetables or other healthful foods.

Some specific foods are linked to specific cancers. A high-salt diet is linked to gastric cancer.[42] Aflatoxin B1, a frequent food contaminant, causes liver cancer.[42] Betel nut chewing can cause oral cancer.[42] National differences in dietary practices may partly explain differences in cancer incidence. For example, gastric cancer is more common in Japan due to its high-salt diet[43] while colon cancer is more common in the United States. Immigrant cancer profiles develop mirror that of their new country, often within one generation.[44]

## Infection

*Main article: Infectious causes of cancer*

Worldwide approximately 18% of cancer deaths are related to infectious diseases.[5] This proportion ranges from a high of 25% in Africa to less than 10% in the developed world.[5] Viruses are the usual infectious agents that cause cancer but cancer bacteria and parasites may also play a role.

*Oncovirus*es (viruses that can cause cancer) include human papillomavirus (cervical cancer), Epstein–Barr virus (B-cell lymphoproliferative disease and nasopharyngeal carcinoma), Kaposi's sarcoma herpesvirus (Kaposi's sarcoma and primary effusion lymphomas), hepatitis B and hepatitis C viruses (hepatocellular carcinoma) and human T-cell leukemia virus-1 (T-cell leukemias). Bacterial infection may also increase the risk of cancer, as seen in *Helicobacter pylori*-induced gastric carcinoma.[45][46] Parasitic infections associated with cancer include *Schistosoma haematobium* (squamous cell carcinoma of the bladder) and the liver flukes, *Opisthorchis viverrini* and *Clonorchis sinensis* (cholangiocarcinoma).[47]

## Radiation

*Main article: Radiation-induced cancer*

Up to 10% of invasive cancers are related to radiation exposure, including both ionizing radiation and non-ionizing ultraviolet radiation.[5] Additionally, the majority of non-invasive cancers are non-melanoma skin cancers caused by non-ionizing ultraviolet radiation, mostly from sunlight. Sources of ionizing radiation include medical imaging and radon gas.

Ionizing radiation is not a particularly strong mutagen.[48] Residential exposure to radon gas, for example, has similar cancer risks as passive smoking.[48] Radiation is a more potent source of cancer when combined with other cancer-causing agents, such as radon plus tobacco smoke.[48] Radiation can cause cancer in

most parts of the body, in all animals and at any age. Children and adolescents are twice as likely to develop radiation-induced leukemia as adults; radiation exposure before birth has ten times the effect.[48]

Medical use of ionizing radiation is a small but growing source of radiation-induced cancers. Ionizing radiation may be used to treat other cancers, but this may, in some cases, induce a second form of cancer.[48] It is also used in some kinds of medical imaging.[49]

Prolonged exposure to ultraviolet radiation from the sun can lead to melanoma and other skin malignancies.[50] Clear evidence establishes ultraviolet radiation, especially the non-ionizing medium wave UVB, as the cause of most non-melanoma skin cancers, which are the most common forms of cancer in the world.[50]

Non-ionizing radio frequency radiation from mobile phones, electric power transmission and other similar sources have been described as a possible carcinogen by the World Health Organization's International Agency for Research on Cancer.[51] However, studies have not found a consistent link between mobile phone radiation and cancer risk.[52]

## Heredity

*Main article: Cancer syndrome*

The vast majority of cancers are non-hereditary (sporadic). Hereditary cancers are primarily caused by an inherited genetic defect. Less than 0.3% of the population are carriers of a genetic mutation that has a large effect on cancer risk and these cause less than 3–10% of cancer.[53] Some of these syndromes include: certain inherited mutations in the genes *BRCA1* and *BRCA2* with a more than 75% risk of breast cancer and ovarian cancer,[53] and hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome), which is present in about 3% of people with colorectal cancer,[54] among others.

## Physical agents

Some substances cause cancer primarily through their physical, rather than chemical, effects.[55] A prominent example of this is prolonged exposure to asbestos, naturally occurring mineral fibers that are a major cause of mesothelioma (cancer of the serous membrane) usually the serous membrane surrounding the lungs.[55] Other substances in this category, including both naturally occurring and synthetic asbestos-like fibers, such as wollastonite, attapulgite, glass wool and rock wool, are believed to have similar effects.[55] Non-fibrous particulate materials that cause cancer include powdered metallic cobalt and nickel and crystalline silica (quartz, cristobalite and tridymite).[55] Usually, physical carcinogens must get inside the body (such as through inhalation) and require years of exposure to produce cancer.[55]

Physical trauma resulting in cancer is relatively rare.[56] Claims that breaking bones resulted in bone cancer, for example, have not been proven.[56] Similarly, physical trauma is not accepted as a cause for cervical cancer, breast cancer or brain cancer.[56] One accepted source is frequent, long-term application of hot objects to the body. It is possible that repeated burns on the same part of the body, such as those produced by kanger and kairo heaters (charcoal hand warmers), may produce skin cancer, especially if carcinogenic chemicals are also present.[56] Frequent consumption of scalding hot tea may produce esophageal cancer.[56] Generally, it is believed that cancer arises, or a pre-existing cancer is encouraged, during the process of healing, rather than directly by the trauma.[56] However, repeated injuries to the same tissues might promote excessive cell proliferation, which could then increase the odds of a cancerous mutation.

Chronic inflammation has been hypothesized to directly cause mutation.[56][57] Inflammation can contribute to proliferation, survival, angiogenesis and migration of cancer cells by influencing the tumor microenvironment.[58][59] Oncogenes build up an inflammatory pro-tumorigenic microenvironment.[60]

## Hormones

Some hormones play a role in the development of cancer by promoting cell proliferation.[61] Insulin-like growth factors and their binding proteins play a key role in cancer cell proliferation, differentiation and apoptosis, suggesting possible involvement in carcinogenesis.[62]

Hormones are important agents in sex-related cancers, such as cancer of the breast, endometrium, prostate, ovary and testis and also of thyroid cancer and bone cancer.[61] For example, the daughters of women who have breast cancer have significantly higher levels of estrogen and progesterone than the daughters of women without breast cancer. These higher hormone levels may explain their higher risk of breast cancer, even in the absence of a breast-cancer gene.[61] Similarly, men of African ancestry have significantly higher levels of testosterone than men of European ancestry and have a correspondingly higher level of prostate cancer.[61] Men of Asian ancestry, with the lowest levels of testosterone-activating androstanediol glucuronide, have the lowest levels of prostate cancer.[61]

Other factors are relevant: obese people have higher levels of some hormones associated with cancer and a higher rate of those cancers.[61] Women who take hormone replacement therapy have a higher risk of developing cancers associated with those hormones.[61] On the other hand, people who exercise far more than average have lower levels of these hormones and lower risk of cancer.[61] Osteosarcoma may be promoted by growth hormones.[61] Some treatments and prevention approaches leverage this cause by artificially reducing hormone levels and thus discouraging hormone-sensitive cancers.[61]

### Autoimmune diseases

There is an association between celiac disease and an increased risk of all cancers. People with untreated celiac disease have a higher risk, but this risk decreases with time after diagnosis and strict treatment, probably due to the adoption of a gluten-free diet, which seems to have a protective role against development of malignancy in people with celiac disease. However, the delay in diagnosis and initiation of a gluten-free diet seems to increase the risk of malignancies.[63] Rates of gastrointestinal cancers are increased in people with Crohn's disease and ulcerative colitis, due to chronic inflammation. Also, immunomodulators and biologic agents used to treat these diseases may promote developing extra-intestinal malignancies.[64]

## Pathophysiology

*Main article: Carcinogenesis*

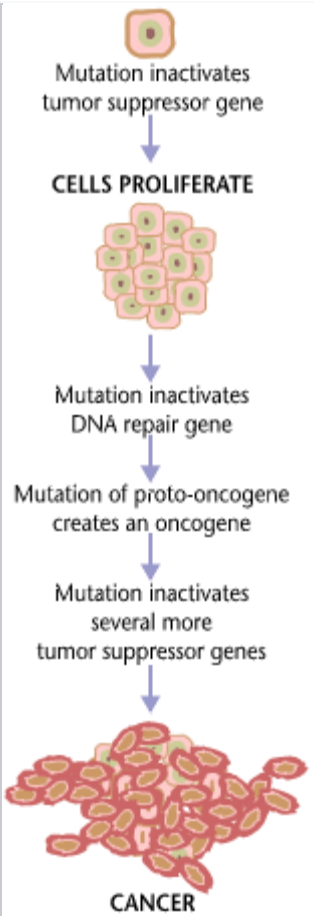
### Genetics

Cancer is fundamentally a disease of tissue growth regulation. In order for a normal cell to transform into a cancer cell, the genes that regulate cell growth and differentiation must be altered.[65]

The affected genes are divided into two broad categories. Oncogenes are genes that promote cell growth and reproduction. Tumor suppressor genes are genes that inhibit cell division and survival. Malignant transformation can occur through the formation of novel oncogenes, the inappropriate over-expression of normal oncogenes, or by the under-expression or disabling of tumor suppressor genes. Typically, changes in multiple genes are required to transform a normal cell into a cancer cell.[66]

Genetic changes can occur at different levels and by different mechanisms. The gain or loss of an entire chromosome can occur through errors in mitosis. More common are mutations, which are changes in the nucleotide sequence of genomic DNA.

Large-scale mutations involve the deletion or gain of a portion of a chromosome. Genomic amplification occurs when a cell gains copies (often 20 or more) of a



Cancers are caused by a series of mutations. Each mutation alters the behavior of the cell somewhat.

small chromosomal locus, usually containing one or more oncogenes and adjacent genetic material. Translocation occurs when two separate chromosomal regions become abnormally fused, often at a characteristic location. A well-known example of this is the Philadelphia chromosome, or translocation of chromosomes 9 and 22, which occurs in chronic myelogenous leukemia and results in production of the BCR-abl fusion protein, an oncogenic tyrosine kinase.

Small-scale mutations include point mutations, deletions, and insertions, which may occur in the promoter region of a gene and affect its expression, or may occur in the gene's coding sequence and alter the function or stability of its protein product. Disruption of a single gene may also result from integration of genomic material from a DNA virus or retrovirus, leading to the expression of *viral* oncogenes in the affected cell and its descendants.

Replication of the data contained within the DNA of living cells will probabilistically result in some errors (mutations). Complex error correction and prevention is built into the process and safeguards the cell against cancer. If a significant error occurs, the damaged cell can self-destruct through programmed cell death, termed apoptosis. If the error control processes fail, then the mutations will survive and be passed along to daughter cells.

Some environments make errors more likely to arise and propagate. Such environments can include the presence of disruptive substances called carcinogens, repeated physical injury, heat, ionising radiation or hypoxia.[67]

The errors that cause cancer are self-amplifying and compounding, for example:

- A mutation in the error-correcting machinery of a cell might cause that cell and its children to accumulate errors more rapidly.
- A further mutation in an oncogene might cause the cell to reproduce more rapidly and more frequently than its normal counterparts.
- A further mutation may cause loss of a tumor suppressor gene, disrupting the apoptosis signaling pathway and immortalizing the cell.
- A further mutation in the signaling machinery of the cell might send error-causing signals to nearby cells.

The transformation of a normal cell into cancer is akin to a chain reaction caused by initial errors, which compound into more severe errors, each progressively allowing the cell to escape more controls that limit normal tissue growth. This rebellion-like scenario is an undesirable survival of the fittest, where the driving forces of evolution work against the body's design and enforcement of order. Once cancer has begun to

develop, this ongoing process, termed *clonal evolution*, drives progression towards more invasive stages.[68] Clonal evolution leads to intra-tumour heterogeneity (cancer cells with heterogeneous mutations) that complicates designing effective treatment strategies.

Characteristic abilities developed by cancers are divided into categories, specifically evasion of apoptosis, self-sufficiency in growth signals, insensitivity to anti-growth signals, sustained angiogenesis, limitless replicative potential, metastasis, reprogramming of energy metabolism and evasion of immune destruction.[24][25]

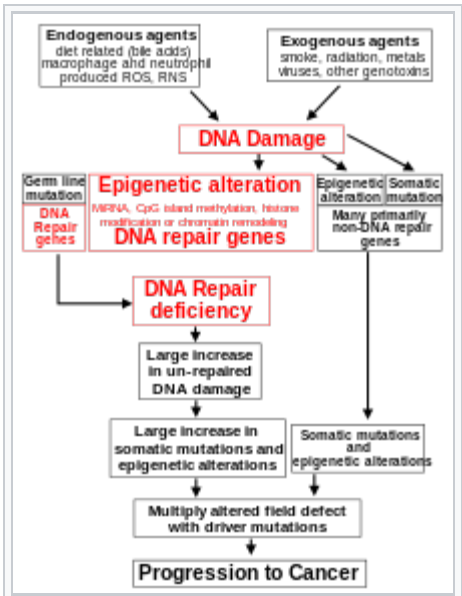
## Epigenetics

*Main article: Cancer epigenetics*

The classical view of cancer is a set of diseases that are driven by progressive genetic abnormalities that include mutations in tumor-suppressor genes and oncogenes and chromosomal abnormalities. Later epigenetic alterations' role was identified.[69]

Epigenetic alterations refer to functionally relevant modifications to the genome that do not change the nucleotide sequence. Examples of such modifications are changes in DNA methylation (hypermethylation and hypomethylation), histone modification[70] and changes in chromosomal architecture (caused by inappropriate expression of proteins such as HMGA2 or HMGA1).[71] Each of these alterations regulates gene expression without altering the underlying DNA sequence. These changes may remain through cell divisions, last for multiple generations and can be considered to be epimutations (equivalent to mutations).

Epigenetic alterations occur frequently in cancers. As an example, one study listed protein coding genes that were frequently altered in their methylation in association with colon cancer. These included 147 hypermethylated and 27 hypomethylated genes. Of the hypermethylated genes, 10 were hypermethylated in 100% of colon cancers and many others were hypermethylated in more than 50% of colon cancers.[72]



The central role of DNA damage and epigenetic defects in DNA repair genes in carcinogenesis

While epigenetic alterations are found in cancers, the epigenetic alterations in DNA repair genes, causing reduced expression of DNA repair proteins, may be of particular importance. Such alterations are thought to occur early in progression to cancer and to be a likely cause of the genetic instability characteristic of cancers.[73][74][75][76]

Reduced expression of DNA repair genes disrupts DNA repair. This is shown in the figure at the 4th level from the top. (In the figure, red wording indicates the central role of DNA damage and defects in DNA repair in progression to cancer.) When DNA repair is deficient DNA damage remains in cells at a higher than usual level (5th level) and cause increased frequencies of mutation and/or epimutation (6th level). Mutation rates increase substantially in cells defective in DNA mismatch repair[77][78] or in homologous recombinational repair (HRR).[79] Chromosomal rearrangements and aneuploidy also increase in HRR defective cells.[80]

Higher levels of DNA damage cause increased mutation (right side of figure) and increased epimutation. During repair of DNA double strand breaks, or repair of other DNA damage, incompletely cleared repair sites can cause epigenetic gene silencing.[81][82]

Deficient expression of DNA repair proteins due to an inherited mutation can increase cancer risks. Individuals with an inherited impairment in any of 34 DNA repair genes (see article DNA repair-deficiency disorder) have increased cancer risk, with some defects ensuring a 100% lifetime chance of cancer (e.g. p53 mutations).[83] Germ line DNA repair mutations are noted on the figure's left side. However, such germline mutations (which cause highly penetrant cancer syndromes) are the cause of only about 1 percent of cancers.[84]

In sporadic cancers, deficiencies in DNA repair are occasionally caused by a mutation in a DNA repair gene but are much more frequently caused by epigenetic alterations that reduce or silence expression of DNA repair genes. This is indicated in the figure at the 3rd level. Many studies of heavy metal-induced carcinogenesis show that such heavy metals cause a reduction in expression of DNA repair enzymes, some through epigenetic mechanisms. DNA repair inhibition is proposed to be a predominant mechanism in heavy metal-induced carcinogenicity. In addition, frequent epigenetic alterations of the DNA sequences code for small RNAs called microRNAs (or miRNAs). miRNAs do not code for proteins, but can "target" protein-coding genes and reduce their expression.

Cancers usually arise from an assemblage of mutations and epimutations that confer a selective advantage leading to clonal expansion (see Field defects in progression to cancer). Mutations, however, may not be as frequent in cancers as epigenetic alterations. An average cancer of the breast or colon can have about 60 to 70 protein-altering mutations, of which about three or four may be "driver" mutations and the remaining ones may be "passenger" mutations.[85]

### Metastasis

*Main article: Metastasis*

Metastasis is the spread of cancer to other locations in the body. The dispersed tumors are called metastatic tumors, while the original is called the primary tumor. Almost all cancers can metastasize.[86] Most cancer deaths are due to cancer that has metastasized.[87]

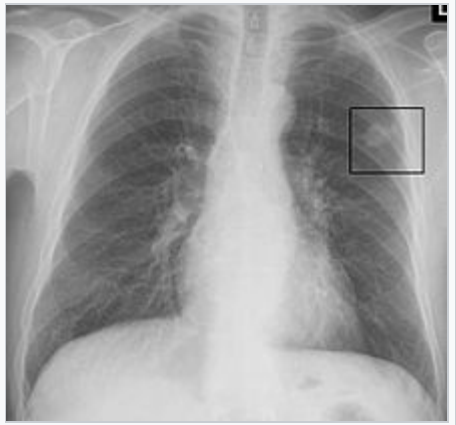
Metastasis is common in the late stages of cancer and it can occur via the blood or the lymphatic system or both. The typical steps in metastasis are local invasion, intravasation into the blood or lymph, circulation through the body, extravasation into the new tissue, proliferation and angiogenesis. Different types of cancers tend to metastasize to particular organs, but overall the most common places for metastases to occur are the lungs, liver, brain and the bones.[86]

## Diagnosis

Most cancers are initially recognized either because of the appearance of signs or symptoms or through screening. Neither of these leads to a definitive diagnosis, which requires the examination of a tissue sample by a pathologist. People with suspected cancer are investigated with medical tests. These commonly include blood tests, X-rays, CT scans and endoscopy.

The tissue diagnosis from the biopsy indicates the type of cell that is proliferating, its histological grade, genetic abnormalities and other features. Together, this information is useful to evaluate the prognosis and to choose the best treatment.

Cytogenetics and immunohistochemistry are other types of tissue tests. These tests provide information about molecular changes (such as mutations, fusion genes and numerical chromosome changes) and may thus also indicate the prognosis and best treatment.



Chest x-ray showing lung cancer in the left lung

## Classification

*Further information: List of cancer types and List of oncology-related terms*

Cancers are classified by the type of cell that the tumor cells resemble and is therefore presumed to be the origin of the tumor. These types include:

- Carcinoma: Cancers derived from epithelial cells. This group includes many of the most common cancers and include nearly all those in the breast, prostate, lung, pancreas and colon.
- Sarcoma: Cancers arising from connective tissue (i.e. bone, cartilage, fat, nerve), each of which

develops from cells originating in mesenchymal cells outside the bone marrow.
- Lymphoma and leukemia: These two classes arise from hematopoietic (blood-forming) cells that leave the marrow and tend to mature in the lymph nodes and blood, respectively.[88]
- Germ cell tumor: Cancers derived from pluripotent cells, most often presenting in the testicle or the ovary (seminoma and dysgerminoma, respectively).
- Blastoma: Cancers derived from immature "precursor" cells or embryonic tissue.

Cancers are usually named using *-carcinoma*, *-sarcoma* or *-blastoma* as a suffix, with the Latin or Greek word for the organ or tissue of origin as the root. For example, cancers of the liver parenchyma arising from malignant epithelial cells is called *hepatocarcinoma*, while a malignancy arising from primitive liver precursor cells is called a hepatoblastoma and a cancer arising from fat cells is called a *liposarcoma*. For some common cancers, the English organ name is used. For example, the most common type of breast cancer is called *ductal carcinoma of the breast*. Here, the adjective *ductal* refers to the appearance of cancer under the microscope, which suggests that it has originated in the milk ducts.

Benign tumors (which are not cancers) are named using *-oma* as a suffix with the organ name as the root. For example, a benign tumor of smooth muscle cells is called a *leiomyoma* (the common name of this frequently occurring benign tumor in the uterus is *fibroid*). Confusingly, some types of cancer use the *-noma* suffix, examples including melanoma and seminoma.

Some types of cancer are named for the size and shape of the cells under a microscope, such as giant cell carcinoma, spindle cell carcinoma and small-cell carcinoma.

An invasive ductal carcinoma of the breast (pale area at the center) surrounded by spikes of whitish scar tissue and yellow fatty tissue

An invasive colorectal carcinoma (top center) in a colectomy specimen

A squamous-cell carcinoma (the whitish tumor) near the bronchi in a lung specimen

A large invasive ductal carcinoma in a mastectomy specimen

# Prevention

*Main article: Cancer prevention*

Cancer prevention is defined as active measures to decrease cancer risk.[89] The vast majority of cancer cases are due to environmental risk factors. Many of these environmental factors are controllable lifestyle choices. Thus, cancer is generally preventable.[90] Between 70% and 90% of common cancers are due to environmental factors and therefore potentially preventable.[91]

Greater than 30% of cancer deaths could be prevented by avoiding risk factors including: tobacco, excess weight/obesity, insufficient diet, physical inactivity, alcohol, sexually transmitted infections and air pollution.[92] Not all environmental causes are controllable, such as naturally occurring background radiation and cancers caused through hereditary genetic disorders and thus are not preventable via personal behavior.

## Dietary

*Main article: Diet and cancer*

While many dietary recommendations have been proposed to reduce cancer risks, the evidence to support them is not definitive.[9][93] The primary dietary factors that increase risk are obesity and alcohol consumption. Diets low in fruits and vegetables and high in red meat have been implicated but reviews and meta-analyses do not come to a consistent conclusion.[94][95] A 2014 meta-analysis find no relationship between fruits and vegetables and cancer.[96] Coffee is associated with a reduced risk of liver cancer.[97] Studies have linked excess consumption of red or processed meat to an increased risk of breast cancer, colon cancer and pancreatic cancer, a phenomenon that could be due to the presence of carcinogens in meats cooked at high temperatures.[98][99] In 2015 the IARC reported that eating processed meat (e.g., bacon, ham, hot dogs, sausages) and, to a lesser degree, red meat was linked to some cancers.[100][101]

Dietary recommendations for cancer prevention typically include an emphasis on vegetables, fruit, whole grains and fish and an avoidance of processed and red meat (beef, pork, lamb), animal fats and refined carbohydrates.[9][93]

### Medication

Medications can be used to prevent cancer in a few circumstances.[102] In the general population, NSAIDs reduce the risk of colorectal cancer; however, due to cardiovascular and gastrointestinal side effects, they cause overall harm when used for prevention.[103] Aspirin has been found to reduce the risk of death from cancer by about 7%.[104] COX-2 inhibitors may decrease the rate of polyp formation in people with familial adenomatous polyposis; however, it is associated with the same adverse effects as NSAIDs.[105] Daily use of tamoxifen or raloxifene reduce the risk of breast cancer in high-risk women.[106] The benefit versus harm for 5-alpha-reductase inhibitor such as finasteride is not clear.[107]

Vitamins are not effective at preventing cancer,[108] although low blood levels of vitamin D are correlated with increased cancer risk.[109][110] People who have cancer are also at a high risk of developing vitamin D deficiency.[111] Whether this relationship is causal and vitamin D supplementation is protective is not determined.[112] Beta-carotene supplementation increases lung cancer rates in those who are high risk.[113] Folic acid supplementation is not effective in preventing colon cancer and may increase colon polyps.[114] It is unclear if selenium supplementation has an effect.[115]

### Vaccination

Vaccines have been developed that prevent infection by some carcinogenic viruses.[116] Human papillomavirus vaccine (Gardasil and Cervarix) decrease the risk of developing cervical cancer.[116] The hepatitis B vaccine prevents infection with hepatitis B virus and thus decreases the risk of liver cancer.[116] The administration of human papillomavirus and hepatitis B vaccinations is recommended when resources allow.[117]

## Screening

*Main article: Cancer screening*

Unlike diagnostic efforts prompted by symptoms and medical signs, cancer screening involves efforts to detect cancer after it has formed, but before any noticeable symptoms appear.[118] This may involve physical examination, blood or urine tests or medical imaging.[118]

Cancer screening is not available for many types of cancers. Even when tests are available, they may not be recommended for everyone. *Universal screening* or *mass screening* involves screening everyone.[119] *Selective screening* identifies people who are at higher risk, such as people with a family history.[119] Several factors are considered to determine whether the benefits of screening outweigh the risks and the costs of screening.[118] These factors include:

- Possible harms from the screening test: for example, X-ray images involve exposure to potentially harmful ionizing radiation
- The likelihood of the test correctly identifying cancer
- The likelihood that cancer is present: Screening is not normally useful for rare cancers.
- Possible harms from follow-up procedures
- Whether suitable treatment is available
- Whether early detection improves treatment outcomes
- Whether the cancer will ever need treatment
- Whether the test is acceptable to the people: If a screening test is too burdensome (for example, extremely painful), then people will refuse to participate.[119]
- Cost

### Recommendations

### U.S. Preventive Services Task Force

The U.S. Preventive Services Task Force (USPSTF) issues recommendations for various cancers:

- Strongly recommends cervical cancer screening in women who are sexually active and have a cervix at least until the age of 65.[120]
- Recommend that Americans be screened for colorectal cancer via fecal occult blood testing, sigmoidoscopy, or colonoscopy starting at age 50 until age 75.[121]
- Evidence is insufficient to recommend for or against screening for skin cancer,[122] oral cancer,[123] lung cancer,[124] or prostate cancer in men under 75.[125]
- Routine screening is not recommended for bladder cancer,[126] testicular cancer,[127] ovarian cancer,[128] pancreatic cancer,[129] or prostate cancer.[130]
- Recommends mammography for breast cancer screening every two years from ages 50–74. Do not recommend either breast self-examination or clinical breast examination.[131] (A 2011 Cochrane review came to slightly different conclusions with respect to breast cancer screening stating that routine mammography may do more harm than good.[132][*needs update*])

### Japan

Screens for gastric cancer using photofluorography due to the high incidence there.[19]

## Genetic testing

*See also: Cancer syndrome*

Genetic testing for

| Gene | Cancer types |
|---|---|
| BRCA1, BRCA2 | Breast, ovarian, pancreatic |
| HNPCC, MLH1, MSH2, MSH6, PMS1, PMS2 | Colon, uterine, small bowel, stomach, urinary tract |

individuals at high-risk of certain cancers is recommended by unofficial groups.[117][133] Carriers of these mutations may then undergo enhanced surveillance, chemoprevention, or preventative surgery to reduce their subsequent risk.[133]

# Management

*Main articles: Management of cancer and oncology*

Many treatment options for cancer exist. The primary ones include surgery, chemotherapy, radiation therapy, hormonal therapy, targeted therapy and palliative care. Which treatments are used depends on the

type, location and grade of the cancer as well as the patient's health and preferences. The treatment intent may or may not be curative.

## Chemotherapy

Chemotherapy is the treatment of cancer with one or more cytotoxic anti-neoplastic drugs (chemotherapeutic agents) as part of a standardized regimen. The term encompasses a variety of drugs, which are divided into broad categories such as alkylating agents and antimetabolites.[134] Traditional chemotherapeutic agents act by killing cells that divide rapidly, a critical property of most cancer cells.

Targeted therapy is a form of chemotherapy that targets specific molecular differences between cancer and normal cells. The first targeted therapies blocked the estrogen receptor molecule, inhibiting the growth of breast cancer. Another common example is the class of Bcr-Abl inhibitors, which are used to treat chronic myelogenous leukemia (CML).[135] Currently, targeted therapies exist for breast cancer, multiple myeloma, lymphoma, prostate cancer, melanoma and other cancers.[136]

The efficacy of chemotherapy depends on the type of cancer and the stage. In combination with surgery, chemotherapy has proven useful in cancer types including breast cancer, colorectal cancer, pancreatic cancer, osteogenic sarcoma, testicular cancer, ovarian cancer and certain lung cancers.[137] Chemotherapy is curative for some cancers, such as some leukemias,[138][139] ineffective in some brain tumors,[140] and needless in others, such as most non-melanoma skin cancers.[141] The effectiveness of chemotherapy is often limited by its toxicity to other tissues in the body. Even when chemotherapy does not provide a permanent cure, it may be useful to reduce symptoms such as pain or to reduce the size of an inoperable tumor in the hope that surgery will become possible in the future.

## Radiation

Radiation therapy involves the use of ionizing radiation in an attempt to either cure or improve symptoms. It works by damaging the DNA of cancerous tissue, killing it. To spare normal tissues (such as skin or organs, which radiation must pass through to treat the tumor), shaped radiation beams are aimed from multiple exposure angles to intersect at the tumor, providing a much larger dose there than in the surrounding, healthy tissue. As with chemotherapy, cancers vary in their response to radiation therapy.[142][143][144]

Radiation therapy is used in about half of cases. The radiation can be either from internal sources (brachytherapy) or external sources. The radiation is most commonly low energy x-rays for treating skin cancers, while higher energy x-rays are used for cancers within the body.[145] Radiation is typically used in addition to surgery and or chemotherapy. For certain types of cancer, such as early head and neck cancer, it may be used alone.[146] For painful bone metastasis, it has been found to be effective in about 70% of patients.[146]

## Surgery

Surgery is the primary method of treatment for most isolated, solid cancers and may play a role in palliation and prolongation of survival. It is typically an important part of definitive diagnosis and staging of tumors, as biopsies are usually required. In localized cancer, surgery typically attempts to remove the entire mass along with, in certain cases, the lymph nodes in the area. For some types of cancer this is sufficient to eliminate the cancer.[137]

## Palliative care

Palliative care refers to treatment that attempts to help the patient feel better and may be combined with an attempt to treat the cancer. Palliative care includes action to reduce physical, emotional, spiritual and psycho-social distress. Unlike treatment that is aimed at directly killing cancer cells, the primary goal of palliative care is to improve quality of life.

People at all stages of cancer treatment typically receive some kind of palliative care. In some cases,

medical specialty professional organizations recommend that patients and physicians respond to cancer only with palliative care.[147] This applies to patients who:[148]

1. display low performance status, implying limited ability to care for themselves[147]
2. received no benefit from prior evidence-based treatments[147]
3. are not eligible to participate in any appropriate clinical trial[147]
4. no strong evidence implies that treatment would be effective[147]

Palliative care may be confused with hospice and therefore only indicated when people approach end of life. Like hospice care, palliative care attempts to help the patient cope with their immediate needs and to increase comfort. Unlike hospice care, palliative care does not require people to stop treatment aimed at the cancer.

Multiple national medical guidelines recommend early palliative care for patients whose cancer has produced distressing symptoms or who need help coping with their illness. In patients first diagnosed with metastatic disease, palliative care may be immediately indicated. Palliative care is indicated for patients with a prognosis of less than 12 months of life even given aggressive treatment.[149][150][151]

### Immunotherapy

*Main article: Cancer immunotherapy*

A variety of therapies using immunotherapy, stimulating or helping the immune system to fight cancer, have come into use since 1997. Approaches include antibodies, checkpoint therapy and adoptive cell transfer.[152]

### Alternative medicine

Complementary and alternative cancer treatments are a diverse group of therapies, practices and products that are not part of conventional medicine.[153] "Complementary medicine" refers to methods and substances used along with conventional medicine, while "alternative medicine" refers to compounds used instead of conventional medicine.[154] Most complementary and alternative medicines for cancer have not been studied or tested using conventional techniques such as clinical trials. Some alternative treatments have been investigated and shown to be ineffective but still continue to be marketed and promoted. Cancer researcher Andrew J. Vickers stated, "The label 'unproven' is inappropriate for such therapies; it is time to assert that many alternative cancer therapies have been 'disproven'."[155]

## Prognosis

*See also: List of cancer mortality rates in the United States and Cancer survivor*

Survival rates vary by cancer type and by the stage at which it is diagnosed, ranging from majority survival to complete mortality five years after diagnosis. Once a cancer has metastasized, prognosis normally becomes much worse. About half of patients receiving treatment for invasive cancer (excluding carcinoma *in situ* and non-melanoma skin cancers) die from that cancer or its treatment.[19]

Survival is worse in the developing world,[19] partly because the types of cancer that are most common there are harder to treat than those associated with developed countries.[156]

Those who survive cancer develop a second primary cancer at about twice the rate of those never diagnosed.[157] The increased risk is believed to be primarily due to the same risk factors that produced the first cancer, partly due to treatment of the first cancer and to better compliance with screening.[157]

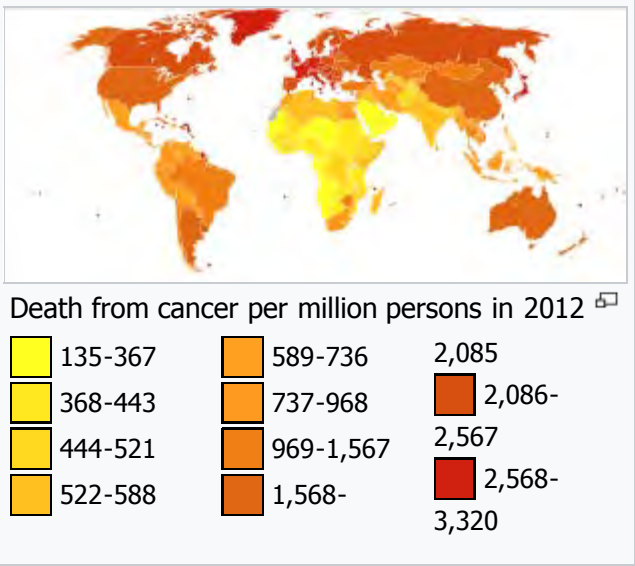
Predicting short- or long-term survival depends on many factors. The most important are the cancer type and the patient's age and overall health. Those who are frail with other health problems have lower survival rates than otherwise healthy people. Centenarians are unlikely to survive for five years even if treatment is successful. People who report a higher quality of life tend to survive longer.[158] People with lower quality

of life may be affected by depression and other complications and/or disease progression that both impairs quality and quantity of life. Additionally, patients with worse prognoses may be depressed or report poorer quality of life because they perceive that their condition is likely to be fatal.

Cancer patients have an increased risk of blood clots in veins. The use of heparin appears to improve survival and decrease the risk of blood clots.[159]

# Epidemiology

*Main article: Epidemiology of cancer*
*See also: List of countries by cancer rate*



In 2008, approximately 12.7 million cancers were diagnosed (excluding non-melanoma skin cancers and other non-invasive cancers)[19] and in 2010 nearly 7.98 million people died.[160] Cancers account for approximately 13% of deaths. The most common are lung cancer (1.4 million deaths), stomach cancer (740,000), liver cancer (700,000), colorectal cancer (610,000) and breast cancer (460,000).[161] This makes invasive cancer the leading cause of death in the developed world and the second leading in the developing world.[19] Over half of cases occur in the developing world.[19]

Deaths from cancer were 5.8 million in 1990.[160] Deaths have been increasing primarily due to longer lifespans and lifestyle changes in the developing world.[19] The most significant risk factor for developing cancer is age.[162] Although it is possible for cancer to strike at any age, most patients with invasive cancer are over 65.[162] According to cancer researcher Robert A. Weinberg, "If we lived long enough, sooner or later we all would get cancer."[163] Some of the association between aging and cancer is attributed to immunosenescence,[164] errors accumulated in DNA over a lifetime[165] and age-related changes in the endocrine system.[166] Aging's effect on cancer is complicated by factors such as DNA damage and inflammation promoting it and factors such as vascular aging and endocrine changes inhibiting it.[167]

Some slow-growing cancers are particularly common, but often are not fatal. Autopsy studies in Europe and Asia showed that up to 36% of people have undiagnosed and apparently harmless thyroid cancer at the time of their deaths and that 80% of men develop prostate cancer by age 80.[168][169] As these cancers do not cause the patient's death, identifying them would have represented overdiagnosis rather than useful medical care.

The three most common childhood cancers are leukemia (34%), brain tumors (23%) and lymphomas (12%).[170] In the United States cancer affects about 1 in 285 children.[171] Rates of childhood cancer increased by 0.6% per year between 1975 and 2002 in the United States[172] and by 1.1% per year between 1978 and 1997 in Europe.[170] Death from childhood cancer decreased by half since 1975 in the United States.[171]

# History

*Main article: History of cancer*

Cancer has existed for all of human history.[173] The earliest written record regarding cancer is from circa 1600 BC in the Egyptian Edwin Smith Papyrus and describes breast cancer.[173] Hippocrates (ca. 460 BC

Engraving with two views of a Dutch woman who had a tumor removed from her neck in 1689

– ca. 370 BC) described several kinds of cancer, referring to them with the Greek word καρκίνος *karkinos* (crab or crayfish).[173] This name comes from the appearance of the cut surface of a solid malignant tumor, with "the veins stretched on all sides as the animal the crab has its feet, whence it derives its name".[174] Galen stated that "cancer of the breast is so called because of the fancied resemblance to a crab given by the lateral prolongations of the tumor and the adjacent distended veins".[175]:738 Celsus (ca. 25 BC – 50 AD) translated *karkinos* into the Latin *cancer*, also meaning crab and recommended surgery as treatment.[173] Galen (2nd century AD) disagreed with the use of surgery and recommended purgatives instead.[173] These recommendations largely stood for 1000 years.[173]

In the 15th, 16th and 17th centuries, it became acceptable for doctors to dissect bodies to discover the cause of death.[176] The German professor Wilhelm Fabry believed that breast cancer was caused by a milk clot in a mammary duct. The Dutch professor Francois de la Boe Sylvius, a follower of Descartes, believed that all disease was the outcome of chemical processes and that acidic lymph fluid was the cause of cancer. His contemporary Nicolaes Tulp believed that cancer was a poison that slowly spreads and concluded that it was contagious.[177]

The physician John Hill described tobacco snuff as the cause of nose cancer in 1761.[176] This was followed by the report in 1775 by British surgeon Percivall Pott that chimney sweeps' carcinoma, a cancer of the scrotum, was a common disease among chimney sweeps.[178] With the widespread use of the microscope in the 18th century, it was discovered that the 'cancer poison' spread from the primary tumor through the lymph nodes to other sites ("metastasis"). This view of the disease was first formulated by the English surgeon Campbell De Morgan between 1871 and 1874.[179]

## Society and culture

Though many diseases (such as heart failure) may have a worse prognosis than most cases of cancer, cancer is the subject of widespread fear and taboos. The euphemism "after a long illness" is still commonly used (2012), reflecting an apparent stigma.[180] This deep belief that cancer is necessarily a difficult and usually deadly disease is reflected in the systems chosen by society to compile cancer statistics: the most common form of cancer—non-melanoma skin cancers, accounting for about one-third of cancer cases worldwide, but very few deaths[181][182]—are excluded from cancer statistics specifically because they are easily treated and almost always cured, often in a single, short, outpatient procedure.[183]

Cancer is regarded as a disease that must be "fought" to end the "civil insurrection"; a War on Cancer was declared in the US. Military metaphors are particularly common in descriptions of cancer's human effects and they emphasize both the state of the patient's health and the need to take immediate, decisive actions himself, rather than to delay, to ignore, or to rely entirely on others. The military metaphors also help rationalize radical, destructive treatments.[184][185]

In the 1970s, a relatively popular alternative cancer treatment in the US was a specialized form of talk therapy, based on the idea that cancer was caused by a bad attitude.[186] People with a "cancer personality"—depressed, repressed, self-loathing and afraid to express their emotions—were believed to have manifested cancer through subconscious desire. Some psychotherapists said that treatment to change the patient's outlook on life would cure the cancer.[186] Among other effects, this belief allowed society to blame the victim for having caused the cancer (by "wanting" it) or having prevented its cure (by not becoming a sufficiently happy, fearless and loving person).[187] It also increased patients' anxiety, as they incorrectly believed that natural emotions of sadness, anger or fear shorten their lives.[187] The idea was ridiculed by Susan Sontag, who published *Illness as Metaphor* while recovering from treatment for breast

cancer in 1978.[186] Although the original idea is now generally regarded as nonsense, the idea partly persists in a reduced form with a widespread, but incorrect, belief that deliberately cultivating a habit of positive thinking will increase survival.[187] This notion is particularly strong in breast cancer culture.[187]

One idea about why people with cancer are blamed or stigmatized, called the just-world hypothesis, is that blaming cancer on the patient's actions or attitudes allows the blamers to regain a sense of control. This is based upon the blamers' belief that the world is fundamentally just and so any dangerous illness, like cancer, must be a type of punishment for bad choices, because in a just world, bad things would not happen to good people.[188]

### Economic effect

In 2007, the overall costs of cancer in the US—including treatment and indirect mortality expenses (such as lost productivity in the workplace) — was estimated to be $226.8 billion. In 2009, 32% of Hispanics and 10% of children 17 years old or younger lacked health insurance; "uninsured patients and those from ethnic minorities are substantially more likely to be diagnosed with cancer at a later stage, when treatment can be more extensive and more costly."[189]

## Research

*Main article: Cancer research*

Because cancer is a class of diseases,[190][191] it is unlikely that there will ever be a single "cure for cancer" any more than there will be a single treatment for all infectious diseases.[192] Angiogenesis inhibitors were once incorrectly thought to have potential as a "silver bullet" treatment applicable to many types of cancer.[193] Angiogenesis inhibitors and other cancer therapeutics are used in combination to reduce cancer morbidity and mortality.[194]

University of Florida Cancer Hospital

Experimental cancer treatments are studied in clinical trials to compare the proposed treatment to the best existing treatment. Treatments that succeeded in one cancer type can be tested against other types.[195] Diagnostic tests are under development to better target the right therapies to the right patients, based on their individual biology.[196]

Cancer research focuses on the following issues:

- Agents (e.g. viruses) and events (e.g. mutations) that cause or facilitate genetic changes in cells destined to become cancer.
- The precise nature of the genetic damage and the genes that are affected by it.
- The consequences of those genetic changes on the biology of the cell, both in generating the defining properties of a cancer cell and in facilitating additional genetic events that lead to further progression of the cancer.

The improved understanding of molecular biology and cellular biology due to cancer research has led to new treatments for cancer since US President Richard Nixon declared the "War on Cancer" in 1971. Since then, the country has spent over $200 billion on cancer research, including resources from public and private sectors.[197] The cancer death rate (adjusting for size and age of the population) declined by five percent between 1950 and 2005.[198]

Competition for financial resources appears to have suppressed the creativity, cooperation, risk-taking and original thinking required to make fundamental discoveries, unduly favoring low-risk research into small incremental advancements over riskier, more innovative research. Other consequences of competition appear to be many studies with dramatic claims whose results cannot be replicated and perverse incentives that encourage grantee institutions to grow without making sufficient investments in their own faculty and facilities.[199][200][201][202]

## Pregnancy

Cancer affects approximately 1 in 1,000 pregnant women. The most common cancers found during pregnancy are the same as the most common cancers found in non-pregnant women during childbearing ages: breast cancer, cervical cancer, leukemia, lymphoma, melanoma, ovarian cancer and colorectal cancer.[203]

Diagnosing a new cancer in a pregnant woman is difficult, in part because any symptoms are commonly assumed to be a normal discomfort associated with pregnancy. As a result, cancer is typically discovered at a somewhat later stage than average. Some imaging procedures, such as MRIs (magnetic resonance imaging), CT scans, ultrasounds and mammograms with fetal shielding are considered safe during pregnancy; some others, such as PET scans, are not.[203]

Treatment is generally the same as for non-pregnant women. However, radiation and radioactive drugs are normally avoided during pregnancy, especially if the fetal dose might exceed 100 cGy. In some cases, some or all treatments are postponed until after birth if the cancer is diagnosed late in the pregnancy. Early deliveries are often used to advance the start of treatment. Surgery is generally safe, but pelvic surgeries during the first trimester may cause miscarriage. Some treatments, especially certain chemotherapy drugs given during the first trimester, increase the risk of birth defects and pregnancy loss (spontaneous abortions and stillbirths).[203]

Elective abortions are not required and, for the most common forms and stages of cancer, do not improve the mother's survival. In a few instances, such as advanced uterine cancer, the pregnancy cannot be continued and in others, the patient may end the pregnancy so that she can begin aggressive chemotherapy.[203]

Some treatments can interfere with the mother's ability to give birth vaginally or to breastfeed.[203] Cervical cancer may require birth by Caesarean section. Radiation to the breast reduces the ability of that breast to produce milk and increases the risk of mastitis. Also, when chemotherapy is given after birth, many of the drugs appear in breast milk, which could harm the baby.[203]

## Other animals

Veterinary oncology, concentrating mainly on cats and dogs, is a growing specialty in wealthy countries and the major forms of human treatment such as surgery and radiotherapy may be offered. The most common types of cancer differ, but the cancer burden seems at least as high in pets as in humans. Animals, typically rodents, are often used in cancer research and studies of natural cancers in larger animals may benefit research into human cancer.[204]

In non-humans, a few types of transmissible cancer have been described, wherein the cancer spreads between animals by transmission of the tumor cells themselves. This phenomenon is seen in dogs with Sticker's sarcoma, also known as canine transmissible venereal tumor.[205]

"A certain irreducible background incidence of cancer is to be expected regardless of circumstances: mutations can never be absolutely avoided, because they are an inescapable consequence of fundamental limitations on the accuracy of DNA replication, as discussed in Chapter 5. If a human could live long enough, it is inevitable that at least one of his or her cells would eventually accumulate a set of mutations sufficient for cancer to develop."

# Cervical cancer

From Wikipedia, the free encyclopedia

**Cervical cancer** is a cancer arising from the cervix.[1] It is due to the abnormal growth of cells that have the ability to invade or spread to other parts of the body.[2] Early on, typically no symptoms are seen. Later symptoms may include abnormal vaginal bleeding, pelvic pain, or pain during sexual intercourse.[1] While bleeding after sex may not be serious, it may also indicate the presence of cervical cancer.[3]

Human papillomavirus (HPV) infection appears to be involved in the development of more than 90% of cases;[4][5] most people who have had HPV infections, however, do not develop cervical cancer.[6][7] Other risk factors include smoking, a weak immune system, birth control pills, starting sex at a young age, and having many sexual partners, but these are less important.[1][8] Cervical cancer typically develops from precancerous changes over 10 to 20 years.[6] About 90% of cervical cancer cases are squamous cell carcinomas, 10% are adenocarcinoma, and a small number are other types.[8] Diagnosis is typically by cervical screening followed by a biopsy. Medical imaging is then done to determine whether or not the cancer has spread.[1]

HPV vaccines protect against between two and seven high-risk strains of this family of viruses and may prevent up to 90% of cervical cancers.[9][10][11] As a risk of cancer still exists, guidelines recommend continuing regular Pap smears.[10] Other methods of prevention include: having few or no sexual partners and the use of condoms.[12] Cervical cancer screening using the Pap smear or acetic acid can identify precancerous changes which when treated can prevent the development of cancer.[13] Treatment of cervical cancer may consist of some combination of surgery, chemotherapy, and radiotherapy.[1] Five year survival rates in the United States are 68%.[14] Outcomes, however, depend very much on how early the cancer is detected.[8]

Worldwide, cervical cancer is both the fourth-most common cause of cancer and the fourth-most common cause of death from cancer in women.[6] In 2012, an estimated 528,000 cases of cervical cancer occurred, with 266,000 deaths.[6] This is about 8% of the total cases and total deaths from cancer.[15] About 70% of cervical cancers occur in developing countries.[6] In low-income countries, it is the most common cause of cancer death.[13] In developed countries, the widespread use of cervical screening programs has dramatically reduced rates of cervical cancer.[16] In medical research, the most famous cell line known as HeLa was developed from cervical cancer cells of a woman named Henrietta Lacks.[17]

## Signs and symptoms [edit]

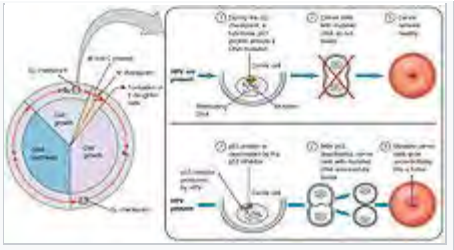
The early stages of cervical cancer may be completely free of symptoms.[4][16] Vaginal bleeding, contact bleeding (one most common form being bleeding after sexual intercourse), or (rarely) a vaginal mass may indicate the presence of malignancy. Also, moderate pain during sexual intercourse and vaginal discharge are symptoms of cervical cancer. In advanced disease, metastases may be present in the abdomen, lungs, or elsewhere.

Symptoms of advanced cervical cancer may include: loss of appetite, weight loss, fatigue, pelvic pain, back pain, leg pain, swollen legs, heavy vaginal bleeding, bone fractures, and/or (rarely) leakage of urine or feces from the vagina.[18] Bleeding after douching or after a pelvic exam is a common symptom of cervical cancer.[19]

## Causes [edit]

Infection with some types of HPV is the greatest risk factor for cervical cancer, followed by smoking.[20] HIV infection is also a risk factor.[20]

Not all of the causes of cervical cancer are known, however, and several other contributing factors have been implicated.[21]



In most cases, cells infected with the HPV virus heal on their own. In some cases, however, the virus continues to spread and becomes an invasive cancer.

## Human papillomavirus [edit]

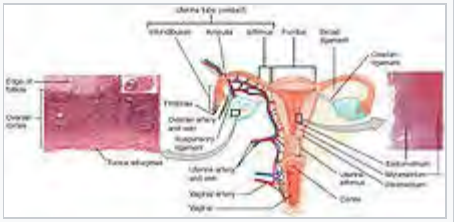
Human papillomavirus types 16 and 18 are the cause of 75% of cervical cancer cases globally, while 31 and 45 are the causes of another 10%.[22]

Women who have many sexual partners (or who have sex with men who have had many other partners) have a greater risk.[23][24]

Of the 150-200 types of HPV known,[25][26] 15 are classified as high-risk types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, and 82), three as probable high-risk (26, 53, and 66), and 12 as low-risk (6, 11, 40, 42, 43, 44, 54, 61, 70, 72, 81, and CP6108).[27]

Genital warts, which are a form of benign tumor of epithelial cells, are also caused by various strains of HPV. However, these serotypes are usually not related to cervical cancer. It is common to have multiple strains at the same time, including those that can cause cervical cancer along with those that cause warts.

Infection with HPV is generally believed to be required for cervical cancer to occur.[28]



Cervix in relation to upper part of vagina and posterior portion of uterus., showing difference in covering epithelium of inner structures.

## Smoking [edit]

Cigarette smoking, both active and passive, increases the risk of cervical cancer. Among HPV-infected women, current and former smokers have roughly two to three times the incidence of invasive cancer. Passive smoking is also associated with increased risk, but to a lesser extent.[29]

Smoking has also been linked to the development of cervical cancer.[30][31][32] Smoking can increase the risk in women a few different ways, which can be by direct and indirect methods of inducing cervical cancer.[30][32][33] A direct way of contracting this cancer is a smoker has a higher chance of CIN3 occurring which has the potential of forming cervical cancer.[30] When CIN3 lesions lead to cancer, most of them have the assistance of the HPV virus, but that is not always the case, which is why it can be considered a direct link to cervical cancer.[33] Heavy smoking and long-term smoking seem to have more of a risk of getting the CIN3 lesions than lighter smoking or not smoking at all.[34] Although smoking has been linked to cervical cancer, it aids in the development of HPV which is the leading cause of this type of cancer.[32] Also, not only does it aid in the development of HPV, but also if the woman is already HPV-positive, she is at an even greater likelihood of contracting cervical cancer.[34]

## Oral contraceptives [edit]

Long-term use of oral contraceptives is associated with increased risk of cervical cancer. Women who have used oral contraceptives for 5 to 9 years have about three times the incidence of invasive cancer, and those who used them for 10 years or longer have about four times the risk.[29]

## Multiple pregnancies [edit]

Having many pregnancies is associated with an increased risk of cervical cancer. Among HPV-infected women, those who have had seven or more full-term pregnancies have around four times the risk of cancer compared with women with no pregnancies, and two to three times the risk of women who have had one [29]

or two full-term pregnancies.

## Diagnosis [edit]

### Biopsy [edit]

The Pap smear can be used as a screening test, but is false negative in up to 50% of cases of cervical cancer.[35][36] Confirmation of the diagnosis of cervical cancer or precancer requires a biopsy of the cervix. This is often done through colposcopy, a magnified visual inspection of the cervix aided by using a dilute acetic acid (e.g. vinegar) solution to highlight abnormal cells on the surface of the cervix.[4] Medical devices used for biopsy of the cervix include punch forceps, SpiraBrush CX, SoftBiopsy, or Soft-ECC.

Colposcopic impression, the estimate of disease severity based on the visual inspection, forms part of the diagnosis.

Further diagnostic and treatment procedures are loop electrical excision procedure and conization, in which the inner lining of the cervix is removed to be examined pathologically. These are carried out if the biopsy confirms severe cervical intraepithelial neoplasia.

Often before the biopsy, the doctor asks for medical imaging to rule out other causes of woman's symptoms. Imaging modalities such as ultrasound, CT scan and MRI have been used to look for alternating disease, spread of tumor and effect on adjacent structures. Typically, they appear as heterogeneous mass in the cervix.[37]

Cervical cancer seen on a T2-weighted saggital MR image of the pelvis

This large squamous carcinoma (bottom of picture) has obliterated the cervix and invaded the lower uterine segment. The uterus also has a round leiomyoma up higher.

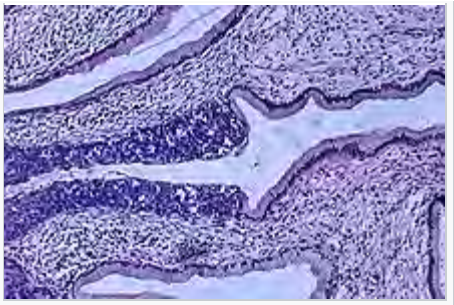
### Precancerous lesions [edit]

Cervical intraepithelial neoplasia, the potential precursor to cervical cancer, is often diagnosed on examination of cervical biopsies by a pathologist. For premalignant dysplastic changes, cervical intraepithelial neoplasia grading is used.

The naming and histologic classification of cervical carcinoma precursor lesions has changed many times over the 20th century. The World Health Organization classification[38][39] system was descriptive of the lesions, naming them mild, moderate, or severe dysplasia or carcinoma in situ (CIS). The term, cervical intraepithelial neoplasia (CIN) was developed to place emphasis on the spectrum of abnormality in these lesions, and to help standardise treatment.[39] It classifies mild dysplasia as CIN1, moderate dysplasia as CIN2, and severe dysplasia and CIS as CIN3. More recently, CIN2 and CIN3 have been combined into CIN2/3. These results are what a pathologist might report from a biopsy.

These should not be confused with the Bethesda system terms for Pap smear (cytopathology) results. Among the Bethesda results: Low-grade Squamous Intraepithelial Lesion (LSIL) and High-grade Squamous Intraepithelial Lesion (HSIL). An LSIL Pap may correspond to CIN1, and HSIL may correspond to CIN2 and CIN3,[39] however they are results of different tests, and the Pap smear results need not match the histologic findings.

### Cancer subtypes [edit]



Histopathologic image (H&E stain) of carcinoma *in situ* (also called CIN III), stage 0: The normal architecture of stratified squamous epithelium is replaced by irregular cells that extend throughout its full thickness. Normal columnar epithelium is also seen.

Histologic subtypes of invasive cervical carcinoma include the following:[40][41] Though squamous cell carcinoma is the cervical cancer with the most incidence, the incidence of adenocarcinoma of the cervix has been increasing in recent decades.[4]

- squamous cell carcinoma (about 80-85%[*citation needed*])
- adenocarcinoma (about 15% of cervical cancers in the UK[38])
- adenosquamous carcinoma
- small cell carcinoma
- neuroendocrine tumour
- glassy cell carcinoma
- villoglandular adenocarcinoma

Noncarcinoma malignancies which can rarely occur in the cervix include melanoma and lymphoma. The FIGO stage does not incorporate lymph node involvement in contrast to the TNM staging for most other cancers.

For cases treated surgically, information obtained from the pathologist can be used in assigning a separate pathologic stage, but is not to replace the original clinical stage.

Cervical cancer with uterine leiomyoma

## Staging [edit]

*Main article: Cervical cancer staging*

Cervical cancer is staged by the International Federation of Gynecology and Obstetrics (FIGO) staging system, which is based on clinical examination, rather than surgical findings. It allows only these diagnostic tests to be used in determining the stage: palpation, inspection, colposcopy, endocervical curettage, hysteroscopy, cystoscopy, proctoscopy, intravenous urography, and X-ray examination of the lungs and skeleton, and cervical conization.

# Prevention [edit]

## Screening [edit]

*Main articles: Cervical screening and Pap test*

Cervical screening test vehicle in Taiwan

Checking the cervix by the Papanicolaou test, or Pap smear, for cervical cancer has been credited with dramatically reducing the number of cases of and mortality from cervical cancer in developed countries.[16] Pap smear screening every 3–5 years with appropriate follow-up can reduce cervical cancer incidence up to 80%.[42] Abnormal results may suggest the presence of precancerous changes, allowing examination and possible preventive treatment. The treatment of low-grade lesions may adversely affect subsequent fertility and pregnancy.[29] Personal invitations encouraging women to get screened are effective at increasing the likelihood they will do so. Educational materials also help increase the likelihood women will go for screening, but they are not as effective as invitations.[43]

Negative visual inspection with acetic acid of the cervix

According to the 2010 European guidelines, the age at which to start screening ranges between 20 and 30 years of age, "but preferentially not before age 25 or 30 years", and depends on burden of the disease in the population and the available resources.[44]

In the United States, screening is recommended to begin at age 21, regardless of age at which a woman began having sex or other risk factors.[45] Pap tests should be done every three years between the ages of 21 and 65.[45] In women over the age of 65, screening may be discontinued if no abnormal screening results were seen within the previous 10 years and no history of CIN 2 or higher exists.[45][46][47] HPV vaccination status does not change screening rates.[46] Screening can occur every 5 years between ages 30 and 65 when a combination of cervical cytology screening and HPV testing is used and this is preferred.[46] However, it is acceptable to screen this age group with a Pap smear alone every 3 years.[46] Screening is not beneficial before age 25 as the rate of disease is low. Screening is not beneficial in women older than 60 years if they have a history of negative results.[29]

Positive visual inspection with acetic acid of the cervix for CIN-1

Liquid-based cytology is another potential screening method.[48][49] Although it was probably intended to improve on the accuracy of the Pap test, its main advantage has been to reduce the number of inadequate smears from around 9% to around 1%.[50] This reduces the need to recall women for a further smear. The United States Preventive Services Task Force supports screening every 5 years in those who are between 30 and 65 years when cytology is used in combination with HPV testing.[51]

Pap smears have not been as effective in developing countries.[52] This is in part because many of these countries have an impoverished health care infrastructure, too few trained and skilled professionals to obtain and interepret Pap smears, uninformed women who get lost to follow-up, and a lengthy turn-around time to get results.[52] These realities have resulted in the investigation of

cervical screening approaches that use fewer resources and offer rapid results such as visual inspection with acetic acid or HPV DNA testing.[52]

### Barrier protection [edit]

Barrier protection and/or spermicidal gel use during sexual intercourse decreases cancer risk.[29] Condoms offer protection against cervical cancer.[53] Evidence on whether condoms protect against HPV infection is mixed, but they may protect against genital warts and the precursors to cervical cancer.[53] They also provide protection against other STIs, such as HIV and *Chlamydia*, which are associated with greater risks of developing cervical cancer.

Condoms may also be useful in treating potentially precancerous changes in the cervix. Exposure to semen appears to increase the risk of precancerous changes (CIN 3), and use of condoms helps to cause these changes to regress and helps clear HPV.[54] One study suggests that prostaglandin in semen may fuel the growth of cervical and uterine tumors and that affected women may benefit from the use of condoms.[55]

Abstinence also prevents HPV infection.[29]

### Vaccination [edit]

Two HPV vaccines (Gardasil and Cervarix) reduce the risk of cancerous or precancerous changes of the cervix and perineum by about 93% and 62%, respectively.[56] The vaccines are between 92% and 100% effective against HPV 16 and 18 up to at least 8 years.[29]

HPV vaccines are typically given to age 9 to 26 as the vaccine is only effective if given before infection occurs. The vaccines have been shown to be effective for at least 4[57] to 6[58] years, and they are believed to be effective for longer;[59] however, the duration of effectiveness and whether a booster will be needed is unknown. The high cost of this vaccine has been a cause for concern. Several countries have considered (or are considering) programs to fund HPV vaccination.

Since 2010, young women in Japan have been eligible to receive the cervical cancer vaccination for free.[60] In June 2013, the Japanese Ministry of Health, Labor and Welfare mandated that, before administering the vaccine, medical institutions must inform women that the Ministry does not recommend it.[60] However, the vaccine is still available at no cost to Japanese women who choose to accept the vaccination.[60]

### Nutrition [edit]

Vitamin A is associated with a lower risk[61] as are vitamin B12, vitamin C, vitamin E, and beta-carotene.[62]

## Treatment [edit]

The treatment of cervical cancer varies worldwide, largely due to access to surgeons skilled in radical pelvic surgery, and the emergence of "fertility-sparing therapy" in developed nations. Because cervical cancers are radiosensitive, radiation may be used in all stages where surgical options do not exist. Surgical intervention may have better outcomes than radiological approaches.[63]

Microinvasive cancer (stage IA) may be treated by hysterectomy (removal of the whole uterus including part of the vagina).[*citation needed*] For stage IA2, the lymph nodes are removed, as well. Alternatives include local surgical procedures such as a loop electrical excision procedure or cone biopsy.[64] For 1A1 disease, a cone biopsy (cervical

Cervical cryotherapy

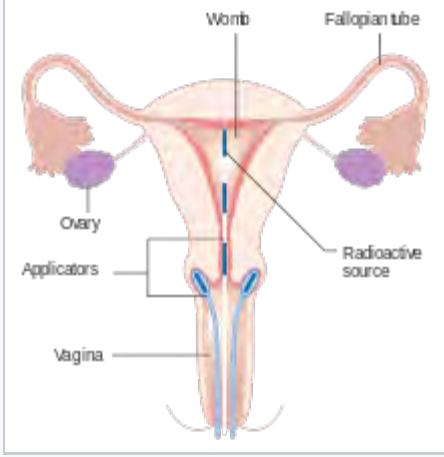
conization) is considered curative.

If a cone biopsy does not produce clear margins[65] (findings on biopsy showing that the tumor is surrounded by cancer free tissue, suggesting all of the tumor is removed), one more possible treatment option for women who want to preserve their fertility is a trachelectomy.[66] This attempts to surgically remove the cancer while preserving the ovaries and uterus, providing for a more conservative operation than a hysterectomy. It is a viable option for those in stage I cervical cancer which has not spread; however, it is not yet considered a standard of care,[67] as few doctors are skilled in this procedure. Even the most experienced surgeon cannot promise that a trachelectomy can be performed until after surgical microscopic examination, as the extent of the spread of cancer is unknown. If the surgeon is not able to microscopically confirm clear margins of cervical tissue once the woman is under general anesthesia in the operating room, a hysterectomy may still be needed. This can only be done during the same operation if the woman has given prior consent. Due to the possible risk of cancer spread to the lymph nodes in stage 1b cancers and some stage 1a cancers, the surgeon may also need to remove some lymph nodes from around the uterus for pathologic evaluation.

A radical trachelectomy can be performed abdominally[68] or vaginally[69] and opinions are conflicting as to which is better.[70] A radical abdominal trachelectomy with lymphadenectomy usually only requires a two- to three-day hospital stay, and most women recover very quickly (about six weeks). Complications are uncommon, although women who are able to conceive after surgery are susceptible to preterm labor and possible late miscarriage.[71] Wait at least one year is generally recommended before attempting to become pregnant after surgery.[72] Recurrence in the residual cervix is very rare if the cancer has been cleared with the trachelectomy.[67] Yet, women are recommended to practice vigilant prevention and follow-up care including Pap screenings/colposcopy, with biopsies of the remaining lower uterine segment as needed (every 3–4 months for at least 5 years) to monitor for any recurrence in addition to minimizing any new exposures to HPV through safe sex practices until one is actively trying to conceive.

Early stages (IB1 and IIA less than 4 cm) can be treated with radical hysterectomy with removal of the lymph nodes or radiation therapy. Radiation therapy is given as external beam radiotherapy to the pelvis and brachytherapy (internal radiation). Women treated with surgery who have high-risk features found on pathologic examination are given radiation therapy with or without chemotherapy to reduce the risk of relapse.

Larger early-stage tumors (IB2 and IIA more than 4 cm) may be treated with radiation therapy and cisplatin-based chemotherapy, hysterectomy (which then usually requires adjuvant radiation therapy), or cisplatin chemotherapy followed by hysterectomy. When cisplatin is present, it is thought to be the most active single agent in periodic diseases.[73] Such addition of platinum-based chemotherapy to chemoradiation seems not only to improve survival but also reduces risk of recurrence in women with early stage cervical cancer (IA2-IIA).[74]



Brachytherapy for cervical cancer

Advanced-stage tumors (IIB-IVA) are treated with radiation therapy and cisplatin-based chemotherapy. On June 15, 2006, the US Food and Drug Administration approved the use of a combination of two chemotherapy drugs, hycamtin and cisplatin, for women with late-stage (IVB) cervical cancer treatment.[75] Combination treatment has significant risk of neutropenia, anemia, and thrombocytopenia side effects.

For surgery to be curative, the entire cancer must be removed with no cancer found at the margins of the removed tissue on examination under a microscope.[76] This procedure is known as exenteration.[76]

Diagram showing the area removed with a posterior surgery

Diagram showing the area removed with a total operation

Diagram showing the area removed with an anterior operation

## Prognosis [edit]

Prognosis depends on the stage of the cancer. The chance of a survival rate around 100% is high for women with microscopic forms of cervical cancer.[77] With treatment, the five-year relative survival rate for the earliest stage of invasive cervical cancer is 92%, and the overall (all stages combined) five-year survival rate is about 72%. These statistics may be improved when applied to women newly diagnosed, bearing in mind that these outcomes may be partly based on the state of treatment five years ago when the women studied were first diagnosed.[78]

With treatment, 80 to 90% of women with stage I cancer and 60 to 75% of those with stage II cancer are alive 5 years after diagnosis. Survival rates decrease to 30 to 40% for women with stage III cancer and 15% or fewer of those with stage IV cancer 5 years after diagnosis.[79]

According to the International Federation of Gynecology and Obstetrics, survival improves when radiotherapy is combined with cisplatin-based chemotherapy.[80]

As the cancer metastasizes to other parts of the body, prognosis drops dramatically because treatment of local lesions is generally more effective than whole-body treatments such as chemotherapy.

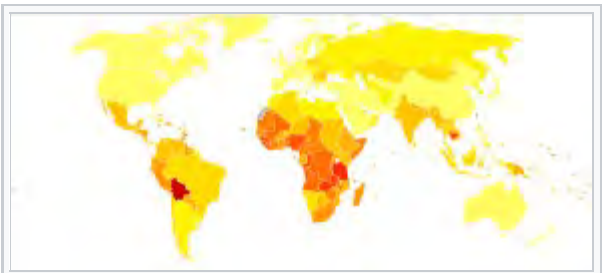
Interval evaluation of the woman after therapy is imperative. Recurrent cervical cancer detected at its earliest stages might be successfully treated with surgery, radiation, chemotherapy, or a combination of the three. About 35% of women with invasive cervical cancer have persistent or recurrent disease after treatment.[81]

Average years of potential life lost from cervical cancer are 25.3.[82] Around 4,600 women were projected to die in 2001 in the US of cervical cancer, and the annual incidence was 13,000 in 2002 in the US, as calculated by SEER. Thus, the ratio of deaths to incidence is about 35.4%.

Regular screening has meant that precancerous changes and early-stage cervical cancers have been detected and treated early. Figures suggest that cervical screening is saving 5,000 lives each year in the UK by preventing cervical cancer.[83] About 1,000 women per year die of cervical cancer in the UK. All of the Nordic countries have cervical cancer-screening programs in place.[84] Pap smear was integrated into clinical practice in the Nordic countries in the 1960s.[84]

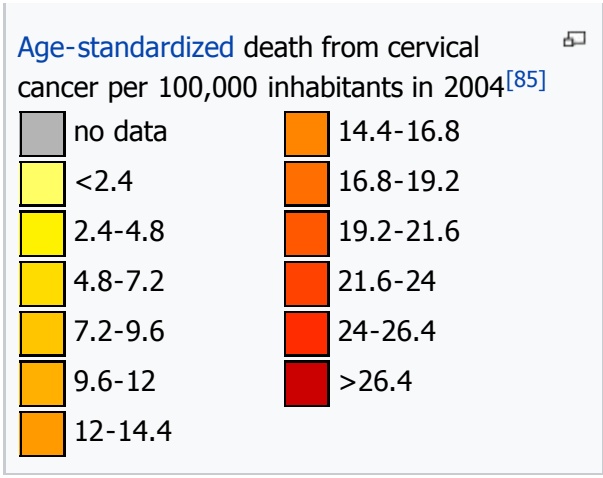
## Epidemiology [edit]

### Worldwide [edit]



Worldwide, cervical cancer is both the fourth-most common cause of cancer and deaths from cancer in women.[6] In 2012, 528,000 cases of cervical cancer were estimated to have occurred, with 266,000 deaths.[6] It is the second-most common cause of female-specific cancer after breast cancer,

accounting for around 8% of both total cancer cases and total cancer deaths in women.[15] About 80% of cervical cancers occur in developing countries.[86]



## United States [edit]

An estimated 12,900 new cervical cancers and 4,100 cervical cancer deaths will occur in the United States in 2015.[29] In the United States, it is the eight-most common cancer of women. The median age at diagnosis is 48. Hispanic women are significantly more likely to be diagnosed with cervical cancer than the general population.[87] In 1998, about 12,800 women were diagnosed in the US and about 4,800 died.[16] In 2014, an estimated 12,360 new cases were expected to be diagnosed, and about 4,020 were expected to die of cervical cancer.[87] Among cancers of the female reproductive tract it is less common than endometrial cancer and ovarian cancer. The rates of new cases in the United States was 7 per 100,000 women in 2004.[88] Cervical cancer deaths decreased by approximately 74% in the last 50 years, largely due to widespread Pap smear screening.[89] The annual direct medical cost of cervical cancer prevention and treatment prior to introduction of the HPV vaccine was estimated at $6 billion.[89]

## EU [edit]

In the European Union, about 34,000 new cases per year and over 16,000 deaths due to cervical cancer occurred in 2004.[42]

## UK [edit]

Cervical cancer is the 12th-most common cancer in women in the UK (around 3,100 women were diagnosed with the disease in 2011), and accounts for 1% of cancer deaths (around 920 died in 2012).[90] With a 42% reduction from 1988-1997, the NHS-implemented screening programme has been highly successful, screening the highest-risk age group (25–49 years) every 3 years, and those ages 50–64 every 5 years.

## Canada [edit]

In Canada, an estimated 1,300 women will have been diagnosed with cervical cancer in 2008 and 380 will have died.[91]

## Australia [edit]

Australia had 734 cases of cervical cancer (2005). The number of women diagnosed with cervical cancer has dropped on average by 4.5% each year since organised screening began in 1991 (1991–2005).[92] Regular twice-yearly Pap tests can reduce the incidence of cervical cancer up to 90% in Australia, and save 1,200 Australian women from dying from the disease each year.[93]

## India [edit]

In India, the number of people with cervical cancer is rising, but overall the age-adjusted rates are decreasing.[94] Usage of condoms in the female population has improved the survival of women with cancers of the cervix.[95]

# History [edit]

400 BCE - Hippocrates noted that cervical cancer was incurable
- 1925 - Hinselmann invented the colposcope
- 1928 - Papanicolaou developed the Papanicolaou technique
- 1941 - Papanicolaou and Traut: Pap smear screening began
- 1946 - Aylesbury spatula was developed to scrape the cervix, collecting the sample for the Pap smear
- 1951 - First successful in-vitro cell line, HeLa, derived from biopsy of cervical cancer of Henrietta Lacks
- 1976 - Harald zur Hausen and Gisam found HPV DNA in cervical cancer and genital warts; Hausen later won the Nobel Prize for his work[96]
- 1988 - Bethesda System for reporting Pap results was developed
- 2006 - First HPV vaccine was approved by the FDA

Epidemiologists working in the early 20th century noted that cervical cancer behaved like a sexually transmitted disease. In summary:

1. Cervical cancer was noted to be common in female sex workers.
2. It was rare in nuns, except for those who had been sexually active before entering the convent. (Rigoni in 1841)
3. It was more common in the second wives of men whose first wives had died from cervical cancer.
4. It was rare in Jewish women.[97]
5. In 1935, Syverton and Berry discovered a relationship between RPV (Rabbit Papillomavirus) and skin cancer in rabbits. (HPV is species-specific and therefore cannot be transmitted to rabbits)[*citation needed*]

These historical observations suggested that cervical cancer could be caused by a sexually transmitted agent. Initial research in the 1940s and 1950s attributed cervical cancer to smegma (e.g. Heins *et al.* 1958).[98] During the 1960s and 1970s it was suspected that infection with herpes simplex virus was the cause of the disease. In summary, HSV was seen as a likely cause because it is known to survive in the female reproductive tract, to be transmitted sexually in a way compatible with known risk factors, such as promiscuity and low socioeconomic status.[99] Herpes viruses were also implicated in other malignant diseases, including Burkitt's lymphoma, Nasopharyngeal carcinoma, Marek's disease and the Lucké renal adenocarcinoma. HSV was recovered from cervical tumour cells.

A description of human papillomavirus (HPV) by electron microscopy was given in 1949, and HPV-DNA was identified in 1963.[*citation needed*] It was not until the 1980s that HPV was identified in cervical cancer tissue.[100] It has since been demonstrated that HPV is implicated in virtually all cervical cancers.[101] Specific viral subtypes implicated are HPV 16, 18, 31, 45 and others.

In work that was initiated in the mid 1980s, the HPV vaccine was developed, in parallel, by researchers at Georgetown University Medical Center, the University of Rochester, the University of Queensland in Australia, and the U.S. National Cancer Institute.[102] In 2006, the U.S. Food and Drug Administration (FDA) approved the first preventive HPV vaccine, marketed by Merck & Co. under the trade name Gardasil.

## Society and culture [edit]

### Australia [edit]

In Australia, Aboriginal women are more than five times more likely to die from cervical cancer than non-Aboriginal women, suggesting that Aboriginal women are less likely to have regular Pap tests.[103] There are several factors that may limit indigenous women from engaging in regular cervical screening practices, including sensitivity in discussing the topic in Aboriginal communities, embarrassment, anxiety and fear about the procedure.[104] Difficulty in accessing screening services (for example, transport difficulties) and a lack of female GPs, trained pap smear providers and trained female Aboriginal Health Workers are also issues.[104]

The Australian Cervical Cancer Foundation (ACCF), founded in 2008, promotes 'women's health by eliminating cervical cancer and enabling treatment for women with cervical cancer and related health

issues, in Australia and in developing countries.'[105] Ian Frazer, one of the developers of the Gardasil cervical cancer vaccine, is the scientific advisor to ACCF.[106] Janette Howard, the wife of former Australian Prime Minister John Howard, was diagnosed with cervical cancer in 1996, and first spoke on her battle with the disease in 2006.[107]

### United States [edit]

A 2007 survey of 3,076 American women found only 40% had heard of HPV infection and less than half of those knew it causes cervical cancer.[108]

## Research [edit]

- Ludwig-McGill HPV Cohort, large longitudinal study of the natural history of human papillomavirus infection and cervical cancer risk

# Colorectal cancer

From Wikipedia, the free encyclopedia

(Redirected from Colon cancer)

**Colorectal cancer** (**CRC**), also known as **bowel cancer**, is the development of cancer from the colon or rectum (parts of the large intestine).[1] It is due to the abnormal growth of cells that have the ability to invade or spread to other parts of the body.[2] Signs and symptoms may include blood in the stool, a change in bowel movements, weight loss, and feeling tired all the time.[3]

Most colorectal cancers are due to old age and lifestyle factors with only a small number of cases due to underlying genetic disorders.[4][5] Some risk factors include diet, obesity, smoking, and lack of physical activity.[4][5] Dietary factors that increase the risk include red and processed meat as well as alcohol.[4] Another risk factor is inflammatory bowel disease, which includes Crohn's disease and ulcerative colitis.[4] Some of the inherited genetic disorders that can cause colorectal cancer include familial adenomatous polyposis and hereditary non-polyposis colon cancer; however, these represent less than 5% of cases.[4][5] It typically starts as a benign tumor, often in the form of a polyp, which over time becomes cancerous.[4]

Bowel cancer may be diagnosed by obtaining a sample of the colon during a sigmoidoscopy or colonoscopy.[3] This is then followed by medical imaging to determine if the disease has spread.[1] Screening is effective for preventing and decreasing deaths from colorectal cancer.[6] Screening is recommended starting from the age of 50 to 75.[6] During colonoscopy, small polyps may be removed if found. If a large polyp or tumor is found, a biopsy may be performed to check if it is cancerous. Aspirin and other non-steroidal anti-inflammatory drugs decrease the risk.[4][7] Their general use is not recommended for this purpose, however, due to side effects.[8]

Treatments used for colorectal cancer may include some combination of surgery, radiation therapy, chemotherapy and targeted therapy.[1] Cancers that are confined within the wall of the colon may be curable with surgery while cancer that has spread widely are usually not curable, with management being directed towards improving quality of life and symptoms.[1] Five year survival rates in the United States are around 65%.[9] This, however, depends on how advanced the cancer is, whether or not all the cancer can be removed with surgery, and the person's overall health.[3] Globally, colorectal cancer is the third most common type of cancer making up about 10% of all cases.[10] In 2012, there were 1.4 million new cases and 694,000 deaths from the disease.[10] It is more common in developed countries, where more than 65% of cases are found.[4] It is less common in women than men.[4]

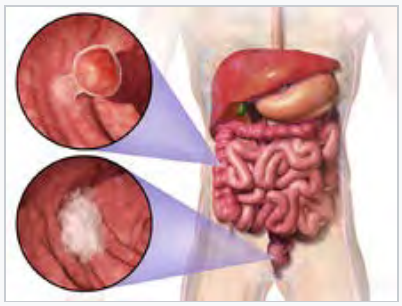
## Signs and symptoms [edit]

The signs and symptoms of colorectal cancer depend on the location of the tumor in the bowel, and whether it has spread elsewhere in the body (metastasis). The classic warning signs include: worsening constipation, blood in the stool, decrease in stool caliber (thickness), loss of appetite, loss of weight, and nausea or vomiting in someone over 50 years old.[11] While rectal bleeding or anemia are high-risk features in those over the age of 50,[12] other commonly described symptoms including weight loss and change in bowel habit are typically only concerning if associated with bleeding.[12][13]



Location and appearance of two example colorectal tumors

## Cause [edit]

Greater than 75–95% of colon cancer occurs in people with little or no genetic risk.[14][15] Risk factors include older age, male gender,[15] high intake of fat, alcohol, red meat, processed meats, obesity, smoking, and a lack of physical exercise.[14][16] Approximately 10% of cases are linked to insufficient activity.[17] The risk for alcohol appears to increase at greater than one drink per day.[18] Drinking 5 glasses of water a day is linked to a decrease in the risk of colorectal cancer and adenomatous polyps.[19]

### Inflammatory bowel disease [edit]

People with inflammatory bowel disease (ulcerative colitis and Crohn's disease) are at increased risk of colon cancer.[20] The risk increases the longer a person has the disease,[21] and the worse the severity of inflammation.[22] In these high risk groups, both prevention with aspirin and regular colonoscopies are recommended.[21] People with inflammatory bowel disease account for less than 2% of colon cancer cases yearly.[22] In those with Crohn's disease 2% get colorectal cancer after 10 years, 8% after 20 years, and 18% after 30 years.[22] In those with ulcerative colitis approximately 16% develop either a cancer precursor or cancer of the colon over 30 years.[22]

## Genetics [edit]

Those with a family history in two or more first-degree relatives (such as a parent or sibling) have a two to threefold greater risk of disease and this group accounts for about 20% of all cases. A number of genetic syndromes are also associated with higher rates of colorectal cancer. The most common of these is hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome) which is present in about 3% of people with colorectal cancer.[15] Other syndromes that are strongly associated with colorectal cancer include Gardner syndrome,[23] and familial adenomatous polyposis (FAP). For people with these syndromes, cancer almost always occurs and makes up 1% of the cancer cases.[24] A total proctocolectomy may be recommended for people with FAP as a preventative measure due to the high risk of malignancy. Colectomy, removal of the colon, may not suffice as a preventative measure because of the high risk of rectal cancer if the rectum remains.[25]

Most deaths due to colon cancer are associated with metastatic disease. A gene that appears to contribute to the potential for metastatic disease, metastasis associated in colon cancer 1 (*MACC1*), has been isolated.[26] It is a transcriptional factor that influences the expression of hepatocyte growth factor. This gene is associated with the proliferation, invasion and scattering of colon cancer cells in cell culture, and tumor growth and metastasis in mice. MACC1 may be a potential target for cancer intervention, but this possibility needs to be confirmed with clinical studies.[27]

Epigenetic factors, such as abnormal DNA methylation of tumor suppressor promoters play a role in the development of colorectal cancer.[28]

# Pathogenesis [edit]

Colorectal cancer is a disease originating from the epithelial cells lining the colon or rectum of the gastrointestinal tract, most frequently as a result of mutations in the Wnt signaling pathway that increase signaling activity. The mutations can be inherited or acquired, and most probably occur in the intestinal crypt stem cell.[29][30][31] The most commonly mutated gene in all colorectal cancer is the *APC* gene, which produces the APC protein. The APC protein prevents the accumulation of β-catenin protein. Without APC, β-catenin accumulates to high levels and translocates (moves) into the nucleus, binds to DNA, and activates the transcription of proto-oncogenes. These genes are normally important for stem cell renewal and differentiation, but when inappropriately expressed at high levels, they can cause cancer. While APC is mutated in most colon cancers, some cancers have increased β-catenin because of mutations in β-catenin (CTNNB1) that block its own breakdown, or have mutations in other genes with function similar to APC such as AXIN1, AXIN2, TCF7L2, or NKD1.[32]

Beyond the defects in the Wnt signaling pathway, other mutations must occur for the cell to become cancerous. The p53 protein, produced by the *TP53* gene, normally monitors cell division and kills cells if they have Wnt pathway defects. Eventually, a cell line acquires a mutation in the *TP53* gene and transforms the tissue from a benign epithelial tumor into an invasive epithelial cell cancer. Sometimes the gene encoding p53 is not mutated, but another protective protein named BAX is mutated instead.[32]

Other proteins responsible for programmed cell death that are commonly deactivated in colorectal cancers are TGF-β and DCC (Deleted in Colorectal Cancer). TGF-β has a deactivating mutation in at least half of colorectal cancers. Sometimes TGF-β is not deactivated, but a downstream protein named SMAD is deactivated.[32] DCC commonly has a deleted segment of a chromosome in colorectal cancer.[33]

Some genes are oncogenes: they are overexpressed in colorectal cancer. For example, genes encoding the proteins KRAS, RAF, and PI3K, which normally stimulate the cell to divide in response to growth factors, can acquire mutations that result in over-activation of cell proliferation. The chronological order of mutations is sometimes important. If a previous APC mutation occurred, a primary KRAS mutation often progresses to cancer rather than a self-limiting hyperplastic or borderline lesion.[34] PTEN, a tumor suppressor, normally inhibits PI3K, but can sometimes become mutated and deactivated.[32]

Comprehensive, genome-scale analysis has revealed that colorectal carcinomas can be categorized into hypermutated and non-hypermutated tumor types.[35] In addition to the oncogenic and inactivating mutations described for the genes above, non-hypermutated samples also contain mutated CTNNB1, FAM123B, SOX9, ATM, and ARID1A. Progressing through a distinct set of genetic events, hypermutated tumors display mutated forms of ACVR2A, TGFBR2, MSH3, MSH6, SLC9A9, TCF7L2, and BRAF. The common theme among these genes, across both tumor types, is their involvement in WNT and TGF-β signaling pathways, which results in increased activity of MYC, a central player in colorectal cancer.[35]

## Field defects [edit]

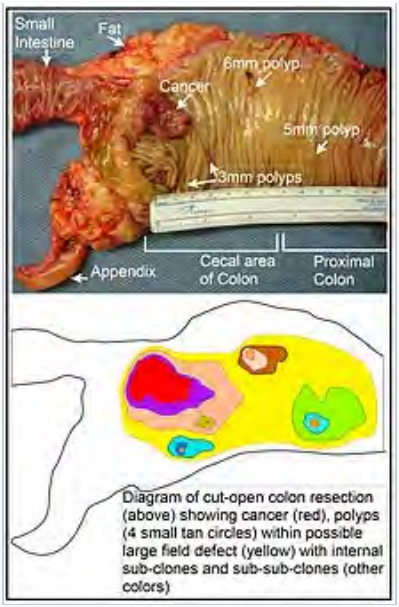
The term "field cancerization" was first used in 1953 to describe an area or

"field" of epithelium that has been preconditioned (by what were largely unknown processes at the time) to predispose it towards development of cancer.[36] Since then, the terms "field cancerization", "field carcinogenesis", "field defect", and "field effect" have been used to describe pre-malignant or pre-neoplastic tissue in which new cancers are likely to arise.[37]

Field defects are important in progression to colon cancer.[38][39][40]

However, in most cancer research, as pointed out by Rubin[41] "The vast majority of studies in cancer research has been done on well-defined tumors *in vivo*, or on discrete neoplastic foci *in vitro*. Yet there is evidence that more than 80% of the somatic mutations found in mutator phenotype human colorectal tumors occur before the onset of terminal clonal expansion."[42] Similarly, Vogelstein et al.[43] pointed out that more than half of somatic mutations identified in tumors occurred in a pre-neoplastic phase (in a field defect), during growth of apparently normal cells. Likewise, epigenetic alterations present in tumors may have occurred in pre-neoplastic field defects.

An expanded view of field effect has been termed "etiologic field effect", which encompasses not only molecular and pathologic changes in pre-neoplastic cells but also influences of exogenous environmental factors and molecular changes in the local microenvironment on neoplastic evolution from tumor initiation to death.[44]



Longitudinally opened freshly resected colon segment showing a cancer and four polyps. Plus a schematic diagram indicating a likely field defect (a region of tissue that precedes and predisposes to the development of cancer) in this colon segment. The diagram indicates sub-clones and sub-sub-clones that were precursors to the tumors.

## Epigenetics [edit]

Epigenetic alterations are much more frequent in colon cancer than genetic (mutational) alterations. As described by Vogelstein et al.,[43] an average cancer of the colon has only 1 or 2 oncogene mutations and 1 to 5 tumor suppressor mutations (together designated "driver mutations"), with about 60 further "passenger" mutations. The oncogenes and tumor suppressor genes are well studied and are described above under Pathogenesis.

However, by comparison, epigenetic alterations in colon cancers are frequent and affect hundreds of genes. For instance, there are types of small RNAs called microRNAs that are about 22 nucleotides long. These microRNAs (or miRNAs) do not code for proteins, but they can target protein coding genes and reduce their expression. Expression of these miRNAs can be epigenetically altered. As one example, the epigenetic alteration consisting of CpG island methylation of the DNA sequence encoding miR-137 reduces its expression. This is a frequent early epigenetic event in colorectal carcinogenesis, occurring in 81% of colon cancers and in 14% of the normal appearing colonic mucosa adjacent to the cancers. The altered adjacent tissues associated with these cancers are called field defects. Silencing of miR-137 can affect expression of about 500 genes, the targets of this miRNA.[45]

Changes in the level of miR-137 expression result in changed mRNA expression of the target genes by 2 to 20-fold and corresponding, though often smaller, changes in expression of the protein products of the genes. Other microRNAs, with likely comparable numbers of target genes, are even more frequently epigenetically altered in colonic field defects and in the colon cancers that arise from them. These include miR-124a, miR-34b/c and miR-342 which are silenced by CpG island methylation of their encoding DNA sequences in primary tumors at rates of 99%, 93% and 86%, respectively, and in the adjacent normal appearing mucosa at rates of 59%, 26% and 56%, respectively.[46][47]

In addition to epigenetic alteration of expression of miRNAs, other common types of epigenetic alterations in cancers that change gene expression levels include direct hypermethylation or hypomethylation of CpG islands of protein-encoding genes and alterations in histones and chromosomal architecture that influence gene expression.[48][49] As an example, 147 hypermethylations and 27 hypomethylations of protein coding genes were frequently associated with colorectal cancers. Of the hypermethylated genes, 10 were hypermethylated in 100% of colon cancers, and many others were hypermethylated in more than 50% of colon cancers.[50] In addition, 11 hypermethylations and 96 hypomethylations of miRNAs were also associated with colorectal cancers.[50]

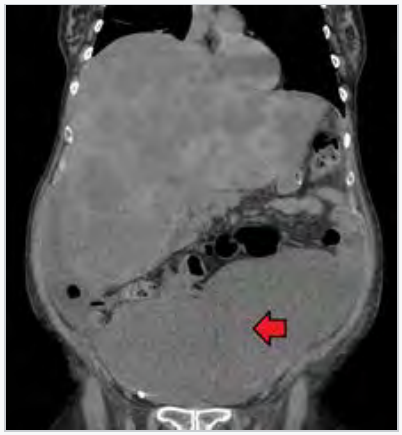
Recent evidence indicates that early epigenetic reductions of DNA repair enzyme expression likely lead to the genomic and epigenomic instability characteristic of cancer.[38][51][52][53]

As summarized in the articles Carcinogenesis and Neoplasm, for sporadic cancers in general, a deficiency in DNA repair is occasionally due to a mutation in a DNA repair gene, but is much more frequently due to epigenetic alterations that reduce or silence expression of DNA repair genes.

# Diagnosis [edit]

Colorectal cancer diagnosis is performed by sampling of areas of the colon suspicious for possible tumor development, typically during colonoscopy or sigmoidoscopy, depending on the location of the lesion. Disease extent is usually determined by a CT scan of the chest, abdomen and pelvis. Other potential imaging tests such as PET and MRI may be used in certain cases. Colon cancer staging is done next, based on the TNM system which considers how much the initial tumor has spread, if and where lymph nodes are involved and the extent of metastatis.[15]

The microscopic cellular characteristics of the tumor are usually reported from the analysis of tissue taken from a biopsy or surgery. A pathology report usually contains a description of cell type and grade. The most common colon cancer cell type is adenocarcinoma (98% of cases).[54] Other, rarer types include lymphoma and squamous cell carcinoma.



Colon cancer with extensive metastases to the liver

## Macroscopy [edit]

Cancers on the right side of the large intestine (ascending colon and cecum) tend to be exophytic, that is, the tumor grows outwards from one location in the bowel wall. This very rarely causes obstruction of feces, and presents with symptoms such as anemia. Left-sided tumors tend to be circumferential, and can obstruct the bowel lumen, much like a napkin ring, and results in thinner caliber stools.

## Microscopy [edit]

Adenocarcinoma is a malignant epithelial tumor, originating from superficial glandular epithelial cells lining the colon and rectum. It invades the wall, infiltrating the muscularis mucosae layer, the submucosa, and then the muscularis propria. Tumor cells describe irregular tubular structures, harboring pluristratification, multiple lumens, reduced stroma ("back to back" aspect). Sometimes, tumor cells are discohesive and secrete mucus, which invades the interstitium producing large pools of mucus/colloid (optically "empty" spaces). This occurs in *mucinous (colloid)* adenocarcinoma, in which cells are poorly differentiated. If the mucus remains inside the tumor cell, it pushes the nucleus at the periphery. This occurs in "signet-ring cell." Depending on glandular architecture, cellular pleomorphism, and mucosecretion of the predominant pattern, adenocarcinoma may present three degrees of differentiation: well, moderately, and poorly differentiated.[55]

## Immunochemistry [edit]

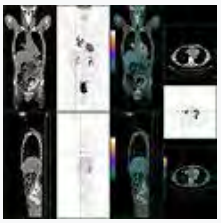
Most (50%) colorectal adenomas and (80–90%) colorectal cancer tumors are thought to over express the cyclooxygenase-2 (COX-2) enzyme.[56] This enzyme is generally not found in healthy colon tissue, but is thought to fuel abnormal cell growth.

### Macroscopy

Appearance of the inside of the colon showing one invasive colorectal carcinoma (the crater-like, reddish, irregularly shaped tumor)

Gross appearance of a colectomy specimen containing two adenomatous polyps (the brownish oval tumors above the labels, attached to the normal beige lining by a stalk) and one invasive

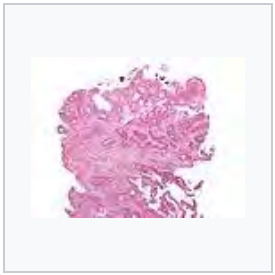
Endoscopic image of colon cancer identified in sigmoid colon on screening colonoscopy in the setting of Crohn's disease



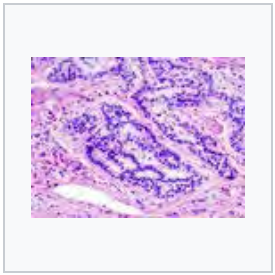
PET/CT of a staging exam of colon carcinoma. Besides the primary tumor a lot of lesions can be seen. On cursor position: lung nodule.

colorectal carcinoma (the crater-like, reddish, irregularly shaped tumor located above the label)

**Micrographs (H&E stain)**

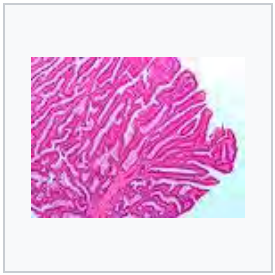


Cancer — Invasive adenocarcinoma (the most common type of colorectal cancer). The cancerous cells are seen in the center and at the bottom right of the image (blue). Near normal colon-lining cells are seen at the top right of the image.



Cancer — Histopathologic image of colonic carcinoid

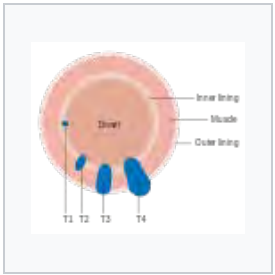
Precancer — Tubular adenoma (left of image), a type of colonic polyp and a precursor of colorectal cancer. Normal colorectal mucosa is seen on the right.



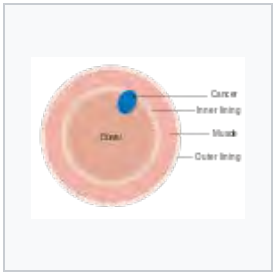
Precancer — Colorectal villous adenoma

## Staging [edit]

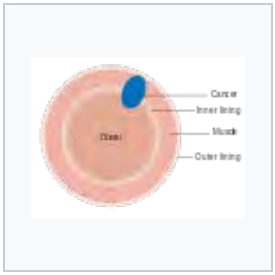
Staging is typically made according to the TNM staging system from the WHO organization, the UICC and the AJCC. The Astler-Coller classification (1954) and the Dukes classification (1932) are now less used.



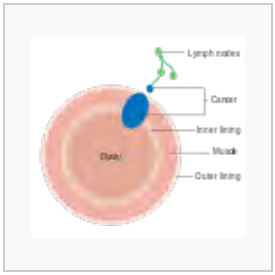
The T stages of bowel cancer.



Dukes stage A bowel cancer; the cancer is only in the inner lining of the bowel.



Dukes stage B bowel cancer; the cancer has invaded the muscle.



Dukes stage C bowel cancer; the cancer has invaded the nearby lymph nodes.

Dukes stage D bowel cancer; the cancer has metastasized.

## Tumor budding [edit]

Tumor budding in colorectal cancer is loosely defined by the presence of individual cells and small clusters of tumor cells at the invasive front of carcinomas. It has been postulated to represent an epithelial–mesenchymal transition (EMT). Tumor budding is a well-established independent marker of a potentially poor outcome in colorectal carcinoma that may allow for dividing people into risk categories more meaningful than those defined by TNM staging, and also potentially guide treatment decisions, especially in T1 and T3 N0 (Stage II, Dukes' B) colorectal carcinoma. Unfortunately, its universal acceptance as a reportable factor has been held back by a lack of definitional uniformity with respect to both qualitative and quantitative aspects of tumor budding.[57]

# Prevention [edit]

It has been estimated that about half of colorectal cancer cases are due to lifestyle factors and about a quarter of

all cases are preventable.[58] Increasing surveillance, engaging in physical activity, consuming a diet high in fiber, and reducing smoking and alcohol consumption decrease the risk.[59][60]

## Lifestyle [edit]

Current dietary recommendations to prevent colorectal cancer include increasing the consumption of whole grains, fruits and vegetables, and reducing the intake of red meat and processed meats.[16][61] Higher physical activity is also recommended.[16][62] Physical exercise is associated with a modest reduction in colon but not rectal cancer risk.[63][64] High levels of physical activity reduce the risk of colon cancer by about 21%.[65] Sitting regularly for prolonged periods is associated with higher mortality from colon cancer. The risk is not negated by regular exercise, though it is lowered.[66] The evidence for any protective effect conferred by fiber and fruits and vegetables is, however, poor.[16][67] The risk of colon cancer can be reduced by maintaining a normal body weight.[68]

## Medication [edit]

Aspirin and celecoxib appear to decrease the risk of colorectal cancer in those at high risk.[69] Aspirin is recommended in those who are 50 to 60 years old, do not have an increased risk of bleeding, and are at risk for cardiovascular disease to prevent colorectal cancer.[70] It is not recommended in those at average risk.[71] There is tentative evidence for calcium supplementation but it is not sufficient to make a recommendation.[72] Vitamin D intake and blood levels are associated with a lower risk of colon cancer.[73][74]

## Screening [edit]

As more than 80% of colorectal cancers arise from adenomatous polyps, screening for this cancer is effective not only for early detection but also for prevention.[75] Diagnosis of cases of colorectal cancer through screening tends to occur 2–3 years before diagnosis of cases with symptoms.[15] Any polyps that are detected can be removed, usually by colonoscopy or sigmoidoscopy, and thus prevented from turning cancerous. Screening has the potential to reduce colorectal cancer deaths by 60%.[76]

The four main screening tests are fecal occult blood testing, flexible sigmoidoscopy, colonoscopy, and stool DNA screening test.[15] Of the three, only sigmoidoscopy cannot screen the right side of the colon where 42% of malignancies are found.[77] Virtual colonoscopy via a CT scan appears as good as standard colonoscopy for detecting cancers and large adenomas but is expensive, associated with radiation exposure, and cannot remove any detected abnormal growths like standard colonoscopy can.[15]

Fecal occult blood testing (FOBT) of the stool is typically recommended every two years and can be either guaiac based or immunochemical.[15] If abnormal FOBT results are found, participants are typically referred for a follow-up colonoscopy examination. Annual to biennial FOBT screening reduce colorectal cancer mortality by 16% and among those participating in screening colorectal cancer mortality can be reduced up to 23%, although it has not been proven to reduce all-cause mortality.[78] Immunochemical tests are highly accurate and do not require dietary or medication changes before testing.[79]

The multitarget stool DNA screening test is a noninvasive test used to screen for the presence of colorectal cancer or precancerous lesions. It uses a stool sample to identify biomarkers associated with colorectal cancer and precancerous lesions, including altered DNA and blood hemoglobin. A positive result may indicate the presence of precancerous lesions or colorectal cancer, and should be followed by colonoscopy. The American Cancer Society recommends screening with multitarget sDNA testing every 3 years, starting at age 50.[*citation needed*]

## Recommendations [edit]

In the United States screening is typically recommended between the age of 50 and 75 years.[6] For those between 76 and 85 years of age the decision to screen should be individualized.[6] A number of screening methods can be used including stool based tests every 3 years, sigmoidoscopy every 5 years and colonoscopy every 10 years. For those at high risk, screenings usually begin at around 40.[15][80] It is unclear which of these two methods is better.[81] Colonoscopy may find more cancers in the first part of the colon but is associated with greater cost and more complications.[81] For people with average risk who have had a high-quality colonoscopy with normal results, the American Gastroenterological Association does not recommend any type of screening in the 10 years following the colonoscopy.[82][83] For people over 75 or those with a life expectancy of less than 10 years, screening is not recommended.[84] It takes about 10 years after screening for one out of a 1000 people [85]

to benefit.

In Canada, among those 50 to 75 at normal risk, fecal immunochemical testing or FOBT is recommended every two years or sigmoidoscopy every 10 years.[86] Colonoscopy is less preferred.[86]

Some countries have national colorectal screening programs which offer FOBT screening for all adults within a certain age group, typically starting between age 50 and 60. Examples of countries with organised screening include the United Kingdom,[87] Australia[88] and the Netherlands.[89]

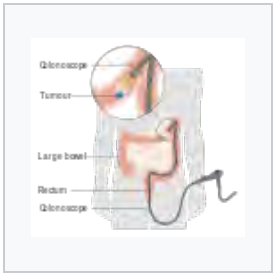
## Management [edit]

The treatment of colorectal cancer can be aimed at cure or palliation. The decision on which aim to adopt depends on various factors, including the person's health and preferences, as well as the stage of the tumor.[90] When colorectal cancer is caught early, surgery can be curative. However, when it is detected at later stages (for which metastases are present), this is less likely and treatment is often directed at palliation, to relieve symptoms caused by the tumour and keep the person as comfortable as possible.[15]

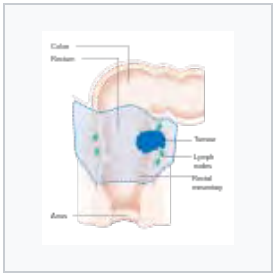
### Surgery [edit]

If the cancer is found at a very early stage, it may be removed during a colonoscopy.[1] For people with localized cancer, the preferred treatment is complete surgical removal with adequate margins, with the attempt of achieving a cure. This can either be done by an open laparotomy or sometimes laparoscopically.[15] The colon may then be reconnected or a person may have a colostomy.[1]

If there are only a few metastases in the liver or lungs they may also be removed. Sometimes chemotherapy is used before surgery to shrink the cancer before attempting to remove it. The two most common sites of recurrence of colorectal cancer are the liver and lungs.[15]



A diagram of a local resection of early stage colon cancer



A diagram of local surgery for rectal cancer

### Chemotherapy [edit]

In both cancer of the colon and rectum, chemotherapy may be used in addition to surgery in certain cases. The decision to add chemotherapy in management of colon and rectal cancer depends on the stage of the disease.

In Stage I colon cancer, no chemotherapy is offered, and surgery is the definitive treatment. The role of chemotherapy in Stage II colon cancer is debatable, and is usually not offered unless risk factors such as T4 tumor or inadequate lymph node sampling is identified. It is also known that the patients who carry abnormalities of the mismatch repair genes do not benefit from chemotherapy. For stage III and Stage IV colon cancer, chemotherapy is an integral part of treatment.[15]

If cancer has spread to the lymph nodes or distant organs, which is the case with stage III and stage IV colon cancer respectively, adding chemotherapy agents fluorouracil, capecitabine or oxaliplatin increases life expectancy. If the lymph nodes do not contain cancer, the benefits of chemotherapy are controversial. If the cancer is widely metastatic or unresectable, treatment is then palliative. Typically in this setting, a number of different chemotherapy medications may be used.[15] Chemotherapy drugs for this condition may include capecitabine, fluorouracil, irinotecan, oxaliplatin and UFT.[91] The drugs capecitabine and fluorouracil are interchangeable, with capecitabine being an oral medication while fluorouracil being an intravenous medicine. Some specific regimens used for CRC are FOLFOX, FOLFOXIRI, and FOLFIRI.[92] Antiangiogenic drugs such as bevacizumab are often added in first line therapy. Another class of drugs used in the second line setting are epidermal growth factor receptor inhibitors, of which the two FDA approved ones are cetuximab and panitumumab.[93]

The primary difference in the approach to low stage rectal cancer is the incorporation of radiation therapy. Often,

it is used in conjunction with chemotherapy in a neoadjuvant fashion to enable surgical resection, so that ultimately as colostomy is not required. However, it may not be possible in low lying tumors, in which case, a permanent colostomy may be required. Stage IV rectal cancer is treated similar to stage IV colon cancer.

## Radiation therapy [edit]

While a combination of radiation and chemotherapy may be useful for rectal cancer,[15] its use in colon cancer is not routine due to the sensitivity of the bowels to radiation.[94] Just as for chemotherapy, radiotherapy can be used in the neoadjuvant and adjuvant setting for some stages of rectal cancer.

## Palliative care [edit]

Palliative care is medical care which focuses on treatment of symptoms from serious illness, like cancer, and improving quality of life.[95] Palliative care is recommended for any person who has advanced colon cancer or has significant symptoms.[96]

Involvement of palliative care may be beneficial to improve the quality of life for both the person and his or her family, by improving symptoms, anxiety and preventing admissions to the hospital.[97]

In people with incurable colorectal cancer, palliative care can consist of procedures that relieve symptoms or complications from the cancer but do not attempt to cure the underlying cancer, thereby improving quality of life. Surgical options may include non-curative surgical removal of some of the cancer tissue, bypassing part of the intestines, or stent placement. These procedures can be considered to improve symptoms and reduce complications such as bleeding from the tumor, abdominal pain and intestinal obstruction.[98] Non-operative methods of symptomatic treatment include radiation therapy to decrease tumor size as well as pain medications.[99]

## Follow-up [edit]

The aims of follow-up are to diagnose, in the earliest possible stage, any metastasis or tumors that develop later, but did not originate from the original cancer (metachronous lesions).

The U.S. National Comprehensive Cancer Network and American Society of Clinical Oncology provide guidelines for the follow-up of colon cancer.[100][101] A medical history and physical examination are recommended every 3 to 6 months for 2 years, then every 6 months for 5 years. Carcinoembryonic antigen blood level measurements follow the same timing, but are only advised for people with T2 or greater lesions who are candidates for intervention. A CT-scan of the chest, abdomen and pelvis can be considered annually for the first 3 years for patients who are at high risk of recurrence (for example, those who had poorly differentiated tumors or venous or lymphatic invasion) and are candidates for curative surgery (with the aim to cure). A colonoscopy can be done after 1 year, except if it could not be done during the initial staging because of an obstructing mass, in which case it should be performed after 3 to 6 months. If a villous polyp, a polyp >1 centimeter or high grade dysplasia is found, it can be repeated after 3 years, then every 5 years. For other abnormalities, the colonoscopy can be repeated after 1 year.

Routine PET or ultrasound scanning, chest X-rays, complete blood count or liver function tests are not recommended.[100][101] A 2016 systematic review concluded that more intense surveillance and close follow-up does not provide additional survival benefits in non-metastatic colorectal cancers.[102]

## Exercise [edit]

Exercise may be recommended in the future as secondary therapy to cancer survivors. In epidemiological studies, exercise may decrease colorectal cancer-specific mortality and all-cause mortality. Results for the specific amounts of exercise needed to observe a benefit were conflicting. These differences may reflect differences in tumour biology and expression of biomarkers. Patients with tumors that lacked CTNNB1 expression (β-catenin), involved in Wnt signalling pathway, required more than 18 Metabolic equivalent (MET) hours per week, a measure of exercise, to observe a reduction in colorectal cancer mortality. The mechanism of how exercise benefits survival may be involved in immune surveillance and inflammation pathways. In clinical studies, a pro-inflammatory response was found in patients with stage II-III colorectal cancer who underwent 2 weeks of moderate exercise after completing their primary therapy. Oxidative balance may be another possible mechanism for benefits observed. A significant decrease in 8-oxo-dG was found in the urine of patients who underwent 2 weeks of moderate exercise after primary therapy. Other possible mechanisms may involve metabolic hormone and sex-steroid hormones, although these pathways may be involved in other types of cancers[103][104]

Another potential biomarker may be p27. Survivors with tumors that expressed p27 and performed greater and equal to 18 MET hours per week were found to have reduced colorectal-cancer mortality survival compared to those with less than 18 MET hours per week. Survivors without p27 expression who exercised were shown to have

worse outcomes. The constitutive activation of PI3K/AKT/mTOR pathway may explain the loss of p27 and excess energy balance may up-regulate p27 to stop cancer cells from dividing.[104]

## Prognosis [edit]

In Europe the five-year survival rate for colorectal cancer is less than 60%. In the developed world about a third of people who get the disease die from it.[15]

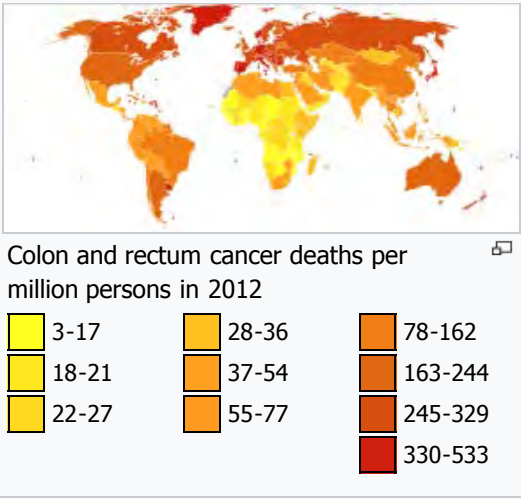
Survival is directly related to detection and the type of cancer involved, but overall is poor for symptomatic cancers, as they are typically quite advanced. Survival rates for early stage detection is about five times that of late stage cancers. People with a tumor that has not breached the muscularis mucosa (TNM stage Tis, N0, M0) have a five-year survival rate of 100%, while those with invasive cancer of T1 (within the submucosal layer) or T2 (within the muscular layer) have an average five-year survival rate of approximately 90%. Those with a more invasive tumor yet without node involvement (T3-4, N0, M0) have an average five-year survival rate of approximately 70%. Patients with positive regional lymph nodes (any T, N1-3, M0) have an average five-year survival rate of approximately 40%, while those with distant metastases (any T, any N, M1) have an average five-year survival rate of approximately 5%.[105]

According to American Cancer Society statistics in 2006,[106] over 20% of people with colorectal cancer come to medical attention when the disease is already advanced (stage IV), and up to 25% of this group will have isolated liver metastasis that is potentially resectable. In this selective group, those who undergo curative resection experience a five-year survival outcome in a third of the cases.[107]

## Epidemiology [edit]

Globally more than 1 million people get colorectal cancer every year[15] resulting in about 715,000 deaths as of 2010 up from 490,000 in 1990.[108]

As of 2012, it is the second most common cause of cancer in women (9.2% of diagnoses) and the third most common in men (10.0%)[109] with it being the fourth most common cause of cancer death after lung, stomach, and liver cancer.[110] It is more common in developed than developing countries.[111] Globally incidences vary 10-fold with highest rates in Australia, New Zealand, Europe and the US and lowest rates in Africa and South-Central Asia.[112]



Colon and rectum cancer deaths per million persons in 2012

### United States [edit]

Based on rates from 2007 to 2009, 4.96% of US men and women born today will be diagnosed with colorectal cancer during their lifetime.[113] From 2005 to 2009, the median age at diagnosis for cancer of the colon and rectum in the US was 69 years of age. Approximately 0.1% were diagnosed under age 20; 1.1% between 20 and 34; 4.0% between 35 and 44; 13.4% between 45 and 54; 20.4% between 55 and 64; 24.0% between 65 and 74; 25.0% between 75 and 84; and 12.0% 85+ years of age. Rates are higher among males (54 per 100,000 c.f. 40 per 100,000 for females).

## History [edit]

*See also: Timeline of colorectal cancer*

Rectal cancer has been diagnosed in an Ancient Egyptian mummy who had lived in the Dakhleh Oasis during the Ptolemaic period.[114]

The Biblical king Jehoram of Judah was recorded in 2 Chronicles 21 to be cursed with an incurable disease of the bowel, leading to his death, due to his supposed evil deeds. Modern scholarship indicates that his condition was most likely colon cancer.[115]

## Society and culture [edit]

[76]

In the United States, March is colorectal cancer awareness month.

### Notable cases [edit]

*Main article: List of people diagnosed with colorectal cancer*

- Corazon Aquino, former president of the Philippines[116]
- Pope John Paul II[117]
- Ronald Reagan, actor and former President of the United States[118]
- Howard Marks, Welsh drug smuggler and author [119]
- Harold Wilson, former Prime Minister of the United Kingdom[120]
- Robin Gibb, musician and member of the Bee Gees[121]
- Humayun Ahmed, Bengali writer and film maker[122]
- J.B.S. Haldane, Geneticist; polymath, popular science author[123]
- Stephen Sutton, Charity activist[124]

## Research [edit]

Preliminary in-vitro evidence suggests lactic acid bacteria (e.g., lactobacilli, streptococci or lactococci) may be protective against the development and progression of colorectal cancer through several mechanisms such as antioxidant activity, immunomodulation, promoting programmed cell death, antiproliferative effects, and epigenetic modification of cancer cells.[125]

Large-scale genome sequencing studies have been done to identify mutations in colorectal cancer patients' genome.[126]

The bacteria clostridium novyi-NT, is also being studied.[127]

- Mouse models of colorectal and intestinal cancer
- The Cancer Genome Atlas[35]
- The Colorectal Cancer Atlas integrating genomic and proteomic data pertaining to colorectal cancer tissues and cell lines have been developed.[128]

# Endometrial cancer

From Wikipedia, the free encyclopedia

**Endometrial cancer** is a cancer that arises from the endometrium (the lining of the uterus or womb).[1] It is the result of the abnormal growth of cells that have the ability to invade or spread to other parts of the body.[2] The first sign is most often vaginal bleeding not associated with a menstrual period. Other symptoms include pain with urination or sexual intercourse, or pelvic pain.[1] Endometrial cancer occurs most commonly after menopause.[3]

Approximately 40% of cases are related to obesity.[4] Endometrial cancer is also associated with excessive estrogen exposure, high blood pressure and diabetes.[1] Whereas taking estrogen alone increases the risk of endometrial cancer, taking both estrogen and a progestogen in combination, as in most birth control pills, decreases the risk.[1][4] Between two and five percent of cases are related to genes inherited from the parents.[4] Endometrial cancer is sometimes loosely referred to as "uterine cancer", although it is distinct from other forms of uterine cancer such as cervical cancer, uterine sarcoma, and trophoblastic disease.[5] The most frequent type of endometrial cancer is endometrioid carcinoma, which accounts for more than 80% of cases.[4] Endometrial cancer is commonly diagnosed by endometrial biopsy or by taking samples during a procedure known as dilation and curettage. A pap smear is not typically sufficient to show endometrial cancer.[6] Regular screening in those at normal risk is not called for.[7]

The leading treatment option for endometrial cancer is abdominal hysterectomy (the total removal by surgery of the uterus), together with removal of the fallopian tubes and ovaries on both sides, called a bilateral salpingo-oophorectomy. In more advanced cases, radiation therapy, chemotherapy or hormone therapy may also be recommended. If the disease is diagnosed at an early stage, the outcome is favorable,[6] and the overall five-year survival rate in the United States is greater than 80%.[8]

In 2012, endometrial cancers occurred in 320,000 women and caused 76,000 deaths.[4] This makes it the third most common cause of death in cancers which only affect women, behind ovarian and cervical cancer. It is more common in the developed world[4] and is the most common cancer of the female reproductive tract in developed countries.[6] Rates of endometrial cancer have risen in a number of countries between the 1980s and 2010.[4] This is believed to be due to the increasing number of elderly people and increasing rates of obesity.[9]

Contents

## Classification [edit]

There are several types of endometrial cancer, including the most common endometrial carcinomas, which are divided into Type I and Type II subtypes. There are also rarer types including uterine papillary serous carcinoma, adenosquamous carcinoma, carcinomasarcoma and uterine clear-cell carcinoma.[10]

## Signs and symptoms [edit]

Vaginal bleeding or spotting in women after menopause occurs in 90% of endometrial cancer.[3][11] Bleeding is especially common with adenocarcinoma, occurring in two-thirds of all cases.[3][7] Abnormal menstrual cycles or extremely long, heavy, or frequent episodes of bleeding in women before menopause may also be a sign of endometrial cancer.[7]

Symptoms other than bleeding are not common. Other symptoms include thin white or clear vaginal discharge in postmenopausal women. More advanced disease shows more obvious symptoms or signs that can be detected on a physical examination. The uterus may become enlarged or the cancer may spread, causing lower abdominal pain or pelvic cramping.[7] Painful sexual intercourse or painful or difficult urination are less common signs of endometrial cancer.[5] The uterus may also fill with pus (pyometrea).[12] Of women with these less common symptoms (vaginal discharge, pelvic pain, and pus), 10–15% have cancer.[13]

## Risk factors [edit]

Risk factors for endometrial cancer include obesity, diabetes mellitus, breast cancer, use of tamoxifen, never having had a child, late menopause, high levels of estrogen, and increasing age.[12][13] Immigration studies (migration studies), which examine the change in cancer risk in populations moving between countries with different rates of cancer, show that there is some environmental component to endometrial cancer.[14] These environmental risk factors are not well characterized.[15]

### Hormones [edit]

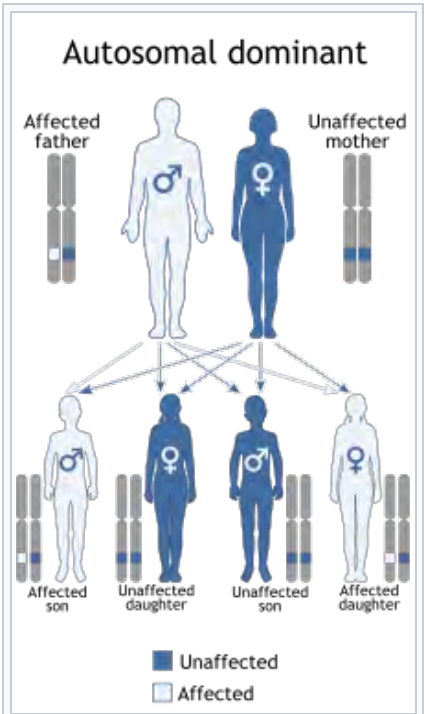
Most of the risk factors for endometrial cancer involve high levels of estrogens. An estimated 40% of cases are thought to be related to obesity.[4] In obesity, the excess of adipose tissue increases conversion of androstenedione into estrone, an estrogen. Higher levels of estrone in the blood causes less or no ovulation and exposes the endometrium to continuously high levels of estrogens.[9][16] Obesity also causes less estrogen to be removed from the blood.[16] Polycystic ovary syndrome (PCOS), which also causes irregular or no ovulation, is associated with higher rates of endometrial cancer for the same reasons as obesity.[14] Specifically, obesity, type II diabetes, and insulin resistance are risk factors for Type I endometrial cancer.[17] Obesity increases the risk for endometrial cancer

by 300–400%.[18]

Estrogen replacement therapy during menopause when not balanced (or "opposed") with progestin is another risk factor. Higher doses or longer periods of estrogen therapy have higher risks of endometrial cancer.[16] Women of lower weight are at greater risk from unopposed estrogen.[4] A longer period of fertility—either from an early first menstrual period or late menopause—is also a risk factor.[19] Unopposed estrogen raises an individual's risk of endometrial cancer by 2–10 fold, depending on weight and length of therapy.[4] In trans men who take testosterone and have not had a hysterectomy, the conversion of testosterone into estrogen via androstenedione may lead to a higher risk of endometrial cancer.[20]

## Genetics [edit]

Genetic disorders can also cause endometrial cancer. Overall, genetic causes contribute to 2–10% of endometrial cancer cases.[4][21] Lynch syndrome, an autosomal dominant genetic disorder that mainly causes colorectal cancer, also causes endometrial cancer, especially before menopause. Women with Lynch syndrome have a 40–60% risk of developing endometrial cancer, higher than their risk of developing colorectal (bowel) or ovarian cancer.[14] Ovarian and endometrial cancer develop simultaneously in 20% of people. Endometrial cancer nearly always develops before colon cancer, on average, 11 years before.[15] Carcinogenesis in Lynch syndrome comes from a mutation in MLH1 and/or MLH2: genes that participate in the process of mismatch repair, which allows a cell to correct mistakes in the DNA.[14] Other genes mutated in Lynch syndrome include MSH2, MSH6, and PMS2, which are also mismatch repair genes. Women with Lynch syndrome represent 2–3% of endometrial cancer cases; some sources place this as high as 5%.[15][18] Depending on the gene mutation, women with Lynch syndrome have different risks of endometrial cancer. With MLH1 mutations, the risk is 54%; with MSH2, 21%; and with MSH6, 16%.[22]



The autosomal dominant inheritance pattern seen in Lynch syndrome

Women with a family history of endometrial cancer are at higher risk.[5] Two genes most commonly associated with some other women's cancers, BRCA1 and BRCA2, do not cause endometrial cancer. There is an apparent link with these genes but it is attributable to the use of tamoxifen, a drug that itself can cause endometrial cancer, in breast and ovarian cancers.[14] The inherited genetic condition Cowden syndrome can also cause endometrial cancer. Women with this disorder have a 5–10% lifetime risk of developing endometrial cancer,[4] compared to the 2–3% risk for unaffected women.[15]

## Other health problems [edit]

Some therapies for other forms of cancer increase the lifetime risk of endometrial cancer, which is a baseline 2–3%.[15] Tamoxifen, a drug used to treat estrogen-positive breast cancers, has been associated with endometrial cancer in approximately 0.1% of users, particularly older women, but the benefits for survival from tamoxifen generally outweigh the risk of endometrial cancer.[23] A one to two-year course of tamoxifen approximately doubles the risk of endometrial cancer, and a five-year course of therapy quadruples that risk.[19] Raloxifene, a similar drug, did not raise the risk of endometrial cancer.[24] Previously having ovarian cancer is a risk factor for endometrial cancer,[25] as is having had previous radiotherapy to the pelvis. Specifically, ovarian granulosa cell tumors and thecomas are tumors associated with endometrial cancer.

Low immune function has also been implicated in endometrial cancer.[12] High blood pressure is also a risk factor,[18] but this may be because of its association with obesity.[22] Sitting regularly for prolonged periods is associated with higher mortality from endometrial cancer. The risk is not negated by regular exercise, though it is lowered.[26]

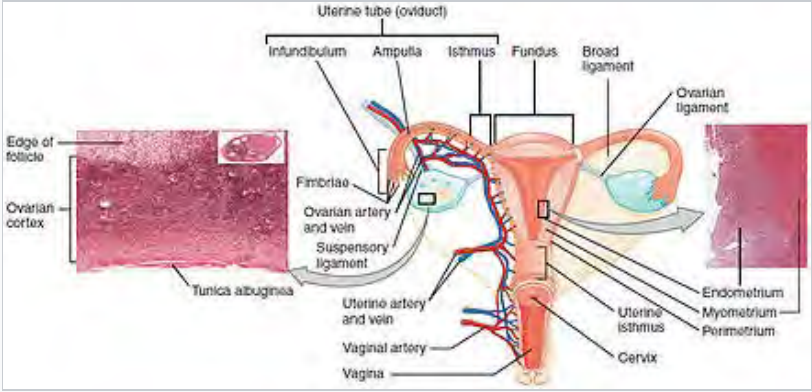
## Protective factors [edit]

Smoking and the use of progestin are both protective against endometrial cancer. Smoking provides protection by altering the metabolism of estrogen and promoting weight loss and early menopause. This protective effect lasts long after smoking is stopped. Progestin is present in the combined oral contraceptive pill and the hormonal intrauterine device (IUD).[14][27] Combined oral contraceptives reduce risk more the longer they are taken: by 56% after four

years, 67% after eight years, and 72% after twelve years. This risk reduction continues for at least fifteen years after contraceptive use has been stopped.[24] Obese women may need higher doses of progestin to be protected.[27] Having had more than five infants (grand multiparity) is also a protective factor,[12] and having at least one child reduces the risk by 35%. Breastfeeding for more than 18 months reduces risk by 23%. Increased physical activity reduces an individual's risk by 38–46%. There is preliminary evidence that consumption of soy is protective.[24]

## Pathophysiology [edit]

Endometrial cancer forms when there are errors in normal endometrial cell growth. Usually, when cells grow old or get damaged, they die, and new cells take their place. Cancer starts when new cells form unneeded, and old or damaged cells do not die as they should. The buildup of extra cells often forms a mass of tissue called a growth or tumor. These abnormal cancer cells have many genetic abnormalities that cause them to grow excessively.[5]



A diagram showing the female reproductive tract with the uterine wall enlarged and normal endometrium visible

**Mutations found in Type I and Type II endometrial cancers**[4][28]

| Gene mutated | Mutation type | Type I prevalence | Type II prevalence |
|---|---|---|---|
| ARID1A | point mutation | 40% | unknown |
| CTNNB1 | point mutation | 14–44% | unknown |
| FGFR2 | point mutation | 16% | unknown |
| KRAS | point mutation | 10–20% | unknown |
| PIK3R1 | point mutation | 43% | unknown |
| TP53 | point mutation | 10–20% | 90% |
| PTEN | point mutation | 37–61% | unknown |
| MLH1 | epigenetic silencing | 30% | unknown |
| RASSF1A | epigenetic silencing | 48% | unknown |
| SPRY2 | epigenetic silencing | 20% | unknown |
| PPP2R1A | point mutation | unknown | 17–41% |
| CDH1 | loss of heterozygosity | unknown | 80–90% |
| CDKN2A | loss of heterozygosity and/or epigenetic silencing | 20% | 40% |
| PIK3CA (oncogene) | point mutation or amplification | 24–39% | 20–30% |
| PIK3R1 (oncogene) | point mutation | unknown | 12% |
| STK15 (oncogene) | amplification | unknown | 60% |
| CCNE1 (oncogene) | amplification | unknown | 55% |
| ERBB2 (oncogene) | amplification | unknown | 30% |
| CCND1 (oncogene) | amplification | unknown | 26% |

In 10–20% of endometrial cancers, mostly Grade 3 (the highest histologic grade), mutations are found in a tumor suppressor gene, commonly p53 or PTEN. In 20% of endometrial hyperplasias and 50% of endometrioid cancers, PTEN suffers a loss-of-function mutation or a null mutation, making it less effective or completely ineffective.[29] Loss of PTEN function leads to up-regulation of the PI3k/Akt/mTOR pathway, which causes cell growth.[18] The p53 pathway can either be suppressed or highly activated in endometrial

cancer. When a mutant version of p53 is overexpressed, the cancer tends to be particularly aggressive.[29] P53 mutations and chromosome instability are associated with serous carcinomas, which tend to resemble ovarian and Fallopian carcinomas. Serous carcinomas are thought to develop from endometrial intraepithelial carcinoma.[18]

PTEN and p27 loss of function mutations are associated with a good prognosis, particularly in obese women. The Her2/neu oncogene, which indicates a poor prognosis, is expressed in 20% of endometrioid and serous carcinomas. CTNNB1 (beta-catenin; a transcription gene) mutations are found in 14–44% of endometrial cancers and may indicate a good prognosis, but the data is unclear.[29] Beta-catenin mutations are commonly found in endometrial cancers with squamous cells.[18] FGFR2 mutations are found in approximately 10% of endometrial cancers, and their prognostic significance is unclear.[29] SPOP is another tumor suppressor gene found to be mutated in some cases of endometrial cancer: 9% of clear cell endometrial carcinomas and 8% of serous endometrial carcinomas have mutations in this gene.[30]

Type I and Type II cancers (explained below) tend to have different mutations involved. ARID1A, which often carries a point mutation in Type I endometrial cancer, is also mutated in 26% of clear cell carcinomas of the endometrium, and 18% of serous carcinomas. Epigenetic silencing and point mutations of several genes are commonly found in Type I endometrial cancer.[4][28] Mutations in tumor suppressor genes are common in Type II endometrial cancer.[4] PIK3CA is commonly mutated in both Type I and Type II cancers.[28] In women with Lynch syndrome-associated endometrial cancer, microsatellite instability is common.[18]

Development of an endometrial hyperplasia (overgrowth of endometrial cells) is a significant risk factor because hyperplasias can and often do develop into adenocarcinoma, though cancer can develop without the presence of a hyperplasia.[16] Within ten years, 8–30% of atypical endometrial hyperplasias develop into cancer, whereas 1–3% of non-atypical hyperplasias do so.[31] An atypical hyperplasia is one with visible abnormalities in the nuclei. Pre-cancerous endometrial hyperplasias are also referred to as endometrial intraepithelial neoplasia.[32] Mutations in the KRAS gene can cause endometrial hyperplasia and therefore Type I endometrial cancer.[29] Endometrial hyperplasia typically occurs after the age of 40.[5] Endometrial glandular dysplasia occurs with an overexpression of p53, and develops into a serous carcinoma.[12]

## Diagnosis [edit]

Diagnosis of endometrial cancer is made first by a physical examination and dilation and curettage (removal of endometrial tissue; D&C). This tissue is then examined histologically for characteristics of cancer. If cancer is found, medical imaging may be done to see whether the cancer has spread or invaded tissue.

### Examination [edit]

Routine screening of asymptomatic people is not indicated, since the disease is highly curable in its early, symptomatic stages. Instead, women, particularly menopausal women, should be aware of the symptoms and risk factors of endometrial cancer. A cervical screening test, such as a Pap smear, is not a useful diagnostic tool for endometrial cancer because the smear will be normal 50% of the time.[7] A Pap smear can detect disease that has spread to the cervix.[5] Results from a pelvic examination are frequently normal, especially in the early stages of disease. Changes in the size, shape or consistency of the uterus and/or its surrounding, supporting structures may exist when the disease is more advanced.[7] Cervical stenosis, the narrowing of the cervical opening, is a sign of endometrial cancer when pus or blood is found collected in the uterus (pyometra or hematometra).[11]

Vaginal ultrasonography with an endometrial fluid accumulation (darker area) in a postmenopausal uterus, a finding that is highly suspicious for endometrial cancer

Women with Lynch syndrome should begin to have annual biopsy screening at the age of 35. Some women with Lynch syndrome elect to have a prophylactic hysterectomy and salpingo-oophorectomy to greatly reduce the risk of endometrial and ovarian cancer.[7]

Transvaginal ultrasound to examine the endometrial thickness in women with postmenopausal bleeding is increasingly being used to aid in the diagnosis of endometrial cancer in the United States.[33] In the United Kingdom, both an endometrial biopsy and a transvaginal ultrasound used in conjunction are the standard of care for diagnosing endometrial cancer.[12] The homogeneity of the

Polypoidal endometrial carcinoma

tissue visible on transvaginal ultrasound can help to indicate whether the thickness is cancerous. Ultrasound findings alone are not conclusive in cases of endometrial cancer, so another screening method (for example endometrial biopsy) must be used in conjunction. Other imaging studies are of limited use. CT scans are used for preoperative imaging of tumors that appear advanced on physical exam or have a high-risk subtype (at high risk of metastasis).[34] They can also be used to investigate extrapelvic disease.[12] An MRI can be of some use in determining if the cancer has spread to the cervix or if it is an endocervical adenocarcinoma.[34] MRI is also useful for examining the nearby lymph nodes.[12]

Dilation and curettage or an endometrial biopsy are used to obtain a tissue sample for histological examination. Endometrial biopsy is the less invasive option, but it may not give conclusive results every time. Hysteroscopy only shows the gross anatomy of the endometrium, which is often not indicative of cancer, and is therefore not used, unless in conjunction with a biopsy.[34] Hysteroscopy can be used to confirm a diagnosis of cancer. New evidence shows that D&C has a higher false negative rate than endometrial biopsy.[18]

Before treatment is begun, several other investigations are recommended. These include a chest x-ray, liver function tests, kidney function tests,[18] and a test for levels of CA-125, a tumor marker that can be elevated in endometrial cancer.[5]

## Types [edit]

Endometrial cancer includes carcinomas, which are divided into Type I and Type II cancers and includes endometrioid adenocarcinoma, uterine papillary serous carcinoma, uterine clear-cell carcinoma, and several other very rare forms.

## Carcinoma [edit]

The vast majority of endometrial cancers are carcinomas (usually adenocarcinomas), meaning that they originate from the single layer of epithelial cells that line the endometrium and form the endometrial glands. There are many microscopic subtypes of endometrial carcinoma, but they are broadly organized into two categories, Type I and Type II, based on clinical features and pathogenesis. The two subtypes are genetically distinct.[7]

Type I endometrial carcinomas occur most commonly before and around the time of menopause. In the United States they are more common in whites, particularly those with a history of endometrial hyperplasia. Type I endometrial cancers are often low-grade, minimally invasive into the underlying uterine wall (myometrium), estrogen-dependent, and have a good outcome with treatment.[7] Type I carcinomas represent 75–90% of endometrial cancer.[12][35]

Type II endometrial carcinomas usually occur in older, post-menopausal people, in the United States are more common in black women, and are not associated with increased exposure to estrogen or a history of endometrial hyperplasia. Type II endometrial cancers are often high-grade, with deep invasion into the underlying uterine wall (myometrium), are of the serous or clear cell type, and carry a poorer prognosis. They can appear to be epithelial ovarian cancer on evaluation of symptoms.[7][35] They tend to present later than Type I tumors and are more aggressive, with a greater risk of relapse and/or metastasis.[12]

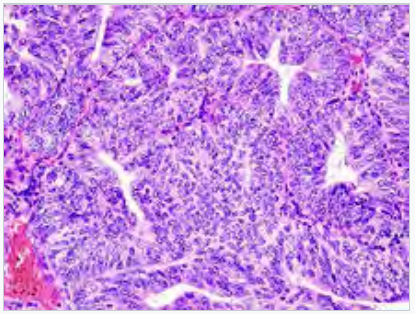
### Endometrioid adenocarcinoma [edit]

In endometrioid adenocarcinoma, the cancer cells grow in patterns reminiscent of normal endometrium, with many new glands formed from columnar epithelium with some abnormal nuclei. Low-grade endometrioid adenocarcinomas have well differentiated cells, have not invaded the myometrium, and are seen alongside endometrial hyperplasia. The tumor's glands form very close together, without the stromal tissue that normally separates them. Higher-grade endometrioid adenocarcinomas have less well-differentiated cells, have more solid sheets of tumor cells no longer organized into glands, and are associated with an atrophied endometrium. There are several subtypes of endometrioid adenocarcinoma with similar prognoses, including villoglandular, secretory, and ciliated cell variants.

There is also a subtype characterized by squamous differentiation. Some endometrioid adenocarcinomas have foci of mucinous carcinoma.[36]

The genetic mutations most commonly associated with endometrioid adenocarcinoma are in the genes PTEN, a tumor suppressor; PIK3CA, a kinase; KRAS, a GTPase that functions in signal transduction; and CTNNB1, involved in adhesion and cell signaling. The CTNNB1 (beta-catenin) gene is most commonly mutated in the squamous subtype of endometrioid adenocarcinoma.[37]

Gross pathology of an endometrial adenocarcinoma



A histologic view of an endometrial adenocarcinoma showing many abnormal nuclei

### Serous carcinoma [edit]

*See also: Uterine papillary serous carcinoma*

Serous carcinoma is a Type II endometrial tumor that makes up 5–10% of diagnosed endometrial cancer and is common in postmenopausal women with atrophied endometrium and black women. Serous endometrial carcinoma is aggressive and often invades the myometrium and metastasizes within the peritoneum (seen as omental caking) or the lymphatic system. Histologically, it appears with many atypical nuclei, papillary structures, and, in contrast to endometrioid adenocarcinomas, rounded cells instead of columnar cells. Roughly 30% of endometrial serous carcinomas also have psammoma bodies.[16][35] Serous carcinomas spread differently than most other endometrial cancers; they can spread outside the uterus without invading the myometrium.[16]

The genetic mutations seen in serous carcinoma are chromosomal instability and mutations in TP53, an important tumor suppressor gene.[37]

### Clear cell carcinoma [edit]

*See also: Uterine clear-cell carcinoma*

Clear cell carcinoma is a Type II endometrial tumor that makes up less than 5% of diagnosed endometrial cancer. Like serous cell carcinoma, it is usually aggressive and carries a poor prognosis. Histologically, it is characterized by the features common to all clear cells: the eponymous clear cytoplasm when H&E stained and visible, distinct cell membranes.[35] The p53 cell signaling system is not active in endometrial clear cell carcinoma.[12] This form of endometrial cancer is more common in postmenopausal women.[16]

### Mucinous carcinoma [edit]

Mucinous carcinomas are a rare form of endometrial cancer, making up less than 1–2% of all diagnosed endometrial cancer. Mucinous endometrial carcinomas are most often stage I and grade I, giving them a good prognosis. They typically have well-differentiated columnar cells organized into glands with the characteristic mucin in the cytoplasm. Mucinous carcinomas must be differentiated from cervical adenocarcinoma.[36]

### Mixed or undifferentiated carcinoma [edit]

Mixed carcinomas are those that have both Type I and Type II cells, with one making up at least 10% of the tumor.[36] These include the malignant mixed Müllerian tumor, which derives from endometrial epithelium and has a poor prognosis.[38]

Undifferentiated endometrial carcinomas make up less than 1–2% of diagnosed endometrial cancers. They have a worse prognosis than grade III tumors. Histologically, these tumors show sheets of identical epithelial cells with no identifiable pattern.[36]

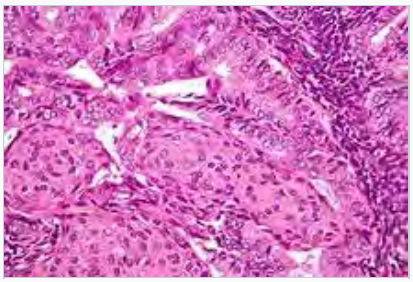
### Other carcinomas [edit]

Non-metastatic squamous cell carcinoma and transitional cell carcinoma are very rare in the endometrium. Squamous cell carcinoma of the endometrium has a poor prognosis.[36] It has been reported fewer than 100 times in the medical literature since its characterization in 1892. For primary squamous cell carcinoma of the endometrium (PSCCE) to be diagnosed, there must be no other primary cancer in the endometrium or cervix and it must not be connected to the cervical epithelium. Because of the rarity of this cancer, there are no guidelines for how it should be treated, nor any typical treatment. The common genetic causes remain uncharacterized.[39] Primary transitional cell carcinomas of the endometrium are even more rare; 16 cases had been reported as of 2008. Its pathophysiology and treatments have not been characterized.[40] Histologically, TCCE resembles endometrioid carcinoma and is distinct from other transitional cell carcinomas.[41]

## Sarcoma [edit]

*Main article: Endometrial stromal sarcoma*

In contrast to endometrial carcinomas, the uncommon endometrial stromal sarcomas are cancers that originate in the non-glandular connective tissue of the endometrium. They are generally non-aggressive and, if they recur, can take decades. Metastases to the lungs and pelvic or peritoneal cavities are the most frequent.[16] They typically have estrogen and/or progesterone receptors.[42] The prognosis for low-grade endometrial stromal sarcoma is good, with 60–90% five-year survival. High-grade undifferentiated endometrial sarcoma (HGUS) has a worse prognosis, with high rates of recurrence and 25% five-year survival.[43] HGUS prognosis is dictated by whether or not the cancer has invaded the arteries and veins. Without vascular invasion, the five-year survival is 83%; it drops to 17% when vascular invasion is observed. Stage I ESS has the best prognosis, with five-year survival of 98% and ten-year survival of 89%. ESS makes up 0.2% of uterine cancers.[44]



Endometrioid endometrial adenocarcinoma—very high magnification—H&E stain

## Metastasis [edit]

Endometrial cancer frequently metastasizes to the ovaries and Fallopian tubes[25] when the cancer is located in the upper part of the uterus, and the cervix when the cancer is in the lower part of the uterus. The cancer usually first spreads into the myometrium and the serosa, then into other reproductive and pelvic structures. When the lymphatic system is involved, the pelvic and para-aortic nodes are usually first to become involved, but in no specific pattern, unlike cervical cancer. More distant metastases are spread by the blood and often occur in the lungs, as well as the liver, brain, and bone.[45] Endometrial cancer metastasizes to the lungs 20–25% of the time, more than any other gynecologic cancer.[46]

## Histopathology [edit]

There is a three-tiered system for histologically classifying endometrial cancers, ranging from cancers with well-differentiated cells (grade I), to very poorly-differentiated cells (grade III).[19] Grade I cancers are the least aggressive and have the best prognosis, while grade III tumors are the most aggressive and likely to recur. Grade II cancers are intermediate between grades I and III in terms of cell differentiation and aggressiveness of disease.[10]

The histopathology of endometrial cancers is highly diverse. The most common finding is a well-differentiated endometrioid adenocarcinoma,[38] which is composed of numerous, small, crowded glands with varying degrees of nuclear atypia, mitotic activity, and stratification. This often appears on a background of endometrial hyperplasia. Frank adenocarcinoma may be distinguished from atypical hyperplasia by the finding of clear stromal invasion, or "back-to-back" glands which represent nondestructive replacement of the endometrial stroma by the cancer. With progression of the disease, the myometrium is infiltrated.[47]

A stage III endometrioid adenocarcinoma that has invaded the myometrium

## Staging [edit]

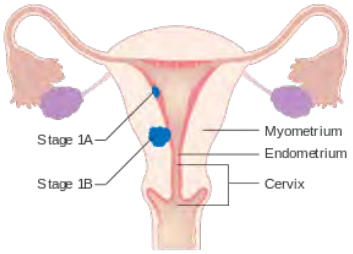
Endometrial carcinoma is surgically staged using the FIGO cancer staging system. The 2009 FIGO staging system is as follows:[48]

| Stage | Description |
|---|---|
| IA | Tumor is confined to the uterus with less than half myometrial invasion |
| IB | Tumor is confined to the uterus with more than half myometrial invasion |
| II | Tumor involves the uterus and the cervical stroma |
| IIIA | Tumor invades serosa or adnexa |
| IIIB | Vaginal and/or parametrial involvement |
| IIIC1 | Pelvic lymph node involvement |

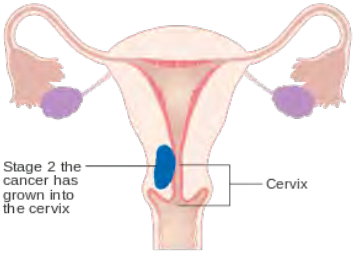
| | |
|---|---|
| IIIC2 | Para-aortic lymph node involvement, with or without pelvic node involvement |
| IVA | Tumor invades bladder mucosa and/or bowel mucosa |
| IVB | Distant metastases including abdominal metastases and/or inguinal lymph nodes |

Metastatic endometrial cancer seen in a removed lung

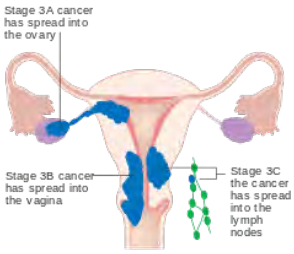
Myometrial invasion and involvement of the pelvic and para-aortic lymph nodes are the most commonly seen patterns of spread.[3] A Stage 0 is sometimes included, in this case it is referred to as "carcinoma in situ".[5] In 26% of presumably early-stage cancers, intraoperative staging revealed pelvic and distant metastases, making comprehensive surgical staging necessary.[22]



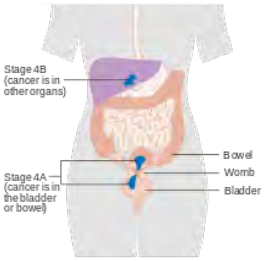
Stage IA and IB endometrial cancer



Stage II endometrial cancer



Stage III endometrial cancer

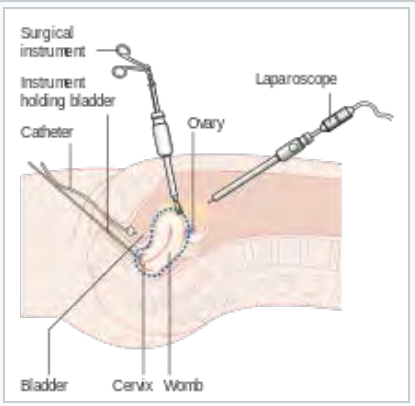


Stage IV endometrial cancer

## Management [edit]

### Surgery [edit]

The primary treatment for endometrial cancer is surgery; 90% of women with endometrial cancer are treated with some form of surgery.[19] Surgical treatment typically consists of hysterectomy including a bilateral salpingo-oophorectomy, which is the removal of the uterus, and both ovaries and Fallopian tubes. Lymphadenectomy, or removal of pelvic and para-aortic lymph nodes, is performed for tumors of histologic grade II or above.[13] Lymphadenectomy is routinely performed for all stages of endometrial cancer in the United States, but in the United Kingdom, the lymph nodes are typically only removed with disease of stage II or greater.[12] The topic of lymphadenectomy and what survival benefit it offers in stage I disease is still being debated.[18] In stage III and IV cancers, cytoreductive surgery is the norm,[13] and a biopsy of the omentum may also be included.[49] In stage IV disease, where there are distant metastases, surgery can be used as part of palliative therapy.[18] Laparotomy, an open-abdomen procedure, is the traditional surgical procedure; however, laparoscopy (keyhole surgery) is associated with lower operative morbidity. The two procedures have no difference in overall survival.[49] Removal of the uterus via the abdomen is recommended over removal of the uterus via the vagina because it gives the opportunity to examine and obtain washings of the abdominal cavity to detect any further evidence of cancer. Staging of the cancer is done during the surgery.[50]



A keyhole hysterectomy, one possible surgery to treat endometrial cancer

The few contraindications to surgery include inoperable tumor, massive obesity, a particularly high-risk operation, or a desire to preserve fertility.[50] These contraindications happen in about 5–10% of cases.[18] Women who wish to preserve their fertility and have low-grade stage I cancer can be treated with progestins, with or without concurrent tamoxifen therapy. This therapy can be continued until the cancer does not respond to treatment or until childbearing is done.[51] Uterine perforation may occur during a D&C or an endometrial biopsy.[52] Side effects of surgery to remove endometrial cancer can specifically include sexual dysfunction, temporary incontinence, and lymphedema, along with more common side effects of any surgery, including constipation.[5]

## Add-on therapy [edit]

There are a number of possible additional therapies. Surgery can be followed by radiation therapy and/or chemotherapy in cases of high-risk or high-grade cancers. This is called adjuvant therapy.[13]

## Chemotherapy [edit]

Adjuvant chemotherapy is a recent innovation, consisting of some combination of paclitaxel (or other taxanes like docetaxel), doxorubicin (and other anthracyclines), and platins (particularly cisplatin and carboplatin). Adjuvant chemotherapy has been found to increase survival in stage III and IV cancer more than added radiotherapy.[13][18][19][53] Mutations in mismatch repair genes, like those found in Lynch syndrome, can lead to resistance against platins, meaning that chemotherapy with platins is ineffective in people with these mutations.[54] Side effects of chemotherapy are common. These include hair loss, low neutrophil levels in the blood, and gastrointestinal problems.[13]

In cases where surgery is not indicated, palliative chemotherapy is an option; higher-dose chemotherapy is associated with longer survival.[13][19][53] Palliative chemotherapy, particularly using capecitabine and gemcitabine, is also often used to treat recurrent endometrial cancer.[53]

## Radiotherapy [edit]

Adjuvant radiotherapy is commonly used in early-stage (stage I or II) endometrial cancer. It can be delivered through vaginal brachytherapy (VBT), which is becoming the preferred route due to its reduced toxicity, or external beam radiotherapy (EBRT). Brachytherapy involves placing a radiation source in the organ affected; in the case of endometrial cancer a radiation source is placed directly in the vagina. External beam radiotherapy involves a beam of radiation aimed at the affected area from outside the body. VBT is used to treat any remaining cancer solely in the vagina, whereas EBRT can be used to treat remaining cancer elsewhere in the pelvis following surgery. However, the benefits of adjuvant radiotherapy are controversial. Though EBRT significantly reduces the rate of relapse in the pelvis, overall survival and metastasis rates are not improved.[3] VBT provides a better quality of life than EBRT.[18]

Radiotherapy can also be used before surgery in certain cases. When pre-operative imaging or clinical evaluation shows tumor invading the cervix, radiation can be given before a total hysterectomy is performed.[11] Brachytherapy and EBRT can also be used, singly or in combination, when there is a contraindication for hysterectomy.[18] Both delivery methods of radiotherapy are associated with side effects, particularly in the gastrointestinal tract.[3]

## Hormonal therapy [edit]

Hormonal therapy is only beneficial in certain types of endometrial cancer. It was once thought to be beneficial in most cases.[3][13] If a tumor is well-differentiated and known to have progesterone and estrogen receptors, progestins may be used in treatment.[53] About 25% of metastatic endometrioid cancers show a response to progestins. Also, endometrial stromal sarcomas can be treated with hormonal agents, including tamoxifen, hydroxyprogesterone caproate, letrozole, megestrol acetate, and medroxyprogesterone.[16] This treatment is effective in endometrial stromal sarcomas because they typically have estrogen and/or progestin receptors. Progestin receptors function as tumor suppressors in endometrial cancer cells.[55] Preliminary research and clinical trials have shown these treatments to have a high rate of response even in metastatic disease.[42]

## Monitoring [edit]

The tumor marker CA-125 is frequently elevated in endometrial cancer and can be used to monitor response to treatment, particularly in serous cell cancer or advanced disease.[25][34][56] Periodic MRIs or CT scans may be recommended in advanced disease and women with a history of endometrial cancer should receive more frequent pelvic examinations for the five years following treatment.[56] Examinations conducted every three to four months are recommended for the first two years following treatment, and every six months for the next three years.[18]

Women with endometrial cancer should not have routine surveillance imaging to monitor the cancer unless new symptoms appear or tumor markers begin rising. Imaging without these indications is discouraged because it is unlikely to detect a recurrence or improve survival, and because it has its own costs and side effects.[57] If a recurrence is suspected, PET/CT scanning is recommended.[18]

# Prognosis [edit]

## Survival rates [edit]

The five-year survival rate for endometrial adenocarcinoma following appropriate treatment is 80%.[59] Most women, over 70%, have FIGO stage I cancer, which has the best prognosis. Stage III and especially Stage IV cancers has a worse prognosis, but these are relatively rare, occurring in only 13% of cases. The median survival time for stage III-IV endometrial cancer is nine to ten months.[60] Older age indicates a worse prognosis.[13] In the United States, white women have a higher survival rate than black women, who tend to develop more aggressive forms of the disease by the time of their diagnosis.[61] Tumors with high progesterone receptor expression have a good prognosis compared to tumors with low progesterone receptor expression; 93% of women with high progesterone receptor disease survived to three years, compared with 36% of women with low progesterone receptor disease.[6] Heart disease is the most common cause of death among those who survive endometrial cancer,[62] with other obesity-related health problems also being common.[63]

**5-year relative survival rates in the US by FIGO stage:**[58]

| Stage | 5-year survival rate |
|---|---|
| I-A | 88% |
| I-B | 75% |
| II | 69% |
| III-A | 58% |
| III-B | 50% |
| III-C | 47% |
| IV-A | 17% |
| IV-B | 15% |

## Recurrence rates [edit]

Recurrence of early stage endometrial cancer ranges from 3 to 17%, depending on primary and adjuvant treatment.[59] Most recurrences (75–80%) occur outside of the pelvis, and most occur two to three years after treatment, 64% after two years and 87% after three years.[46]

Higher-staged cancers are more likely to recur, as are those that have invaded the myometrium or cervix, or that have metastasized into the lymphatic system. Papillary serous carcinoma, clear cell carcinoma, and endometrioid carcinoma are the subtypes at the highest risk of recurrence.[19] High-grade histological subtypes are also at elevated risk for recurrence.[12]

The most common site of recurrence is in the vagina;[3] vaginal relapses of endometrial cancer have the best prognosis. If relapse occurs from a cancer that has not been treated with radiation, EBRT is the first-line treatment and is often successful. If a cancer treated with radiation recurs, pelvic exenteration is the only option for curative treatment. Palliative chemotherapy, cytoreductive surgery, and radiation are also performed.[64] Radiation therapy (VBT and EBRT) for a local vaginal recurrence has a 50% five-year survival rate. Pelvic recurrences are treated with surgery and radiation, and abdominal recurrences are treated with radiation and, if possible, chemotherapy.[18] Other common recurrence sites are the pelvic lymph nodes, para-aortic lymph nodes, peritoneum (28% of recurrences), and lungs, though recurrences can also occur in the brain (<1%), liver (7%), adrenal glands (1%), bones (4–7%; typically the axial skeleton), lymph nodes outside the abdomen (0.4–1%), spleen, and muscle/soft tissue (2–6%).[46]

# Epidemiology [edit]

As of 2014, approximately 320,000 women are diagnosed with endometrial cancer worldwide each year and 76,000 die, making it the sixth most common cancer in women.[4] It is more common in developed countries, where the lifetime risk of endometrial cancer in people born with uteri is 1.6%, compared to 0.6% in developing countries.[13] It occurs in 12.9 out of 100,000 women annually in developed countries.[19]

In the United States, endometrial cancer is the most frequently diagnosed gynecologic cancer and, in women, the fourth most common cancer overall,[9][16] representing 6% of all cancer cases in women.[65] In that country, as of 2014 it was estimated that 52,630 women were diagnosed yearly and 8,590 would die from the disease.[22] Northern Europe, Eastern Europe, and North America have the highest rates of endometrial cancer, whereas Africa and West Asia have the lowest rates. Asia saw 41% of the world's endometrial cancer diagnoses in 2012, whereas Northern Europe, Eastern Europe, and North America together comprised 48% of diagnoses.[4] Unlike most cancers, the number of new cases has risen in recent years, including an increase of over 40% in the United Kingdom between 1993 and 2013.[13] Some of this rise may be due to the increase in obesity rates in developed countries,[19] increasing life expectancies, and lower birth rates.[9] The average lifetime risk for endometrial cancer is approximately 2–3% in people with uteruses.[15] In the UK, approximately 7,400 cases are diagnosed annually, and in the EU,

approximately 88,000.[18]

Endometrial cancer appears most frequently during perimenopause (the period just before, just after, and during menopause), between the ages of 50 and 65;[16] overall, 75% of endometrial cancer occurs after menopause.[3] Women younger than 40 make up 5% of endometrial cancer cases and 10–15% of cases occur in women under 50 years of age. This age group is at risk for developing ovarian cancer at the same time.[16] The worldwide median age of diagnosis is 63 years of age;[18] in the United States, the average age of diagnosis is 60 years of age. White American women are at higher risk for endometrial cancer than black American women, with a 2.88% and 1.69% lifetime risk respectively.[22] Japanese-American women and American Latina women have a lower rates and Native Hawaiian women have higher rates.[24]

## Research [edit]

There are several experimental therapies for endometrial cancer under research, including immunologic, hormonal, and chemotherapeutic treatments. Trastuzumab (Herceptin), an antibody against the Her2 protein, has been used in cancers known to be positive for the Her2/neu oncogene, but research is still underway. Immunologic therapies are also under investigation, particularly in uterine papillary serous carcinoma.[29]

Cancers can be analyzed using genetic techniques (including DNA sequencing and immunohistochemistry) to determine if certain therapies specific to mutated genes can be used to treat it. PARP inhibitors are used to treat endometrial cancer with PTEN mutations,[4] specifically, mutations that lower the expression of PTEN. The PARP inhibitor shown to be active against endometrial cancer is olaparib. Research is ongoing in this area as of the 2010s.[21][66][67]

Research is ongoing on the use of metformin, a diabetes medication, in obese women with endometrial cancer before surgery. Early research has shown it to be effective in slowing the rate of cancer cell proliferation.[17][28] Preliminary research has shown that preoperative metformin administration can reduce expression of tumor markers. Long-term use of metformin has not been shown to have a preventative effect against developing cancer, but may improve overall survival.[17]

Temsirolimus, an mTOR inhibitor, is under investigation as a potential treatment.[18] Research shows that mTOR inhibitors may be particularly effective for cancers with mutations in PTEN.[4] Ridaforolimus (deforolimus) is also being researched as a treatment for people who have previously had chemotherapy. Preliminary research has been promising, and a stage II trial for ridaforolimus was completed by 2013.[18] There has also been research on combined ridaforolimus/progestin treatments for recurrent endometrial cancer.[68] Bevacizumab and tyrosine kinase inhibitors, which inhibit angiogenesis, are being researched as potential treatments for endometrial cancers with high levels of vascular endothelial growth factor.[4] Ixabepilone is being researched as a possible chemotherapy for advanced or recurrent endometrial cancer.[68] Treatments for rare high-grade undifferentiated endometrial sarcoma are being researched, as there is no established standard of care yet for this disease. Chemotherapies being researched include doxorubicin and ifosfamide.[43]

There is also research in progress on more genes and biomarkers that may be linked to endometrial cancer. The protective effect of combined oral contraceptives and the IUD is being investigated. Preliminary research has shown that the levonorgestrel IUD placed for a year, combined with 6 monthly injections of gonadotropin-releasing hormone, can stop or reverse the progress of endometrial cancer in young women.[69] An experimental drug that combines a hormone with doxorubicin is also under investigation for greater efficacy in cancers with hormone receptors. Hormone therapy that is effective in treating breast cancer, including use of aromatase inhibitors, is also being investigated for use in endometrial cancer. One such drug is anastrozole, which is currently being researched in hormone-positive recurrences after chemotherapy.[68] Research into hormonal treatments for endometrial stromal sarcomas is ongoing as well. It includes trials of drugs like mifepristone, a progestin antagonist, and aminoglutethimide and letrozole, two aromatase inhibitors.[42]

Research continues into the best imaging method for detecting and staging endometrial cancer. In surgery, research has shown that complete pelvic lymphadenectomy along with hysterectomy in stage 1 endometrial cancer does not improve survival and increases the risk of negative side effects, including lymphedema. Other research is exploring the potential of identifying the sentinel lymph nodes for biopsy by injecting the tumor with dye that shines under infrared light. Intensity modulated radiation therapy is currently under investigation, and already used in some centers, for application in endometrial cancer, to reduce side effects from traditional radiotherapy. Its risk of recurrence has not yet been quantified. Research on hyperbaric oxygen therapy to reduce side effects is also ongoing. The results of the PORTEC 3 trial assessing combining adjuvant radiotherapy with chemotherapy were awaited in late [68]

2014.

## History and culture [edit]

Endometrial cancer is not widely known by the general populace, despite its frequency. There is low awareness of the symptoms, which can lead to later diagnosis and worse survival.[70]

# Esophageal cancer

From Wikipedia, the free encyclopedia

**Esophageal cancer** is cancer arising from the esophagus—the food pipe that runs between the throat and the stomach.[1] Symptoms often include difficulty in swallowing and weight loss. Other symptoms may include pain when swallowing, a hoarse voice, enlarged lymph nodes ("glands") around the collarbone, a dry cough, and possibly coughing up or vomiting blood.[2]

The two main sub-types of the disease are esophageal squamous-cell carcinoma (often abbreviated to ESCC),[3] which is more common in the developing world, and esophageal adenocarcinoma (EAC), which is more common in the developed world.[1] A number of less common types also occur.[1] Squamous-cell carcinoma arises from the epithelial cells that line the esophagus.[4] Adenocarcinoma arises from glandular cells present in the lower third of the esophagus, often where they have already transformed to intestinal cell type (a condition known as Barrett's esophagus).[1][5] Causes of the squamous-cell type include tobacco, alcohol, very hot drinks, poor diet, and chewing betel nut.[6][7] The most common causes of the adenocarcinoma type are smoking tobacco, obesity, and acid reflux.[6]

The disease is diagnosed by biopsy done by an endoscope (a fiberoptic camera).[8] Prevention includes stopping smoking and eating a healthy diet.[1][2] Treatment is based on the cancer's stage and location, together with the person's general condition and individual preferences. Small localized squamous-cell cancers may be treated with surgery alone with the hope of a cure. In most other cases, chemotherapy with or without radiation therapy is used along with surgery.[8] Larger tumors may have their growth slowed with chemotherapy and radiation therapy.[1] In the presence of extensive disease or if the affected person is not fit enough to undergo surgery, palliative care is often recommended.[8]

As of 2012, esophageal cancer is the eighth-most common cancer globally with 456,000 new cases during the year.[1] It caused about 400,000 deaths that year, up from 345,000 in 1990.[1][9] Rates vary widely among countries, with about half of all cases occurring in China. It is around three times more common in men than in women.[1] Outcomes are related to the extent of the disease and other medical conditions, but generally tend to be fairly poor, as diagnosis is often late.[1][10] Five-year survival rates are around 13% to 18%.[2][11]

## Signs and symptoms [edit]

Endoscopic image of an esophageal adenocarcinoma

Prominent symptoms usually do not appear until the cancer has infiltrated over 60% of the circumference of the esophageal tube, by which time the tumor is already in an advanced stage.[12] Onset of symptoms is usually caused by narrowing of the tube due to the physical presence of the tumor.[13]

The first and the most common symptom is usually difficulty in swallowing, which is often experienced first with solid foods and later with softer foods and liquids.[2] Pain when swallowing is less usual at first.[2] Weight loss is often an initial symptom in cases of squamous-cell carcinoma, though not usually in cases of adenocarcinoma.[14] Eventual weight loss due to reduced appetite and undernutrition is common.[15] Pain behind the breastbone or in the region around the stomach often feels like heartburn. The pain can frequently be severe, worsening when food of any sort is swallowed. Another sign may be an unusually husky, raspy, or hoarse-sounding cough, a result of the tumor affecting the recurrent laryngeal nerve.

The presence of the tumor may disrupt the normal contractions of the esophagus when swallowing. This can lead to nausea and vomiting, regurgitation of food and coughing.[12] There is also an increased risk of aspiration pneumonia[12] due to food entering the airways through the abnormal connections (fistulas) that may develop between the esophagus and the trachea (windpipe).[10] Early signs of this serious complication may be coughing on drinking or eating.[16] The tumor surface may be fragile and bleed, causing vomiting of blood. Compression of local structures occurs in advanced disease, leading to such problems as upper airway obstruction and superior vena cava syndrome. Hypercalcemia (excess calcium in the blood) may occur.[12]

If the cancer has spread elsewhere, symptoms related to metastatic disease may appear. Common sites of spread include nearby lymph nodes, the liver, lungs and bone.[12] Liver metastasis can cause jaundice and abdominal swelling (ascites). Lung metastasis can cause, among other symptoms, impaired breathing due to excess fluid around the lungs (pleural effusion), and dyspnea (the feelings often associated with impaired breathing).

## Causes [edit]

The two main types (i.e. squamous-cell carcinoma and adenocarcinoma) have distinct sets of risk factors.[14] Squamous-cell carcinoma is linked to lifestyle factors such as smoking and alcohol.[17] Adenocarcinoma has been linked to effects of long-term acid reflux.[17] Tobacco is a risk factor for both types.[14] Both types are more common in men and in the over-60s.[18]

### Squamous-cell carcinoma [edit]

The two major risk factors for esophageal squamous-cell carcinoma are tobacco (smoking or chewing) and alcohol.[1] The combination of tobacco and alcohol has a strong synergistic effect.[19] Some data suggest that about half of all cases are due to tobacco and about one-third to alcohol, while over three-quarters of the cases in men are due to the combination of smoking and heavy drinking.[1] Risks associated with alcohol appear to be linked to its aldehyde metabolite and to mutations in certain related enzymes.[14] Such metabolic variants are relatively common in Asia.[1]

Other relevant risk factors include regular consumption of very hot drinks (over 65 °C)[20][21] and ingestion of caustic substances.[1] High levels of dietary exposure to nitrosamines (chemical compounds found both in tobacco smoke and certain foodstuffs) also appear to be a relevant risk factor.[14] Unfavorable dietary patterns seem to involve exposure to nitrosamines through processed and barbecued meats, pickled vegetables, etc., and a low intake of fresh foods.[1] Other associated factors include nutritional deficiencies, low socioeconomic status, and poor oral hygiene.[14] Chewing betel nut (areca) is an important risk factor in Asia.[7]

Physical trauma may increase the risk.[22] This may include the drinking of very hot drinks.[6]

### Adenocarcinoma [edit]

Male predominance is particularly strong in this type of esophageal cancer, which occurs about 7 to 10 times more frequently in men.[23] This imbalance may be related to the characteristics and interactions of other known risk factors, including acid reflux and obesity.[23]

The long-term erosive effects of acid reflux (an extremely common condition, also known as gastroesophageal reflux disease or GERD) have been strongly linked to this type of cancer.[24] Longstanding GERD can induce a change of cell type in the lower portion of the esophagus in response to erosion of its squamous lining.[24] This phenomenon, known as Barrett's esophagus, seems to appear about 20 years later in women than in men, maybe due to hormonal factors.[24] Having symptomatic GERD or bile reflux makes Barrett's esophagus more likely, which in turn raises the risk of further changes that can ultimately lead to adenocarcinoma.[14] The risk of developing adenocarcinoma in the presence of Barrett's esophagus is unclear, and may in the past have been overestimated.[1]

Being obese or overweight both appear to be associated with increased risk.[25] The association with obesity seems to be the strongest of any type of obesity-related cancer, though the reasons for this remain unclear.[26] Abdominal obesity seems to be of particular relevance, given the closeness of its association with this type of cancer, as well as with both GERD and Barrett's esophagus.[26] This type of obesity is characteristic of men.[26] Physiologically, it stimulates GERD and also has other chronic inflammatory effects.[24]

*Helicobacter pylori* infection (a common occurrence thought to have affected over half of the world's population) is not a risk factor for esophageal adnocarcinoma and actually appears to be protective. Despite being a cause of GERD and a risk factor for gastric cancer, the infection seems to be associated with a reduced risk of esophageal adenocarcinoma of as much as 50%.[27][28] The biological explanation for a protective effect is somewhat unclear.[28] One explanation is that some strains of *H. pylori* reduce stomach acid, thereby reducing damage by GERD.[29] Decreasing rates of *H. pylori* infection in Western populations over recent decades, which have been linked to better hygiene and increased refrigeration of food, could be a factor in the concurrent increase in esophageal adenocarcinoma.[27]

Female hormones may also have a protective effect, as EAC is not only much less common in women but develops later in life, by an average of 20 years. Although studies of many reproductive factors have not produced a clear picture, risk seems to decline for the mother in line with prolonged periods of breastfeeding.[27]

Tobacco smoking increases risk, but the effect in esophageal adenocarcinoma is slight compared to that in squamous cell carcinoma, and alcohol has not been demonstrated to be a cause.[27]

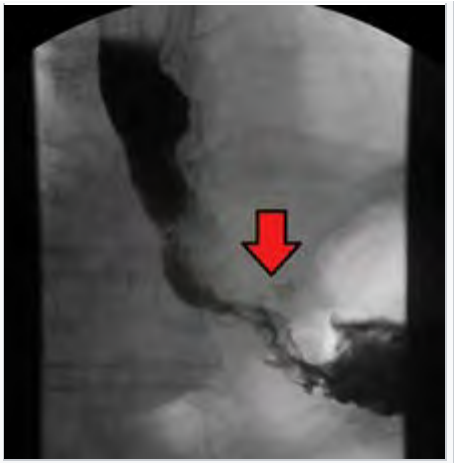
### Related conditions [edit]

- Head and neck cancer is associated with second primary tumors in the region, including esophageal squamous-cell carcinomas, due to field cancerization (i.e. a regional reaction to long-term carcinogenic exposure).[30][31]
- History of radiation therapy for other conditions in the chest is a risk factor for esophageal adenocarcinoma.[14]
- Corrosive injury to the esophagus by accidentally or intentionally swallowing caustic substances is a risk factor for squamous cell carcinoma.[1]
- Tylosis with esophageal cancer is a rare familial disease that has been linked to a mutation in the *RHBDF2* gene: it involves thickening of the skin of the palms and soles and a high lifetime risk of squamous cell carcinoma.[1][32]
- Achalasia (i.e. lack of the involuntary reflex in the esophagus after swallowing) appears to be a risk factor for both main types of esophageal cancer, at least in men, due to stagnation of trapped food and drink.[33]
- Plummer–Vinson syndrome (a rare disease that involves esophageal webs) is also a risk factor.[1]
- There is some evidence suggesting a possible causal association between human papillomavirus (HPV) and esophageal squamous-cell carcinoma.[34] The relationship is unclear.[35] Possible relevance of HPV could be greater in places that have a particularly high incidence of this form of the disease,[36] as in some Asian countries, including China.[37]
- There is an association between celiac disease and esophageal cancer. People with untreated celiac disease have a higher risk, but this risk decreases with time after diagnosis, probably due to the adoption of a gluten-free diet, which seems to have a protective role against development of malignancy in people with celiac disease. However, the delay in diagnosis and initiation of a gluten-free diet seems to increase the risk of malignancy. Moreover, in some cases the detection of celiac disease is due to the development of cancer, whose early symptoms are similar to some that may appear in celiac disease.[38]

## Diagnosis [edit]

### Clinical evaluation [edit]

Although an occlusive tumor may be suspected on a barium swallow or barium meal, the diagnosis is best made with an examination using an endoscope. This involves the passing of a flexible tube with a light and camera down the esophagus and examining the wall, and is called an esophagogastroduodenoscopy. Biopsies taken of suspicious lesions are



Esophageal cancer as shown by a filling defect during an upper GI series

then examined histologically for signs of malignancy.

Additional testing is needed to assess how much the cancer has spread (see #Staging, below). Computed tomography (CT) of the chest, abdomen and pelvis can evaluate whether the cancer has spread to adjacent tissues or distant organs (especially liver and lymph nodes). The sensitivity of a CT scan is limited by its ability to detect masses (e.g. enlarged lymph nodes or involved organs) generally larger than 1 cm. Positron emission tomography is also used to estimate the extent of the disease and is regarded as more precise than CT alone. Esophageal endoscopic ultrasound can provide staging information regarding the level of tumor invasion, and possible spread to regional lymph nodes.

The location of the tumor is generally measured by the distance from the teeth. The esophagus (25 cm or 10 in long) is commonly divided into three parts for purposes of determining the location. Adenocarcinomas tend to occur nearer the stomach and squamous cell carcinomas nearer the throat, but either may arise anywhere in the esophagus.

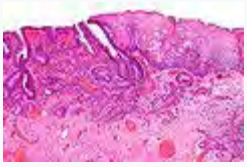
Esophageal cancer



Micrograph showing histopathological appearance of an esophageal adenocarcinoma (dark blue – upper-left of image) and normal squamous

epithelium (upper-right of image) at H&E staining

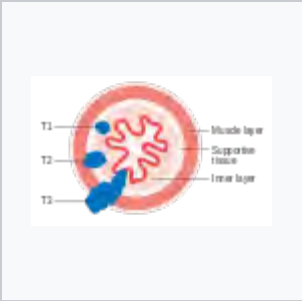
## Types [edit]

Esophageal cancers are typically carcinomas that arise from the epithelium, or surface lining, of the esophagus. Most esophageal cancers fall into one of two classes: esophageal squamous-cell carcinomas (ESCC), which are similar to head and neck cancer in their appearance and association with tobacco and alcohol consumption—and esophageal adenocarcinomas (EAC), which are often associated with a history of GERD and Barrett's esophagus. A rule of thumb is that a cancer in the upper two-thirds is likely to be ESCC and one in the lower one-third EAC.

Rare histologic types of esophageal cancer include different variants of squamous-cell carcinoma, and non-epithelial tumors, such as leiomyosarcoma, malignant melanoma, rhabdomyosarcoma and lymphoma, among others.[39][40]

## Staging [edit]

Staging is based on the TNM staging system, which classifies the amount of tumor invasion (T), involvement of lymph nodes (N), and distant metastasis (M).[14] The currently preferred classification is the 2010 AJCC staging system for cancer of the esophagus and the esophagogastric junction.[14] To help guide clinical decision making, this system also incorporates information on cell type (ESCC, EAC, etc.), grade (degree of differentiation – an indication of the biological aggressiveness of the cancer cells), and tumor location (upper, middle, lower, or junctional[41]).[42]



T1, T2, and T3 stages of esophageal cancer

Stage T4 esophageal cancer

Esophageal cancer with spread to lymph nodes

# Prevention [edit]

Prevention includes stopping smoking or chewing tobacco.[1] Overcoming addiction to areca chewing in Asia is another promising strategy for the prevention of esophageal squamous-cell carcinoma.[7] The risk can also be reduced by maintaining a normal body weight.[43]

According to the National Cancer Institute, "diets high in cruciferous (cabbage, broccoli/broccolini, cauliflower, Brussels sprouts) and green and yellow vegetables and fruits are associated with a decreased risk of esophageal cancer."[44] Dietary fiber is thought to be protective, especially against esophageal adenocarcinoma.[45] There is no evidence that vitamin supplements change the risk.[2]

## Screening [edit]

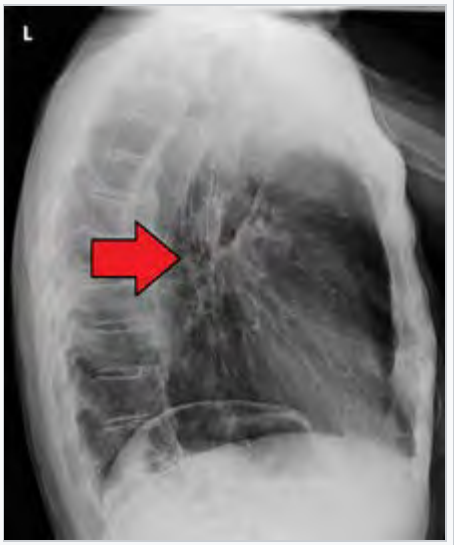
People with Barrett esophagus (a change in the cells lining the lower esophagus) are at much higher risk,[46] and may receive regular endoscopic screening for the early signs of cancer.[47] Because the benefit of screening for adenocarcinoma in people without symptoms is unclear,[1] it is not recommended in the

United States.[2] Some areas of the world with high rates of squamous-carcinoma have screening programs.[1]

## Management [edit]

Treatment is best managed by a multidisciplinary team covering the various specialties involved.[48][49] Adequate nutrition must be assured, and appropriate dental care is essential. Factors that influence treatment decisions include the stage and cellular type of cancer (EAC, ESCC, and other types), along with the person's general condition and any other diseases that are present.[14]

In general, treatment with a curative intention is restricted to localized disease, without distant metastasis: in such cases a combined approach that includes surgery may be considered. Disease that is widespread, metastatic or recurrent is managed palliatively: in this case, chemotherapy may be used to lengthen survival, while treatments such as radiotherapy or stenting may be used to relieve symptoms and make it easier to swallow.[14]



Esophageal stent for esophageal cancer

Esophageal stent for esophageal cancer

### Surgery [edit]

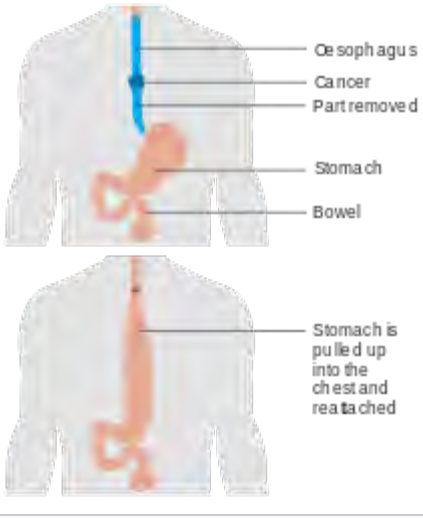
*Further information: Esophagectomy*

If the cancer has been diagnosed while still in an early stage, surgical treatment with a curative intention may be possible. Some small tumors that only involve the mucosa or lining of the esophagus may be removed by endoscopic mucosal resection (EMR).[50][51] Otherwise, curative surgery of early-stage lesions may entail removal of all or part of the esophagus (esophagectomy), although this is a difficult operation with a relatively high risk of mortality or post-operative difficulties. The benefits of surgery are less clear in early-stage ESCC than EAC. There are a number of surgical options, and the best choices for particular situations remain the subject of research and discussion.[48][52][53] As well as characteristics and location of the tumor, other factors include the patient's condition, and the type of operation the surgical team is most experienced with.

The likely quality of life after treatment is a relevant factor when considering surgery.[54] Surgical outcomes are likely better in large centers where the procedures are frequently performed.[52] If the cancer has spread to other parts of the body, esophagectomy is nowadays not normally performed.[52][55]

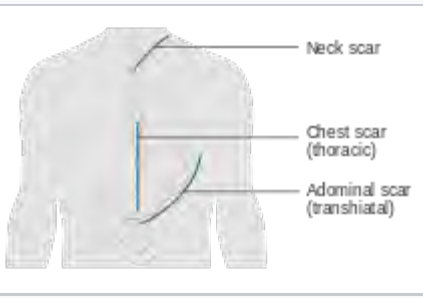
Esophagectomy is the removal of a segment of the esophagus; as this shortens the length of the remaining esophagus, some other segment of the digestive tract is pulled up through the chest cavity and interposed. This is usually the stomach or part of the large intestine (colon) or jejunum. Reconnection of the stomach to a shortened esophagus is called an esophagogastric anastomosis.[52]

Esophagectomy can be performed using several methods. The choice of the surgical approach depends on the characteristics and location of the tumor, and the preference of the surgeon. Clear evidence from clinical trials for which approaches give the best outcomes in different circumstances is lacking.[52] A first decision, regarding the point of



Before and after a total esophagectomy

entry, is between a transhiatial and a transthoracic procedure. The more recent transhiatial approach avoids the need to open the chest; instead the surgeon enters the body through an incision in the lower abdomen and another in the neck. The lower part of the esophagus is freed from the surrounding tissues and cut away as necessary. The stomach is then pushed through the esophageal hiatus (the hole where the esophagus passes through the diaphragm) and is joined to the remaining upper part of the esophagus at the neck.[52]



Typical scar lines after the two main methods of surgery

The traditional transthoracic approach enters the body through the chest, and has a number of variations. The thoracoabdominal approach opens the abdominal and thoracic cavities together, the two-stage Ivor Lewis (also called Lewis–Tanner) approach involves an initial laparotomy and construction of a gastric tube, followed by a right thoracotomy to excise the tumor and create an esophagogastric anastomosis. The three-stage McKeown approach adds a third incision in the neck to complete the cervical anastomosis. Recent approaches by some surgeons use what is called extended esophagectomy, where more surrounding tissue, including lymph nodes, is removed *en bloc*.[52]

If the person cannot swallow at all, an esophageal stent may be inserted to keep the esophagus open; stents may also assist in occluding fistulas. A nasogastric tube may be necessary to continue feeding while treatment for the tumor is given, and some patients require a gastrostomy (feeding hole in the skin that gives direct access to the stomach). The latter two are especially important if the patient tends to aspirate food or saliva into the airways, predisposing for aspiration pneumonia.

## Chemotherapy and radiotherapy [edit]

Chemotherapy depends on the tumor type, but tends to be cisplatin-based (or carboplatin or oxaliplatin) every three weeks with fluorouracil (5-FU) either continuously or every three weeks. In more recent studies, addition of epirubicin was better[*clarification needed*] than other comparable regimens in advanced nonresectable cancer.[56][*medical citation needed*] Chemotherapy may be given after surgery (adjuvant, i.e. to reduce risk of recurrence), before surgery (neoadjuvant) or if surgery is not possible; in this case, cisplatin and 5-FU are used. Ongoing trials compare various combinations of chemotherapy; the phase II/III REAL-2 trial – for example – compares four regimens containing epirubicin and either cisplatin or oxaliplatin, and either continuously infused fluorouracil or capecitabine.

Radiotherapy is given before, during, or after chemotherapy or surgery, and sometimes on its own to control symptoms. In patients with localised disease but contraindications to surgery, "radical radiotherapy" may be used with curative intent.

## Other approaches [edit]

Forms of endoscopic therapy have been used for stage 0 and I disease: endoscopic mucosal resection [57]

(EMR) and mucosal ablation using radiofrequency ablation, photodynamic therapy, Nd-YAG laser, or argon plasma coagulation.

Laser therapy is the use of high-intensity light to destroy tumor cells while affecting only the treated area. This is typically done if the cancer cannot be removed by surgery. The relief of a blockage can help with pain and difficulty swallowing. Photodynamic therapy, a type of laser therapy, involves the use of drugs that are absorbed by cancer cells; when exposed to a special light, the drugs become active and destroy the cancer cells.

Internal radiotherapy for esophageal cancer

Self-expandable metallic stents are sometimes used for palliative care

## Follow-up [edit]

Patients are followed closely after a treatment regimen has been completed. Frequently, other treatments are used to improve symptoms and maximize nutrition.

# Prognosis [edit]

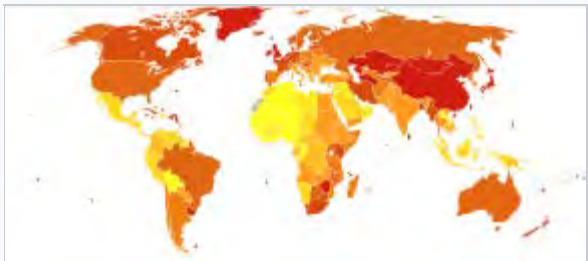
In general, the prognosis of esophageal cancer is quite poor, because most patients present with advanced disease. By the time the first symptoms (such as difficulty swallowing) appear, the disease has already progressed. The overall five-year survival rate (5YSR) in the United States is around 15%, with most people dying within the first year of diagnosis.[58] The latest survival data for England and Wales (patients diagnosed during 2007) show that only one in ten people survive esophageal cancer for at least ten years.[59]

Individualized prognosis depends largely on stage. Those with cancer restricted entirely to the esophageal mucosa have about an 80% 5YSR, but submucosal involvement brings this down to less than 50%. Extension into the muscularis propria (muscle layer of the esophagus) suggests a 20% 5YSR, and extension to the structures adjacent to the esophagus predict a 7% 5YSR. Patients with distant metastases (who are not candidates for curative surgery) have a less than 3% 5YSR.[*citation needed*]

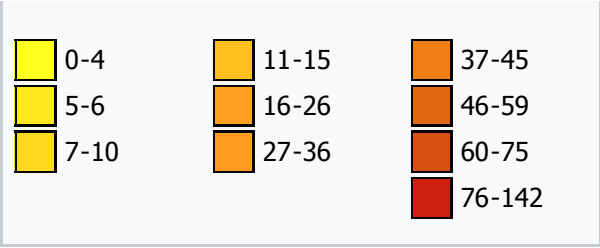
# Epidemiology [edit]

Esophageal cancer is the eighth most frequently diagnosed cancer worldwide,[1] and because of its poor prognosis it is the sixth most common cause of cancer-related death.[46] It caused about 400,000 deaths in 2012, accounting for about 5% of all cancer deaths (about 456,000 new cases were diagnosed, representing about 3% of all cancers).[1]

ESCC comprises 60–70% of all cases of esophageal cancer worldwide, while EAC accounts for a further 20–30% (melanomas, leiomyosarcomas, carcinoids and lymphomas are



Death from esophageal cancer per million persons in 2012



less common types).[60] The incidence of the two main types of esophageal cancer varies greatly between different geographical areas.[61] In general, ESCC is more common in the developing world, and EAC is more common in the developed world.[1]

The worldwide incidence rate of ESCC in 2012 was 5.2 new cases per 100,000 person-years, with a male predominance (7.7 per 100,000 in men vs. 2.8 in women).[62] It was the common type in 90% of the countries studied.[62] ESCC is particularly frequent in the so-called "Asian esophageal cancer belt", an area that passes through northern China, southern Russia, north-eastern Iran, northern Afghanistan and eastern Turkey.[60] In 2012, about 80% of ESCC cases worldwide occurred in central and south-eastern Asia, and over half (53%) of all cases were in China.[62] The countries with the highest estimated national incidence rates were (in Asia) Mongolia and Turkmenistan and (in Africa) Malawi, Kenya and Uganda.[62] The problem of esophageal cancer has long been recognized in the eastern and southern parts of Sub-Saharan Africa, where ESCC appears to predominate.[63]

In Western countries, EAC has become the dominant form of the disease, following an increase in incidence over recent decades (in contrast to the incidence of ESCC, which has remained largely stable).[8][27] In 2012, the global incidence rate for EAC was 0.7 per 100,000 with a strong male predominance (1.1 per 100,000 in men vs. 0.3 in women) Areas with particularly high incidence rates include northern and western Europe, North America and Oceania. The countries with highest recorded rates were the UK, Netherlands, Ireland, Iceland and New Zealand.[62]

### USA [edit]

In the United States, esophageal cancer is the seventh-leading cause of cancer death among males (making up 4% of the total).[64] The National Cancer Institute estimated there were about 18,000 new cases and more than 15,000 deaths from esophageal cancer in 2013 (the American Cancer Society estimated that during 2014, about 18,170 new esophageal cancer cases would be diagnosed, resulting in 15,450 deaths).[61][64] The squamous-cell carcinoma type is more common among African American males with a history of heavy smoking or alcohol use. Until the 1970s, squamous-cell carcinoma accounted for the vast majority of esophageal cancers in the United States. In recent decades, incidence of adenocarcinoma of the esophagus (which is associated with Barrett's esophagus) steadily rose in the United States to the point that it has now surpassed squamous-cell carcinoma. In contrast to squamous-cell carcinoma, esophageal adenocarcinoma is more common in Caucasian men (over the age of 60) than it is in African Americans. Multiple reports indicate esophageal adenocarcinoma incidence has increased during the past 20 years, especially in non-Hispanic white men. Esophageal adenocarcinoma age-adjusted incidence increased in New Mexico from 1973 to 1997. This increase was found in non-Hispanic whites and Hispanics and became predominant in non-Hispanic whites.[65] Esophageal cancer incidence and mortality rates for African Americans continue to be higher than the rate for Causasians. However, incidence and mortality of esophageal cancer has significantly decreased among African Americans since the early 1980s, whereas with Caucasians it has continued to increase.[66] Between 1975 and 2004, incidence of the adenocarcinoma type increased among white American males by over 460% and among white American females by 335%.[61]

### UK [edit]

The incidence of esophageal adenocarcinoma has risen considerably in the UK in recent decades.[14] Overall, esophageal cancer is the thirteenth most common cancer in the UK (around 8,300 people were diagnosed with the disease in 2011), and it is the sixth most common cause of cancer death (around 7,700 people died in 2012).[67]

## Society and culture [edit]

## Notable cases [edit]

*See also: Category:Deaths from esophageal cancer*

Christopher Hitchens, an author who is well known for the book "God is Not Great," also wrote about his life with esophageal cancer.[68]

Morrissey in October 2015 stated he has the disease and describes his experience when he first heard he had it.[69]

# Research directions [edit]

The risk of esophageal squamous-cell carcinoma may be reduced in people using aspirin or related NSAIDs,[70] but in the absence of randomized controlled trials the current evidence is inconclusive.[1][27]

# Glioblastoma

From Wikipedia, the free encyclopedia
(Redirected from Glioblastoma multiforme)

**Glioblastoma**, also known as **glioblastoma multiforme** (**GBM**), is the most aggressive cancer that begins within the brain.[1] Signs and symptoms of glioblastoma are initially non-specific. They may include headaches, personality changes, nausea, and symptoms similar to those of a stroke.[2] Worsening of symptoms is often rapid. This can progress to unconsciousness.[3]

The cause of most cases is unclear.[3] Uncommon risk factors include genetic disorders such as neurofibromatosis and Li Fraumeni syndrome and previous radiation therapy.[3][4] Glioblastomas represent 15% of brain tumors.[2] They can either start from normal brain cells or develop from an already existing low-grade astrocytoma.[5] The diagnosis is typically made by a combination of CT scan, MRI scan, and tissue biopsy.[2]

There is no clear way to prevent the disease. Typically treatment involves surgery after which chemotherapy and radiation therapy are used.[4] The medication temozolomide is frequently used as part of chemotherapy.[4][6][7] High dose steroids may be used to help reduce swelling and decrease symptoms.[2] It is unclear whether trying to remove all or simply most of the cancer is better.[8]

Despite maximum treatment, the cancer usually recurs.[4] The most common length of survival following diagnosis is 12 to 15 months with less than 3% to 5% of people surviving longer than five years.[3][4] Without treatment survival is typically 3 months.[9] It is the most common cancer that begins within the brain and the second most common brain tumor after meningioma.[1][10] About 3 per 100,000 people develop the disease a year.[4] It most often begins around 64 years of age and occurs more commonly in males than females.[3][4] Immunotherapy is being studied in glioblastoma with promising results.[11]

## Signs and symptoms [edit]

Although common symptoms of the disease include seizure, nausea and vomiting, headache, memory loss, and hemiparesis, the single most prevalent symptom is a progressive memory, personality, or neurological deficit due to temporal and frontal lobe involvement. The kind of symptoms produced depends more on the location of the tumor than on its pathological properties. The tumor can start producing symptoms quickly, but occasionally is an asymptomatic condition until it reaches an enormous size.

## Risk factors [edit]

For unknown reasons, GBM occurs more commonly in males.[12] Most glioblastoma tumors appear to be sporadic, without any genetic predisposition. No links have been found between glioblastoma and smoking,[13] consumption of cured meat,[14] or electromagnetic fields.[15][16][17][18] Alcohol consumption may be a possible risk factor.[19] Glioblastoma has been associated with the viruses SV40,[20] HHV-6,[21][22] and cytomegalovirus.[23] There also appears to be a small link between ionizing radiation and glioblastoma.[24] A 2006 analysis links brain cancer to lead exposure in the work-place.[25] There is an association of brain tumor incidence and malaria, suggesting that the anopheles mosquito, the carrier of malaria, might transmit a virus or other agent that could cause glioblastoma[26] or that the immunosuppression associated with malaria could enhance viral replication. Also HHV-6 reactivates in response to hypersensitivity reactions from drugs and environmental chemicals.[27]

Other risk factors include:[28]

- Sex: male (slightly more common in men than women)
- Age: over 50 years old
- Ethnicity: Caucasians, Hispanics, and Asians[29]
- Having a low-grade astrocytoma (brain tumor), which often, given enough time, develops into a higher-grade tumor
- Having one of the following genetic disorders is associated with an increased incidence of gliomas:
  - Neurofibromatosis
  - Tuberous sclerosis
  - Von Hippel-Lindau disease
  - Li-Fraumeni syndrome
  - Turcot syndrome

# Pathogenesis [edit]

Glioblastoma multiforme tumors are characterized by the presence of small areas of necrotizing tissue that are surrounded by anaplastic cells. This characteristic, as well as the presence of hyperplastic blood vessels, differentiates the tumor from Grade 3 astrocytomas, which do not have these features.

GBMs usually form in the cerebral white matter, grow quickly, and can become very large before producing symptoms. Less than 10% form more slowly following degeneration of low-grade astrocytoma or anaplastic astrocytoma. These are called secondary GBMs and are more common in younger patients (mean age 45 versus 62 years).[30] The tumor may extend into the meninges or ventricular wall, leading to high protein content in the cerebrospinal fluid (CSF) (> 100 mg/dL), as well as an occasional pleocytosis of 10 to 100 cells, mostly lymphocytes. Malignant cells carried in the CSF may spread (rarely) to the spinal cord or cause meningeal gliomatosis. However, metastasis of GBM beyond the central nervous system is extremely unusual. About 50% of GBMs occupy more than one lobe of a hemisphere or are bilateral. Tumors of this type usually arise from the cerebrum and may rarely exhibit the classic infiltration across the corpus callosum, producing a butterfly (bilateral) glioma.

The tumor may take on a variety of appearances, depending on the amount of hemorrhage, necrosis, or its age. A CT scan will usually show an inhomogeneous mass with a hypodense center and a variable ring of enhancement surrounded by edema. Mass effect from the tumor and edema may compress the ventricles and cause hydrocephalus.

## Molecular alterations [edit]

Four subtypes of glioblastoma have been identified:[31]

- Classical : Ninety-seven percent of tumors in the 'classical' subtype carry extra copies of the epidermal growth factor receptor (EGFR) gene, and most have higher than normal expression of epidermal growth factor receptor (EGFR), whereas the gene TP53, which is often mutated in glioblastoma, is rarely mutated in this subtype.[32]
- The Proneural subtype often has high rates of alterations in TP53, and in PDGFRA, the gene encoding a-type platelet-derived growth factor receptor, and in IDH1, the gene encoding isocitrate dehydrogenase-1.
- The Mesenchymal subtype is characterized by high rates of mutations or other alterations in NF1, the gene encoding Neurofibromin 1 and fewer alterations in the EGFR gene and less expression of EGFR than other types.[33]
- The Neural subtype was typified by the expression of neuron markers such as NEFL, GABRA1, SYT1 and SLC12A5.[31]

Many other genetic alterations have been described in glioblastoma, and the majority of them are clustered in three pathways, the P53, RB, and the PI3K/AKT.[34] Glioblastomas have alterations in 64-87%, 68-78% and 88% of these pathways, respectively.[1]

Another important alteration is methylation of MGMT, a "suicide" DNA repair enzyme. Methylation is described to impair DNA transcription and therefore, expression of the MGMT enzyme. Since an MGMT enzyme can only repair one DNA alkylation due to its suicide repair mechanism, reverse capacity is low and methylation of the MGMT gene promoter greatly affects DNA-repair capacity.[35][36] Indeed, MGMT methylation is associated with an improved response to treatment with DNA-damaging chemotherapeutics, such as temozolomide.[37]

## Glioblastoma stem-like cells [edit]

Cancer cells with stem cell-like properties have been found in glioblastomas (this may be a cause of their resistance to conventional treatments, and high recurrence rate).[38] These so-called glioblastoma stem-like cells reside in a niche around arterioles, which protects these cells against therapy by maintaining a relatively hypoxic environment.[39] A biomarker for cells in glioblastomas that exhibit cancer stem cell properties, the transcription factor Hes3, has been shown to regulate their number when placed in

culture.[40]

### Metabolism [edit]

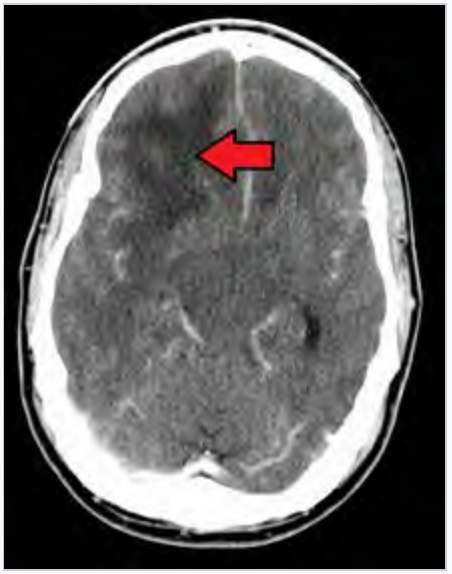
The *IDH1* gene encodes for the enzyme isocitrate dehydrogenase 1 and is frequently mutated in glioblastoma (primary GBM: 5%, secondary GBM >80%).[36] By producing very high concentrations of the "oncometabolite" D-2-hydroxyglutarate and dysregulating the function of the wild-type IDH1-enzyme it induces profound changes to the metabolism of *IDH1*-mutated glioblastoma, compared with *IDH1* wild-type glioblastoma or healthy astrocytes. Among others, it increases the glioblastoma cells' dependence on glutamine or glutamate as an energy source.[41] It has been hypothesized that *IDH1*-mutated glioblastoma are in a very high demand for glutamate and use this amino acid and neurotransmitter as a chemotactic signal. Since healthy astrocytes excrete glutamate, *IDH1*-mutated glioblastoma cells do not favor dense tumor structures but instead migrate, invade and disperse into healthy parts of the brain where glutamate concentrations are higher. This may explain the invasive behaviour of these *IDH1*-mutated glioblastoma.[42]

### Ion channels [edit]

Furthermore, glioblastoma multiforme exhibits numerous alterations in genes that encode for ion channels, including upregulation of gBK potassium channels and ClC-3 chloride channels. It has been hypothesized that by upregulating these ion channels, glioblastoma tumor cells can facilitate increased ion movement over the cell membrane, thereby increasing $H_2O$ movement through osmosis, which aids glioblastoma cells in changing cellular volume very rapidly. This is helpful in their extremely aggressive invasive behavior, because quick adaptations in cellular volume can facilitate movement through the sinuous extracellular matrix of the brain.[43]

## Diagnosis [edit]

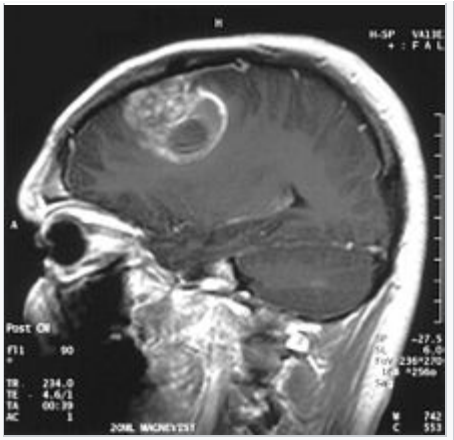
When viewed with MRI, glioblastomas often appear as ring-enhancing lesions. The appearance is not specific, however, as other lesions such as abscess, metastasis, tumefactive multiple sclerosis, and other entities may have a similar appearance.[44] Definitive diagnosis of a suspected GBM on CT or MRI requires a stereotactic biopsy or a craniotomy with tumor resection and pathologic confirmation. Because the tumor grade is based upon the most malignant portion of the tumor, biopsy or subtotal tumor resection can result in undergrading of the lesion. Imaging of tumor blood flow using perfusion MRI and measuring tumor metabolite concentration with MR spectroscopy may add value to standard MRI in select cases by showing increased relative cerebral blood volume and increased choline peak respectively, but pathology remains the gold standard for diagnosis and molecular characterization.



GBM in the frontal right lobe as seen on CT scan

It is important to distinguish primary glioblastoma from secondary glioblastoma. These tumors occur spontaneously (*de novo*) or have progressed from a lower-grade glioma, respectively.[45] Primary glioblastomas have a worse prognosis, different tumor biology and may have a different response to therapy, which makes this a critical evaluation to determine patient prognosis and therapy.[35] Over 80% of secondary glioblastoma carries a mutation in *IDH1*, whereas this mutation is rare in primary glioblastoma (5-10%). Thus, *IDH1* mutations are a useful tool to distinguish primary and secondary glioblastomas since histopathologically they are very similar and the distinction without molecular biomarkers is unreliable.[46]

## Treatment [edit]



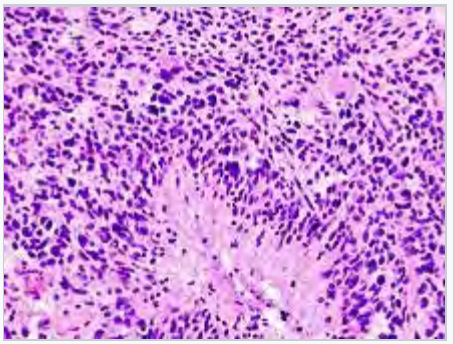
Sagittal MRI with contrast of a glioblastoma WHO grade IV in a 15-year-old boy.

It is very difficult to treat glioblastoma due to several complicating factors:[47]

- The tumor cells are very resistant to conventional therapies.
- The brain is susceptible to damage due to conventional therapy.
- The brain has a very limited capacity to repair itself.
- Many drugs cannot cross the blood–brain barrier to act on the tumor.

Treatment of primary brain tumors and brain metastases consists of both symptomatic and palliative therapies.

## Symptomatic therapy [edit]



Glioblastoma (histology slide)

Supportive treatment focuses on relieving symptoms and improving the patient's neurologic function. The primary supportive agents are anticonvulsants and corticosteroids.

- Historically, around 90% of patients with glioblastoma underwent anticonvulsant treatment, although it has been estimated that only approximately 40% of patients required this treatment. Recently, it has been recommended that neurosurgeons not administer anticonvulsants prophylactically, and should wait until a seizure occurs before prescribing this medication.[48] Those receiving phenytoin concurrent with radiation may have serious skin reactions such as erythema multiforme and Stevens–Johnson syndrome.
- Corticosteroids, usually dexamethasone given 4 to 8 mg every 4 to 6 h, can reduce peritumoral edema (through rearrangement of the blood–brain barrier), diminishing mass effect and lowering intracranial pressure, with a decrease in headache or drowsiness.

## Palliative therapy [edit]

Palliative treatment usually is conducted to improve quality of life and to achieve a longer survival time. It includes surgery, radiation therapy, and chemotherapy. A maximally feasible resection with maximal tumor-free margins is usually performed along with external beam radiation and chemotherapy. Gross total resection of tumor is associated with a better prognosis.

### Surgery [edit]

Surgery is the first stage of treatment of glioblastoma. An average GBM tumor contains $10^{11}$ cells, which is on average reduced to $10^{9}$ cells after surgery (a reduction of 99%). Benefits of surgery include resection for a pathological diagnosis, alleviation of symptoms related to mass effect, and potentially removing disease before secondary resistance to radiotherapy and chemotherapy occurs.

The greater the extent of tumor removal, the better. Removal of 98% or more of the tumor has been associated with a significantly longer healthier time than if less than 98% of the tumor is removed in retrospective analyses.[49] The chances of near-complete initial removal of the tumor may be increased if the surgery is guided by a fluorescent dye known as 5-aminolevulinic acid.[50] GBM cells are widely infiltrative through the brain at diagnosis, and so despite a "total resection" of all obvious tumor, most people with GBM later develop recurrent tumors either near the original site or at more distant locations within the brain. Other modalities, typically radiation and chemotherapy, are used after surgery in an effort

to suppress and slow recurrent disease.

### Radiotherapy [edit]

Subsequent to surgery, radiotherapy becomes the mainstay of treatment for people with glioblastoma. It is typically performed along with giving temozolomide (TMZ).[6] A pivotal clinical trial carried out in the early 1970s showed that among 303 GBM patients randomized to radiation or nonradiation therapy, those who received radiation had a median survival more than double those who did not.[51] Subsequent clinical research has attempted to build on the backbone of surgery followed by radiation. On average, radiotherapy after surgery can reduce the tumor size to $10^7$ cells. Whole-brain radiotherapy does not improve when compared to the more precise and targeted three-dimensional conformal radiotherapy.[52] A total radiation dose of 60–65 Gy has been found to be optimal for treatment.[53]

GBM tumors are well known to contain zones of tissue exhibiting hypoxia which are highly resistant to radiotherapy. Various approaches to chemotherapy radiosensitizers have been pursued with limited success as of 2016. As of 2010 newer research-approaches included preclinical and clinical investigations into the use of an oxygen diffusion-enhancing compound such as trans sodium crocetinate (TSC) as radiosensitizers,[54] and as of 2015 a clinical trial was underway.[55]

Boron neutron capture therapy has been tested as an alternative treatment for glioblastoma multiforme but is not in common use.

### Chemotherapy [edit]

Most studies show no benefit from the addition of chemotherapy. However, a large clinical trial of 575 participants randomized to standard radiation versus radiation plus temozolomide chemotherapy showed that the group receiving temozolomide survived a median of 14.6 months as opposed to 12.1 months for the group receiving radiation alone.[6][56] This treatment regime is now standard for most cases of glioblastoma where the person is not enrolled in a clinical trial.[57][58] Temozolomide seems to work by sensitizing the tumor cells to radiation.[59]

High doses of temozolomide in high-grade gliomas yield low toxicity, but the results are comparable to the standard doses.[60]

Antiangiogenic therapy with medications such as bevacizumab control symptoms but do not affect overall survival.[61]

### Other modalities [edit]

Alternating electric field therapy is an FDA-approved therapy for newly diagnosed[62] and recurrent glioblastoma.[63] In 2015, initial results from a phase-three randomized clinical trial of alternating electric field therapy plus temozolomide in newly diagnosed glioblastoma reported a three-month improvement in progression-free survival, and a five-month improvement in overall survival compared to temozolomide therapy alone,[64][65] representing the first large trial in a decade to show a survival improvement in this setting.[65] Despite these results, the efficacy of this approach remains controversial among medical experts.[66]

## Prognosis [edit]

The median survival time from the time of diagnosis without any treatment is 3 months, but with treatment survival of 1–2 years is common. Increasing age (> 60 years of age) carries a worse prognostic risk. Death is usually due to widespread tumor infiltration with cerebral edema and increased intracranial pressure.[67]

A good initial Karnofsky Performance Score (KPS) and MGMT methylation are associated with longer survival.[67] A DNA test can be conducted on glioblastomas to determine whether or not the promoter of the *MGMT* gene is methylated. Patients with a methylated MGMT promoter have longer survival than those

with an unmethylated MGMT promoter, due in part to increased sensitivity to temozolomide.[68] This DNA characteristic is intrinsic to the patient and currently cannot be altered externally. Another positive prognostic marker for glioblastoma patients is mutation of the *IDH1* gene,[1] which can be tested by DNA-based methods or by immunohistochemistry using an antibody against the most common mutation, namely IDH1-R132H.[69]

More prognostic power can be obtained by combining the mutational status of *IDH1* and the methylation status of *MGMT* into a two-gene predictor. Patients with both *IDH1* mutations and *MGMT* methylation have the longest survival, patients with an *IDH1* mutation or *MGMT* methylation an intermediate survival and patients without either genetic event have the shortest survival.[70]

Long-term benefits have also been associated with those patients who receive surgery, radiotherapy, and temozolomide chemotherapy.[67] However, much remains unknown about why some patients survive longer with glioblastoma. Age of under 50 is linked to longer survival in glioblastoma multiforme, as is 98%+ resection and use of temozolomide chemotherapy and better Karnofsky performance scores. A recent study confirms that younger age is associated with a much better prognosis, with a small fraction of patients under 40 years of age achieving a population-based cure. The population-based cure is thought to occur when a population's risk of death returns to that of the normal population, and in GBM, this is thought to occur after 10 years.[71]

UCLA Neuro-Oncology publishes real-time survival data for patients with this diagnosis.[72] They are the only institution in the United States that shows how their patients are performing. They also show a listing of chemotherapy agents used to treat GBM tumors. Despite a poor prognosis, there is a small number of survivors who have been GBM free for more than 10–20 years.

According to a 2003 study, glioblastoma multiforme prognosis can be divided into three subgroups dependent on KPS, the age of the patient, and treatment.[73]

| Recursive partitioning analysis (RPA) class | Definition | Historical Median Survival Time | Historical 1-Year Survival | Historical 3-Year Survival | Historical 5-Year Survival |
|---|---|---|---|---|---|
| III | Age < 50, KPS ≥ 90 | 17.1 months | 70% | 20% | 14% |
| IV | Age < 50, KPS < 90 | 11.2 months | 46% | 7% | 4% |
| | Age >= 50, KPS ≥ 70, surgical removal with good neurologic function | | | | |
| V + VI | Age ≥ 50, KPS ≥ 70, surgical removal with poor neurologic function | 7.5 months | 28% | 1% | 0% |
| | Age ≥ 50, KPS ≥ 70, no surgical removal | | | | |
| | Age ≥ 50, KPS < 70 | | | | |

## Epidemiology [edit]

About 3 per 100,000 people develop the disease a year.[4] It most often begins around 64 years of age and occurs more commonly in males than females.[3][4] It is the second most common central nervous system cancer after meningiomas, which arise from the meninges.[10]

## History [edit]

The term glioblastoma multiforme was introduced in 1926 by Percival Bailey and Harvey Cushing, based on the idea that the tumor originates from primitive precursors of glial cells (glioblasts), and the highly variable appearance due to the presence of necrosis, hemorrhage and cysts (multiform).[74]

# Research [edit]

A 2014 investigation made a screening of various drugs for anti-glioblastoma activity and identified 22 drugs with potent anti-glioblastoma activity, including the combination of irinotecan and statins.[75]

Laboratory research using genetically engineered stem cells to target glioblastomas in mice was reported in 2014 to show promise.[76]

## MicroRNA [edit]

RNA interference, usually microRNA, is being studied in tissue culture, pathology specimens and in preclinical animal studies.[77] MicroRNA-screening of plasma is used to determine the prognosis of glioblastoma.[78][79]

## Immunotherapy [edit]

Relapse of glioblastoma is attributed to the recurrence and persistence of tumor stem cells.[80] In a small trial, a tumor B-cell hybridoma vaccine against tumor stem cells elicited a specific tumor immune reaction thus enhancing immune response to the disease.[81] Larger trials, including tests of different EGFR signaling patterns and their relationship to tumor stem cells are being conducted.[*citation needed*] The test of rindopepimut failed in a phase III trial in 2016.[82] Other immunotherapeutic and vaccine-type approaches are at different stages of development, but conclusive results are not yet available.[83][84]

## Gene therapy [edit]

Gene therapy is a promising approach for fighting cancers including brain cancer.[85] Unlike current conventional cancer treatments such as chemotherapy and radiation therapy, gene transfer has the potential to selectively kill cancer cells while leaving healthy cells unharmed. Over the past two decades significant advances have been made in gene transfer technology and the field has matured to the point of clinical and commercial feasibility. Advances include vector (gene delivery vehicle) construction, vector producer cell efficiency and scale-up processes, preclinical models for target diseases and regulatory guidance regarding clinical trial design including endpoint definitions and measurements.

In one such approach, researchers at UCLA in 2005 reported a long-term survival benefit in an experimental brain tumor animal model.[86] Subsequently, in preparation for human clinical trials, this technology was further developed by Tocagen, and Toca 511 is since 2010 under clinical investigation in a Phase I trial for the potential treatment of recurrent high grade glioma including glioblastoma multiforme (GBM) and anaplastic astrocytoma.[87] Study due to complete July 2016.[87] As of January 2016 Six different trials of Toca 511 are registered.[88]

## Intranasal drug delivery [edit]

Direct nose-to-brain drug delivery is being explored as a means to achieve higher, and hopefully more effective, drug concentrations in the brain.[89][90] A clinical phase I/II study with glioblastoma patients in Brazil investigated the natural compound perillyl alcohol for intranasal delivery as an aerosol. The results were encouraging[91][92][93] and as of 2016 a similar trial has been initiated in the United States.[94]

# Leukemia

*For the journal, see Leukemia (journal). For animal diseases, see Leucosis.*

**Leukemia**, also spelled **leukaemia**, is a group of cancers that usually begin in the bone marrow and result in high numbers of abnormal white blood cells.[2] These white blood cells are not fully developed and are called *blasts* or *leukemia cells*. Symptoms may include bleeding and bruising problems, feeling tired, fever, and an increased risk of infections.[3] These symptoms occur due to a lack of normal blood cells.[3] Diagnosis is typically made by blood tests or bone marrow biopsy.[3]

The exact cause of leukemia is unknown. Different kinds of leukemia are believed to have different causes. Both inherited and environmental (non-inherited) factors are believed to be involved.[4] Risk factors include smoking, ionizing radiation, some chemicals (such as benzene), prior chemotherapy, and Down syndrome.[4][5] People with a family history of leukemia are also at higher risk.[5] There are four main types of leukemia — acute lymphoblastic leukemia (ALL), acute myeloid leukemia (AML), chronic lymphocytic leukemia (CLL) and chronic myeloid leukemia (CML) — as well as a number of less common types.[5][6] Leukemias and lymphomas both belong to a broader group of tumors that affect the blood, bone marrow, and lymphoid system, known as tumors of the hematopoietic and lymphoid tissues.[7][8]

Treatment may involve some combination of chemotherapy, radiation therapy, targeted therapy, and bone marrow transplant, in addition to supportive care and palliative care as needed. Certain types of leukemia may be managed with watchful waiting.[5] The success of treatment depends on the type of leukemia and the age of the person. Outcomes have improved in the developed world.[6] The average five-year survival rate is 57% in the United States.[9] In children under 15, the five-year survival rate is greater than 60 to 85%, depending on the type of leukemia.[10] In children with acute leukemia who are cancer-free after five years, the cancer is unlikely to return.[10]

In 2012, leukemia developed in 352,000 people globally and caused 265,000 deaths.[6] It is the most common type of cancer in children, with three quarters of leukemia cases in children being the acute lymphoblastic type.[5] However, about 90% of all leukemias are diagnosed in adults, with AML and CLL being most common in adults.[5] It occurs more commonly in the developed world.[6]

## Classification [edit]

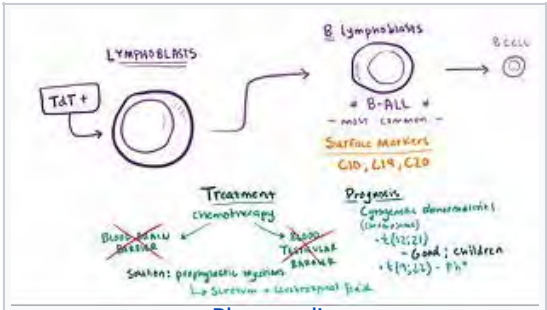
### General classification [edit]

**Four major kinds of leukemia**

| Cell type | Acute | Chronic |
|---|---|---|
| **Lymphocytic leukemia** (or "lymphoblastic") | Acute lymphoblastic leukemia (ALL) | Chronic lymphocytic leukemia (CLL) |
| **Myelogenous leukemia** ("myeloid" or "nonlymphocytic") | Acute myelogenous leukemia (AML or myeloblastic) | Chronic myelogenous leukemia (CML) |

Clinically and pathologically, leukemia is subdivided into a variety of large groups. The first division is between its *acute* and *chronic* forms:

- Acute leukemia is characterized by a rapid increase in the number of immature blood cells. The crowding that results from such cells makes the bone marrow unable to produce healthy blood cells. Immediate treatment is required in acute leukemia because of the rapid progression and accumulation of the malignant cells, which then spill over into the bloodstream and spread to other organs of the body. Acute forms of leukemia are the most common forms of leukemia in children.
- Chronic leukemia is characterized by the excessive buildup of relatively mature, but still abnormal, white blood cells. Typically taking months or years to progress, the cells are produced at a much higher rate than normal, resulting in many abnormal white blood cells. Whereas acute leukemia must be treated immediately, chronic forms are sometimes monitored for some time before treatment to ensure maximum effectiveness of therapy. Chronic leukemia mostly occurs in older people, but can occur in any age group.



Play media

An explanation of acute leukemia

Additionally, the diseases are subdivided according to which kind of blood cell is affected. This divides leukemias into lymphoblastic or *lymphocytic leukemias* and myeloid or *myelogenous leukemias*:

- In lymphoblastic or lymphocytic leukemias, the cancerous change takes place in a type of marrow cell that normally goes on to form lymphocytes, which are infection-fighting immune system cells. Most lymphocytic leukemias involve a specific subtype of lymphocyte, the B cell.
- In myeloid or myelogenous leukemias, the cancerous change takes place in a type of marrow cell that normally goes on to form red blood cells, some other types of white cells, and platelets.

Combining these two classifications provides a total of four main categories. Within each of these main categories, there are typically several subcategories. Finally, some rarer types are usually considered to be outside of this classification scheme.

### Specific types [edit]

- Acute lymphoblastic leukemia (ALL) is the most common type of leukemia in young children. It also affects adults, especially those 65 and older. Standard treatments involve chemotherapy and radiotherapy. The survival rates vary by age: 85% in children and 50% in adults.[11] Subtypes include precursor B acute lymphoblastic leukemia, precursor T acute lymphoblastic leukemia, Burkitt's leukemia, and acute biphenotypic leukemia.
- Chronic lymphocytic leukemia (CLL) most often affects adults over the age of 55. It sometimes occurs in younger adults, but it almost never affects children. Two-thirds of affected people are men. The five-year survival rate is 75%.[12] It is incurable, but there are many effective treatments. One subtype is B-cell prolymphocytic leukemia, a more aggressive disease.
- Acute myelogenous leukemia (AML) occurs more commonly in adults than in children, and more commonly in men than women. It is treated with chemotherapy. The five-year survival rate is 40%, except for APL (Acute Promyelocytic Leukemia), which has a survival rate greater than 90%.[13] Subtypes of AML include acute promyelocytic leukemia, acute myeloblastic leukemia, and acute megakaryoblastic leukemia.

中

- Chronic myelogenous leukemia (CML) occurs mainly in adults; a very small number of children also develop this disease. It is treated with imatinib (Gleevec in United States, Glivec in Europe) or other drugs.[14] The five-year survival rate is 90%.[15][16] One subtype is chronic myelomonocytic leukemia.
- Hairy cell leukemia (HCL) is sometimes considered a subset of chronic lymphocytic leukemia, but does not fit neatly into this category. About 80% of affected people are adult men. No cases in children have been reported. HCL is incurable but easily treatable. Survival is 96% to 100% at ten years.[17]
- T-cell prolymphocytic leukemia (T-PLL) is a very rare and aggressive leukemia affecting adults; somewhat more men than women are diagnosed with this disease.[18] Despite its overall rarity, it is the most common type of mature T cell leukemia;[19] nearly all other leukemias involve B cells. It is difficult to treat, and the median survival is measured in months.
- Large granular lymphocytic leukemia may involve either T-cells or NK cells; like hairy cell leukemia, which involves solely B cells, it is a rare and indolent (not aggressive) leukemia.[20]
- Adult T-cell leukemia is caused by human T-lymphotropic virus (HTLV), a virus similar to HIV. Like HIV, HTLV infects CD4+ T-cells and replicates within them; however, unlike HIV, it does not destroy them. Instead, HTLV "immortalizes" the infected T-cells, giving them the ability to proliferate abnormally. Human T-cell lymphotropic virus types I and II (HTLV-I/II) are endemic in certain areas of the world.

## Signs and symptoms [edit]

Damage to the bone marrow, by way of displacing the normal bone marrow cells with higher numbers of immature white blood cells, results in a lack of blood platelets, which are important in the blood clotting process. This means people with leukemia may easily become bruised, bleed excessively, or develop pinprick bleeds (petechiae).

White blood cells, which are involved in fighting pathogens, may be suppressed or dysfunctional. This could cause the patient's immune system to be unable to fight off a simple infection or to start attacking other body cells. Because leukemia prevents the immune system from working normally, some patients experience frequent infection, ranging from infected tonsils, sores in the mouth, or diarrhea to life-threatening pneumonia or opportunistic infections.

Finally, the red blood cell deficiency leads to anemia, which may cause dyspnea and pallor.

Some patients experience other symptoms, such as feeling sick, having fevers, chills, night sweats, feeling fatigued and other flu-like symptoms. Some patients experience nausea or a feeling of fullness due to an enlarged liver and spleen; this can result in unintentional weight loss. Blasts affected by the disease may come together and become swollen in the liver or in the lymph nodes causing pain and leading to nausea.[22]

Common symptoms of chronic or acute leukemia[21]

If the leukemic cells invade the central nervous system, then neurological symptoms (notably headaches) can occur. Uncommon neurological symptoms like migraines, seizures, or coma can occur as a result of brain stem pressure. All symptoms associated with leukemia can be attributed to other diseases. Consequently, leukemia is always diagnosed through medical tests.

The word *leukemia*, which means 'white blood', is derived from the characteristic high white blood cell count that presents in most afflicted patients before treatment. The high number of white blood cells are apparent when a blood sample is viewed under a microscope, with the extra white blood cells frequently being immature or dysfunctional. The excessive number of cells can also interfere with the level of other cells, causing further harmful imbalance in the blood count.

Some leukemia patients do not have high white blood cell counts visible during a regular blood count. This less-common condition is called *aleukemia*. The bone marrow still contains cancerous white blood cells which disrupt the normal production of blood cells, but they remain in the marrow instead of entering the bloodstream, where they would be visible in a blood test. For an aleukemic patient, the white blood cell counts in the bloodstream can be normal or low. Aleukemia can occur in any of the four major types of leukemia, and is particularly common in hairy cell leukemia.[23]

## Causes [edit]

There is no single known cause for any of the different types of leukemias. The few known causes, which are not generally factors within the control of the average person, account for relatively few cases.[24] The cause for most cases of leukemia is unknown. The different leukemias likely have different causes.

Leukemia, like other cancers, results from mutations in the DNA. Certain mutations can trigger leukemia by activating oncogenes or deactivating tumor suppressor genes, and thereby disrupting the regulation of cell death, differentiation or [25]

division. These mutations may occur spontaneously or as a result of exposure to radiation or carcinogenic substances.

Among adults, the known causes are natural and artificial ionizing radiation, a few viruses such as human T-lymphotropic virus, and some chemicals, notably benzene and alkylating chemotherapy agents for previous malignancies.[26][27][28] Use of tobacco is associated with a small increase in the risk of developing acute myeloid leukemia in adults.[26] Cohort and case-control studies have linked exposure to some petrochemicals and hair dyes to the development of some forms of leukemia. Diet has very limited or no effect, although eating more vegetables may confer a small protective benefit.[24]

Viruses have also been linked to some forms of leukemia. For example, human T-lymphotropic virus (HTLV-1) causes adult T-cell leukemia.[29]

A few cases of maternal-fetal transmission (a baby acquires leukemia because its mother had leukemia during the pregnancy) have been reported.[26] Children born to mothers who use fertility drugs to induce ovulation are more than twice as likely to develop leukemia during their childhoods than other children.[30]

### Radiation [edit]

Large doses of Sr-90 emission from nuclear reactor, nicknamed bone seeker increases the risk of bone cancer and leukemia in animals, and is presumed to do so in people.[31]

### Genetic conditions [edit]

Some people have a genetic predisposition towards developing leukemia. This predisposition is demonstrated by family histories and twin studies.[26] The affected people may have a single gene or multiple genes in common. In some cases, families tend to develop the same kinds of leukemia as other members; in other families, affected people may develop different forms of leukemia or related blood cancers.[26]

In addition to these genetic issues, people with chromosomal abnormalities or certain other genetic conditions have a greater risk of leukemia.[27] For example, people with Down syndrome have a significantly increased risk of developing forms of acute leukemia (especially acute myeloid leukemia), and Fanconi anemia is a risk factor for developing acute myeloid leukemia.[26] Mutation in SPRED1 gene has been associated with a predisposition to childhood leukemia.[32]

### Non ionizing radiation [edit]

Whether or not non-ionizing radiation causes leukemia has been studied for several decades. The International Agency for Research on Cancer expert working group undertook a detailed review of all data on static and extremely low frequency electromagnetic energy, which occurs naturally and in association with the generation, transmission, and use of electrical power.[33] They concluded that there is limited evidence that high levels of ELF magnetic (but not electric) fields might cause some cases of childhood leukemia.[33] No evidence for a relationship to leukemia or another form of malignancy in adults has been demonstrated.[33] Since exposure to such levels of ELFs is relatively uncommon, the World Health Organization concludes that ELF exposure, if later proven to be causative, would account for just 100 to 2400 cases worldwide each year, representing 0.2 to 4.9% of the total incidence of childhood leukemia for that year (about 0.03 to 0.9% of all leukemias).[34]

## Diagnosis [edit]

Diagnosis is usually based on repeated complete blood counts and a bone marrow examination following observations of the symptoms. Sometimes, blood tests may not show that a person has leukemia, especially in the early stages of the disease or during remission. A lymph node biopsy can be performed to diagnose certain types of leukemia in certain situations.

Following diagnosis, blood chemistry tests can be used to determine the degree of liver and kidney damage or the effects of chemotherapy on the patient. When concerns arise about other damage due to leukemia, doctors may use an X-ray, MRI, or ultrasound. These can potentially show leukemia's effects on such body parts as bones (X-ray), the brain (MRI), or the kidneys, spleen, and liver (ultrasound). CT scans can be used to check lymph nodes in the chest, though this is almost never done.

Despite the use of these methods to diagnose whether or not a patient has leukemia, many people have not been diagnosed because many of the symptoms are vague, non-specific, and can refer to other diseases. For this reason, the American Cancer Society estimates that at least one-fifth of the people with leukemia have not yet been diagnosed.[23]

## Treatment [edit]

Most forms of leukemia are treated with pharmaceutical medication, typically combined into a multi-drug chemotherapy regimen. Some are also treated with radiation therapy. In some cases, a bone marrow transplant is effective.

### Acute lymphoblastic [edit]

*Further information: Acute lymphoblastic leukemia § Treatment*

Management of ALL is directed towards control of bone marrow and systemic (whole-body) disease. Additionally, treatment must prevent leukemic cells from spreading to other sites, particularly the central nervous system (CNS) e.g. monthly lumbar punctures. In general, ALL treatment is divided into several phases:

- *Induction chemotherapy* to bring about bone marrow remission. For adults, standard induction plans include prednisone, vincristine, and an anthracycline drug; other drug plans may include L-asparaginase or cyclophosphamide. For children with low-risk ALL, standard therapy usually consists of three drugs (prednisone, L-asparaginase, and vincristine) for the first month of treatment.
- *Consolidation therapy* or *intensification therapy* to eliminate any remaining leukemia cells. There are many different approaches to consolidation, but it is typically a high-dose, multi-drug treatment that is undertaken for a few months. Patients with low- to average-risk ALL receive therapy with antimetabolite drugs such as methotrexate and 6-mercaptopurine (6-MP). High-risk patients receive higher drug doses of these drugs, plus additional drugs.
- *CNS prophylaxis* (preventive therapy) to stop the cancer from spreading to the brain and nervous system in high-risk patients. Standard prophylaxis may include radiation of the head and/or drugs delivered directly into the spine.
- *Maintenance treatments* with chemotherapeutic drugs to prevent disease recurrence once remission has been achieved. Maintenance therapy usually involves lower drug doses, and may continue for up to three years.
- Alternatively, *allogeneic bone marrow transplantation* may be appropriate for high-risk or relapsed patients.[35]

## Chronic lymphocytic [edit]

*Further information: Chronic lymphocytic leukemia § Treatment*

### Decision to treat [edit]

Hematologists base CLL treatment on both the stage and symptoms of the individual patient. A large group of CLL patients have low-grade disease, which does not benefit from treatment. Individuals with CLL-related complications or more advanced disease often benefit from treatment. In general, the indications for treatment are:

- Falling hemoglobin or platelet count
- Progression to a later stage of disease
- Painful, disease-related overgrowth of lymph nodes or spleen
- An increase in the rate of lymphocyte production[36]

### Treatment approach [edit]

For most people with CLL, it is incurable by present treatments, so treatment is directed towards suppressing the disease for many years, rather than totally and permanently eliminating it. The primary chemotherapeutic plan is combination chemotherapy with chlorambucil or cyclophosphamide, plus a corticosteroid such as prednisone or prednisolone. The use of a corticosteroid has the additional benefit of suppressing some related autoimmune diseases, such as immunohemolytic anemia or immune-mediated thrombocytopenia. In resistant cases, single-agent treatments with nucleoside drugs such as fludarabine,[37] pentostatin, or cladribine may be successful. Younger and healthier patients may choose allogeneic or autologous bone marrow transplantation in the hope of a permanent cure.[38]

## Acute myelogenous [edit]

*Further information: Acute myeloid leukemia § Treatment*

Many different anti-cancer drugs are effective for the treatment of AML. Treatments vary somewhat according to the age of the patient and according to the specific subtype of AML. Overall, the strategy is to control bone marrow and systemic (whole-body) disease, while offering specific treatment for the central nervous system (CNS), if involved.

In general, most oncologists rely on combinations of drugs for the initial, *induction phase* of chemotherapy. Such combination chemotherapy usually offers the benefits of early remission and a lower risk of disease resistance. *Consolidation* and *maintenance* treatments are intended to prevent disease recurrence. Consolidation treatment often entails a repetition of induction chemotherapy or the intensification chemotherapy with additional drugs. By contrast, maintenance treatment involves drug doses that are lower than those administered during the induction phase.[39]

## Chronic myelogenous [edit]

*Further information: Chronic myelogenous leukemia § Treatment*

There are many possible treatments for CML, but the standard of care for newly diagnosed patients is imatinib (Gleevec) therapy.[40] Compared to most anti-cancer drugs, it has relatively few side effects and can be taken orally at home. With this drug, more than 90% of patients will be able to keep the disease in check for at least five years,[40] so that CML becomes a chronic, manageable condition.

In a more advanced, uncontrolled state, when the patient cannot tolerate imatinib, or if the patient wishes to attempt a permanent cure, then an allogeneic bone marrow transplantation may be performed. This procedure involves high-dose

chemotherapy and radiation followed by infusion of bone marrow from a compatible donor. Approximately 30% of patients die from this procedure.[40]

### Hairy cell [edit]

*Further information: Hairy cell leukemia § Treatment*

**Decision to treat**
Patients with hairy cell leukemia who are symptom-free typically do not receive immediate treatment. Treatment is generally considered necessary when the patient shows signs and symptoms such as low blood cell counts (e.g., infection-fighting neutrophil count below 1.0 K/μL), frequent infections, unexplained bruises, anemia, or fatigue that is significant enough to disrupt the patient's everyday life.

**Typical treatment approach**
Patients who need treatment usually receive either one week of cladribine, given daily by intravenous infusion or a simple injection under the skin, or six months of pentostatin, given every four weeks by intravenous infusion. In most cases, one round of treatment will produce a prolonged remission.[41]

Other treatments include rituximab infusion or self-injection with Interferon-alpha. In limited cases, the patient may benefit from *splenectomy* (removal of the spleen). These treatments are not typically given as the first treatment because their success rates are lower than cladribine or pentostatin.[42]

### T-cell prolymphocytic [edit]

*Further information: T-cell prolymphocytic leukemia § Treatment*

Most patients with T-cell prolymphocytic leukemia, a rare and aggressive leukemia with a median survival of less than one year, require immediate treatment.[43]

T-cell prolymphocytic leukemia is difficult to treat, and it does not respond to most available chemotherapeutic drugs.[43] Many different treatments have been attempted, with limited success in certain patients: purine analogues (pentostatin, fludarabine, cladribine), chlorambucil, and various forms of combination chemotherapy (cyclophosphamide, doxorubicin, vincristine, prednisone CHOP, cyclophosphamide, vincristine, prednisone [COP], vincristine, doxorubicin, prednisone, etoposide, cyclophosphamide, bleomycin VAPEC-B). Alemtuzumab (Campath), a monoclonal antibody that attacks white blood cells, has been used in treatment with greater success than previous options.[43]

Some patients who successfully respond to treatment also undergo stem cell transplantation to consolidate the response.[43]

### Juvenile myelomonocytic [edit]

*Further information: Juvenile myelomonocytic leukemia § Treatment*

Treatment for juvenile myelomonocytic leukemia can include splenectomy, chemotherapy, and bone marrow transplantation.[44]

## Prognosis [edit]

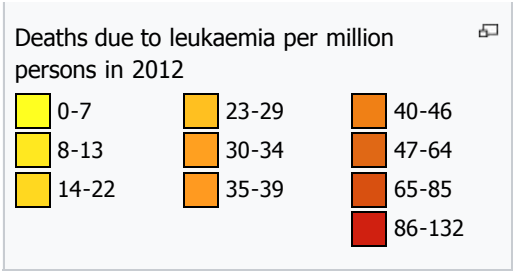
The success of treatment depends on the type of leukemia and the age of the person. Outcomes have improved in the developed world.[6] The average five-year survival rate is 57% in the United States.[9] In children under 15, the five-year survival rate is greater than 60 to 85%, depending on the type of leukemia.[10] In children with acute leukemia who are cancer-free after five years, the cancer is unlikely to return.[10]

Outcomes depend on whether it is acute, which is generally more severe, versus chronic; the specific abnormal white blood cell type; the stage of progression; the grade- degree of tissue abnormality; and the presence of proximal and/or distant metastasis and lymph node and bone marrow infiltration, the availability of current therapies and the skills of the health care team (cancer treatment outcomes are better at accredited academic cancer centers).[*citation needed*]

## Epidemiology [edit]

In 2010, globally, approximately 281,500 people died of leukemia.[45] In 2000, approximately 256,000 children and adults around the world developed a form of leukemia, and 209,000 died from it.[46] This represents about 3% of the almost seven million deaths due to cancer that year, and about 0.35% of all deaths from any cause.[46] Of the sixteen separate sites the body compared, leukemia was the 12th most common class of neoplastic disease, and the 11th most common cause of cancer-related death.[46] Leukemia occurs more commonly in the developed [47]

world.



## United States [edit]

About 245,000 people in the United States are affected with some form of leukemia, including those that have achieved remission or cure. Rates from 1975 to 2011 have increased by 0.7% per year among children.[48] Approximately 44,270 new cases of leukemia were diagnosed in the year 2008 in the US.[49] This represents 2.9% of all cancers (excluding simple basal cell and squamous cell skin cancers) in the United States, and 30.4% of all blood cancers.[50]

Among children with some form of cancer, about a third have a type of leukemia, most commonly acute lymphoblastic leukemia.[49] A type of leukemia is the second most common form of cancer in infants (under the age of 12 months) and the most common form of cancer in older children.[51] Boys are somewhat more likely to develop leukemia than girls, and white American children are almost twice as likely to develop leukemia than black American children.[51] Only about 3% cancer diagnoses among adults are for leukemias, but because cancer is much more common among adults, more than 90% of all leukemias are diagnosed in adults.[49]

Race is a risk factor in the United States. Hispanics, especially those under the age of 20, are at the highest risk for leukemia, while whites, Native Americans, Asian Americans, and Alaska Natives are at higher risk than African Americans.[52]

More men than women are diagnosed with leukemia and die from the disease. Around 30 percent more men than women have leukemia.[53]

## UK [edit]

Overall, leukaemia is the eleventh most common cancer in the UK (around 8,600 people were diagnosed with the disease in 2011), and it is the ninth most common cause of cancer death (around 4,800 people died in 2012).[54]

# History [edit]

*See also: Timeline of leukemia*

Leukemia was first described by anatomist and surgeon Alfred-Armand-Louis-Marie Velpeau in 1827. A more complete description was given by pathologist Rudolf Virchow in 1845. Observing an abnormally large number of white blood cells in a blood sample from a patient, Virchow called the condition *Leukämie* in German, which he formed from the two Greek words *leukos* (λευκός), meaning "white", and *haima* (αἷμα), meaning "blood". Around ten years after Virchow's findings, pathologist Franz Ernst Christian Neumann found that one deceased leukemia patient's bone marrow was colored "dirty green-yellow" as opposed to the normal red. This finding allowed Neumann to conclude that a bone marrow problem was responsible for the abnormal blood of leukemia patients.

Rudolf Virchow

By 1900 leukemia was viewed as a family of diseases as opposed to a single disease. By 1947 Boston pathologist Sidney Farber believed from past experiments that aminopterin, a folic acid mimic, could potentially cure leukemia in children. The majority of the children with ALL who were tested showed signs of improvement in, their bone marrow, but none of them were actually cured. This, however, led to further experiments.

In 1962, researchers Emil J. Freireich, Jr. and Emil Frei III used combination chemotherapy to attempt to cure leukemia. The tests were successful with some patients surviving long after the tests.[55]

# Society and culture [edit]

According to Susan Sontag, leukemia was often romanticized in 20th-century fiction, portrayed as a joy-ending, clean disease whose fair, innocent and gentle victims die young or at the wrong time. As such, it was the cultural successor to tuberculosis, which held this cultural position until it was discovered to be an infectious disease.[56] The 1970 romance novel *Love Story* is an example of this romanticization of leukemia.

In the United States, around $5.4 billion is spent on treatment a year.[57]

# Research directions [edit]

Significant research into the causes, prevalence, diagnosis, treatment, and prognosis of leukemia is being performed. Hundreds [58]

of clinical trials are being planned or conducted at any given time. Studies may focus on effective means of treatment, better ways of treating the disease, improving the quality of life for patients, or appropriate care in remission or after cures.

In general, there are two types of leukemia research: clinical or translational research and basic research. Clinical/translational research focuses on studying the disease in a defined and generally immediately patient-applicable way, such as testing a new drug in patients. By contrast, basic science research studies the disease process at a distance, such as seeing whether a suspected carcinogen can cause leukemic changes in isolated cells in the laboratory or how the DNA changes inside leukemia cells as the disease progresses. The results from basic research studies are generally less immediately useful to patients with the disease.[59]

Treatment through gene therapy is currently being pursued. One such approach used genetically modified T cells to attack cancer cells. In 2011, a year after treatment, two of the three patients with advanced chronic lymphocytic leukemia were reported to be cancer-free[60] and in 2013, three of five subjects who had acute lymphocytic leukemia were reported to be in remission for five months to two years.[61] Identifying stem cells that cause different types of leukaemia is also being researched.[62]

## Pregnancy [edit]

Leukemia is rarely associated with pregnancy, affecting only about 1 in 10,000 pregnant women.[63] How it is handled depends primarily on the type of leukemia. Nearly all leukemias appearing in pregnant women are acute leukemias.[64] Acute leukemias normally require prompt, aggressive treatment, despite significant risks of pregnancy loss and birth defects, especially if chemotherapy is given during the developmentally sensitive first trimester.[63] Chronic myelogenous leukemia can be treated with relative safety at any time during pregnancy with Interferon-alpha hormones.[63] Treatment for chronic lymphocytic leukemias, which are rare in pregnant women, can often be postponed until after the end of the pregnancy.[63][64]

# Lung cancer

From Wikipedia, the free encyclopedia

*This article is about lung carcinomas. For other lung tumors, see Lung tumor.*

**Lung cancer**, also known as **lung carcinoma**,[1] is a malignant lung tumor characterized by uncontrolled cell growth in tissues of the lung.[2] If left untreated, this growth can spread beyond the lung by the process of metastasis into nearby tissue or other parts of the body.[3] Most cancers that start in the lung, known as primary lung cancers, are carcinomas.[4] The two main types are small-cell lung carcinoma (SCLC) and non-small-cell lung carcinoma (NSCLC).[5] The most common symptoms are coughing (including coughing up blood), weight loss, shortness of breath, and chest pains.[6]

The vast majority (85%) of cases of lung cancer are due to long-term tobacco smoking.[7] About 10–15% of cases occur in people who have never smoked.[8] These cases are often caused by a combination of genetic factors and exposure to radon gas, asbestos, second-hand smoke, or other forms of air pollution.[7][9][10][11] Lung cancer may be seen on chest radiographs and computed tomography (CT) scans.[1] The diagnosis is confirmed by biopsy which is usually performed by bronchoscopy or CT-guidance.[12][13]

Prevention is by avoiding risk factors including smoking and air pollution.[14] Treatment and long-term outcomes depend on the type of cancer, the stage (degree of spread), and the person's overall health.[1] Most cases are not curable.[5] Common treatments include surgery, chemotherapy, and radiotherapy.[1] NSCLC is sometimes treated with surgery, whereas SCLC usually responds better to chemotherapy and radiotherapy.[15]

Worldwide in 2012, lung cancer occurred in 1.8 million people and resulted in 1.6 million deaths.[4] This makes it the most common cause of cancer-related death in men and second most common in women after breast cancer.[16] The most common age at diagnosis is 70 years. Overall, 17.4% of people in the United States diagnosed with lung cancer survive five years after the diagnosis,[17] while outcomes on average are worse in the developing world.[18]

## Signs and symptoms [edit]

Signs and symptoms which may suggest lung cancer include:[6]

- Respiratory symptoms: coughing, coughing up blood, wheezing, or shortness of breath
- Systemic symptoms: weight loss, weakness, fever, or clubbing of the fingernails
- Symptoms due to the cancer mass pressing on adjacent structures: chest pain, bone pain, superior vena cava obstruction, or difficulty swallowing

If the cancer grows in the airways, it may obstruct airflow, causing breathing difficulties. The obstruction can lead to accumulation of secretions behind the blockage, and predispose to pneumonia.[6]

Depending on the type of tumor, paraneoplastic phenomena—symptoms not due to the local presence of cancer—may initially attract attention to the disease.[19] In lung cancer, these phenomena may include hypercalcemia, syndrome of inappropriate antidiuretic hormone (SIADH, abnormally concentrated urine and diluted blood), ectopic ACTH production, or Lambert–Eaton myasthenic syndrome (muscle weakness due to autoantibodies). Tumors in the top of the lung, known as Pancoast tumors, may invade the local part of the sympathetic nervous system, leading to Horner's syndrome (dropping of the eyelid and a small pupil on that side), as well as damage to the brachial plexus.[6]

Many of the symptoms of lung cancer (poor appetite, weight loss, fever, fatigue) are not specific.[12] In many people, the cancer has already spread beyond the original site by the time they have symptoms and seek medical attention.[20] Symptoms that suggest the presence of metastatic disease include weight loss, bone pain and neurological symptoms (headaches, fainting, convulsions, or limb weakness).[6] Common sites of spread include the brain, bone, adrenal glands, opposite lung, liver, pericardium, and kidneys.[20] About 10% of people with lung cancer do not have symptoms at diagnosis; these cancers are incidentally [13]

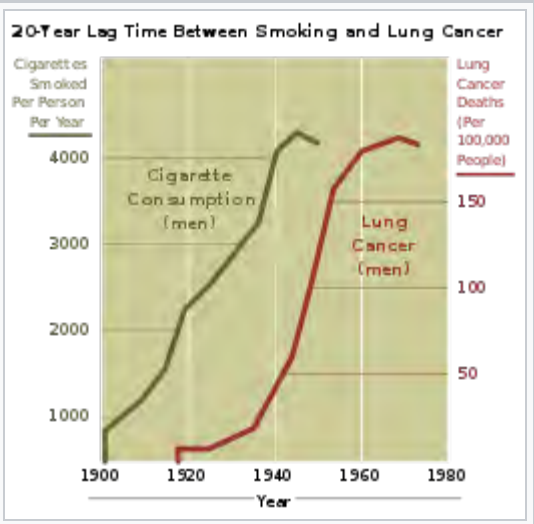
found on routine chest radiography.

## Causes [edit]

Cancer develops following genetic damage to DNA and epigenetic changes. These changes affect the normal functions of the cell, including cell proliferation, programmed cell death (apoptosis) and DNA repair. As more damage accumulates, the risk of cancer increases.[21]

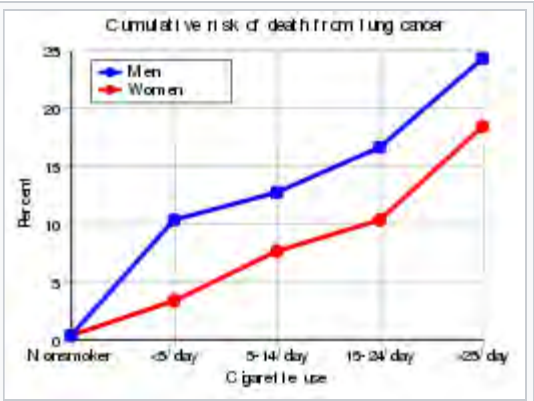
## Smoking [edit]

Smoking, particularly of cigarettes, is by far the main contributor to lung cancer.[22] Cigarette smoke contains at least 73 known carcinogens,[23] including benzo[*a*]pyrene,[24] NNK, 1,3-butadiene and a radioactive isotope of polonium, polonium-210.[23] Across the developed world, 90% of lung cancer deaths in men during the year 2000 were attributed to smoking (70% for women).[25] Smoking accounts for about 85% of lung cancer cases.[1]



Graph showing how a general increase in sales of tobacco products in the USA in the first four decades of the 20th century (cigarettes per person per year) led to a corresponding rapid increase in the rate of lung cancer during the 1930s, '40s and '50s (lung cancer deaths per 100,000 male population per year)

Passive smoking—the inhalation of smoke from another's smoking—is a cause of lung cancer in nonsmokers. A passive smoker can be defined as someone living or working with a smoker. Studies from the US,[26][27][28] Europe[29] and the UK[30] have consistently shown a significantly increased risk among those exposed to passive smoke.[31] Those who live with someone who smokes have a 20–30% increase in risk while those who work in an environment with secondhand smoke have a 16–19% increase in risk.[32] Investigations of sidestream smoke suggest it is more dangerous than direct smoke.[33] Passive smoking causes about 3,400 deaths from lung cancer each year in the USA.[28]



Risk of death from lung cancer is strongly correlated with smoking

Marijuana smoke contains many of the same carcinogens as those in tobacco smoke.[34] However, the effect of smoking cannabis on lung cancer risk is not clear.[35][36] A 2013 review did not find an increased risk from light to moderate use.[37] A 2014 review found that smoking cannabis doubled the risk of lung cancer.[38]

## Radon gas [edit]

Radon is a colourless and odorless gas generated by the breakdown of radioactive radium, which in turn is the decay product of uranium, found in the Earth's crust. The radiation decay products ionize genetic material, causing mutations that sometimes turn cancerous. Radon is the second-most common cause of lung cancer in the USA,[39] causing about 21,000 deaths each year.[40] The risk increases 8–16% for every 100 Bq/m³ increase in the radon concentration.[41] Radon gas levels vary by locality and the composition of the underlying soil and rocks. About one in 15 homes in the US has radon levels above the recommended guideline of 4 picocuries per liter (pCi/l) (148 Bq/m³).[42]

## Asbestos [edit]

Asbestos can cause a variety of lung diseases, including lung cancer. Tobacco smoking and asbestos have a

synergistic effect on the formation of lung cancer.[10] In smokers who work with asbestos, the risk of lung cancer is increased 45-fold compared to the general population.[43] Asbestos can also cause cancer of the pleura, called mesothelioma (which is different from lung cancer).[44]

### Air pollution [edit]

Outdoor air pollutants, especially chemicals released from the burning of fossil fuels, increase the risk of lung cancer.[7] Fine particulates ($PM_{2.5}$) and sulfate aerosols, which may be released in traffic exhaust fumes, are associated with slightly increased risk.[7][45] For nitrogen dioxide, an incremental increase of 10 parts per billion increases the risk of lung cancer by 14%.[46] Outdoor air pollution is estimated to account for 1–2% of lung cancers.[7]

Tentative evidence supports an increased risk of lung cancer from indoor air pollution related to the burning of wood, charcoal, dung or crop residue for cooking and heating.[47] Women who are exposed to indoor coal smoke have about twice the risk and a number of the by-products of burning biomass are known or suspected carcinogens.[48] This risk affects about 2.4 billion people globally,[47] and is believed to account for 1.5% of lung cancer deaths.[48]

### Genetics [edit]

About 8% of lung cancer is due to inherited factors.[49] In relatives of people with lung cancer, the risk is doubled. This is likely due to a combination of genes.[50] Polymorphisms on chromosomes 5, 6 and 15 are known to affect the risk of lung cancer.[51]

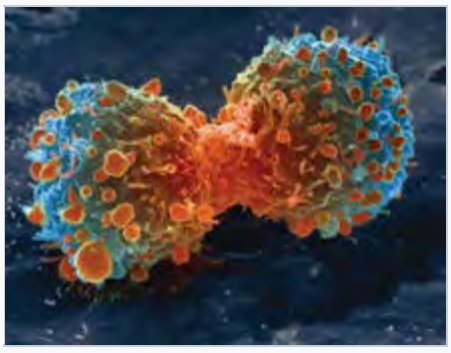
### Other causes [edit]

Numerous other substances, occupations, and environmental exposures have been linked to lung cancer. The International Agency for Research on Cancer (IARC) states there is "sufficient evidence" to show the following are carcinogenic in the lungs:[52]

- Some metals (aluminum production, cadmium and cadmium compounds, chromium(VI) compounds, beryllium and beryllium compounds, iron and steel founding, nickel compounds, arsenic and inorganic arsenic compounds, underground hematite mining)
- Some products of combustion (incomplete combustion, coal (indoor emissions from household coal burning), coal gasification, coal-tar pitch, coke production, soot, diesel engine exhaust)
- Ionizing radiation (X-radiation, gamma radiation, plutonium)
- Some toxic gases (methyl ether (technical grade), Bis-(chloromethyl) ether, sulfur mustard, MOPP (vincristine-prednisone-nitrogen mustard-procarbazine mixture), fumes from painting)
- Rubber production and crystalline silica dust

## Pathogenesis [edit]

*See also: Carcinogenesis*



Similar to many other cancers, lung cancer is initiated by activation of oncogenes or inactivation of tumor suppressor genes.[53] Carcinogens cause mutations in these genes which induce the development of cancer.[54]

Mutations in the *K-ras* proto-oncogene are responsible for 10–30% of lung adenocarcinomas.[55][56] About 4% of non-small-cell lung carcinomas involve an EML4-ALK tyrosine kinase fusion gene.[57]

Epigenetic changes—such as alteration of DNA methylation, histone tail modification, or microRNA regulation—may lead to inactivation of tumor [58]

False-color scanning electron micrograph of a lung cancer cell dividing

suppressor genes.

The epidermal growth factor receptor (EGFR) regulates cell proliferation, apoptosis, angiogenesis, and tumor invasion.[55] Mutations and amplification of EGFR are common in non-small-cell lung carcinoma and provide the basis for treatment with EGFR-inhibitors. Her2/neu is affected less frequently.[55] Other genes that are often mutated or amplified are *c-MET*, *NKX2-1*, *LKB1*, *PIK3CA*, and *BRAF*.[55]

The cell lines of origin are not fully understood.[6] The mechanism may involve abnormal activation of stem cells. In the proximal airways, stem cells that express keratin 5 are more likely to be affected, typically leading to squamous-cell lung carcinoma. In the middle airways, implicated stem cells include club cells and neuroepithelial cells that express club cell secretory protein. Small-cell lung carcinoma may be derived from these cell lines[59] or neuroendocrine cells,[6] and may express CD44.[59]

Metastasis of lung cancer requires transition from epithelial to mesenchymal cell type. This may occur through activation of signaling pathways such as Akt/GSK3Beta, MEK-ERK, Fas, and Par6.[60]

## Diagnosis [edit]

Performing a chest radiograph is one of the first investigative steps if a person reports symptoms that may suggest lung cancer. This may reveal an obvious mass, widening of the mediastinum (suggestive of spread to lymph nodes there), atelectasis (collapse), consolidation (pneumonia) or pleural effusion.[1] CT imaging is typically used to provide more information about the type and extent of disease. Bronchoscopy or CT-guided biopsy is often used to sample the tumor for histopathology.[13]

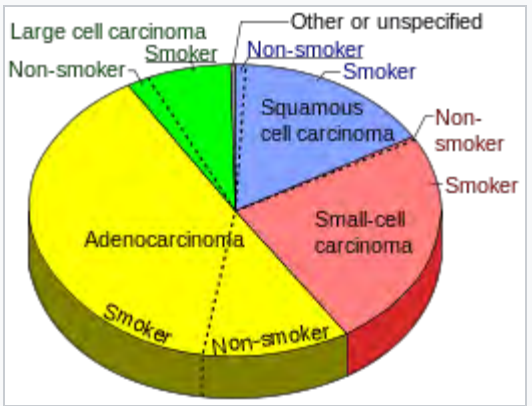
CT scan showing a cancerous tumor in the left lung

Lung cancer often appears as a solitary pulmonary nodule on a chest radiograph. However, the differential diagnosis is wide. Many other diseases can also give this appearance, including metastatic cancer, hamartomas, and infectious granulomas such as tuberculosis, histoplasmosis and coccidioidomycosis.[61] Lung cancer can also be an incidental finding, as a solitary pulmonary nodule on a chest radiograph or CT scan done for an unrelated reason.[62] The definitive diagnosis of lung cancer is based on histological examination of the suspicious tissue[6] in the context of the clinical and radiological features.[12]

Clinical practice guidelines recommend frequencies for pulmonary nodule surveillance.[63] CT imaging should not be used for longer or more frequently than indicated as extended surveillance exposes people to increased radiation.[63]

### Classification [edit]

Lung cancers are classified according to histological type.[12] This classification is important for determining management and predicting outcomes of the disease. Lung cancers are carcinomas—malignancies that arise from epithelial cells. Lung carcinomas are categorized by the size and appearance of the malignant cells seen by a histopathologist under a microscope. For therapeutic purposes, two broad classes are distinguished: non-small-cell lung carcinoma and small-cell lung carcinoma.[65]

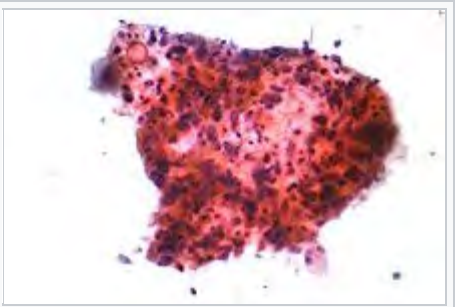


### Non-small-cell lung carcinoma [edit]

The three main subtypes of NSCLC are adenocarcinoma,

squamous-cell carcinoma and large-cell carcinoma.[6]

Nearly 40% of lung cancers are adenocarcinoma, which usually originates in peripheral lung tissue.[12] Although most cases of adenocarcinoma are associated with smoking, adenocarcinoma is also the most common form of lung cancer among people who have smoked fewer than 100 cigarettes in their lifetimes ("never-smokers")[6][66] and ex-smokers with a modest smoking history.[6]



Micrograph of squamous-cell carcinoma, a type of non-small-cell carcinoma, FNA specimen, Pap stain

A subtype of adenocarcinoma, the bronchioloalveolar carcinoma, is more common in female never-smokers, and may have a better long-term survival.[67]

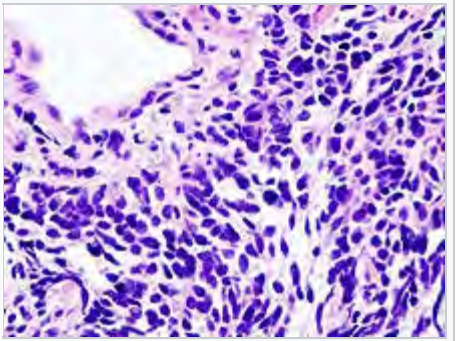
Squamous-cell carcinoma accounts for about 30% of lung cancers. They typically occur close to large airways. A hollow cavity and associated cell death are commonly found at the center of the tumor.[12] About 9% of lung cancers are large-cell carcinoma. These are so named because the cancer cells are large, with excess cytoplasm, large nuclei and conspicuous nucleoli.[12]

Pie chart showing incidences of non-small cell lung cancers as compared to small cell carcinoma shown at right, with fractions of smokers versus non-smokers shown for each type.[64]

**Age-adjusted incidence of lung cancer by histological type**[7]

| Histological type | Incidence per 100,000 per year |
|---|---|
| All types | 66.9 |
| Adenocarcinoma | 22.1 |
| Squamous-cell carcinoma | 14.4 |
| Small-cell carcinoma | 9.8 |

## Small-cell lung carcinoma [edit]



Small-cell lung carcinoma (microscopic view of a core needle biopsy)

In small-cell lung carcinoma (SCLC), the cells contain dense neurosecretory granules (vesicles containing neuroendocrine hormones), which give this tumor an endocrine/paraneoplastic syndrome association.[68] Most cases arise in the larger airways (primary and secondary bronchi).[13] Sixty to seventy percent have extensive disease (which cannot be targeted within a single radiation therapy field) at presentation.[6]

### Others [edit]

Four main histological subtypes are recognised, although some cancers may contain a combination of different subtypes,[65] such as adenosquamous carcinoma.[12] Rare subtypes include carcinoid tumors, bronchial gland carcinomas and sarcomatoid carcinomas.[12]

## Metastasis [edit]

The lung is a common place for the spread of tumors from other parts of the body. Secondary cancers are classified by the site of origin; e.g., breast cancer that has spread to the lung is called metastatic breast cancer. Metastases often have a characteristic round appearance on chest radiograph.[69]

Primary lung cancers themselves most commonly metastasize to the brain, bones, liver and adrenal glands.[12] Immunostaining of a biopsy is often helpful to determine the original source.[70] The presence of Napsin-A, TTF-1, CK7 and CK20 are helpful in confirming the subtype of lung carcinoma. SCLC derived from neuroendocrine cells may express CD56, neural cell adhesion molecule, synaptophysin or chromogranin.[6]

**Typical Napsin-A and TTF-1 immunostaining in primary lung carcinoma**[6]

| Histological type | Napsin-A | TTF-1 |
|---|---|---|
| Squamous-cell carcinoma | Negative | Negative |
| Adenocarcinoma | Positive | Positive |
| Small-cell carcinoma | Negative | Positive |

## Staging [edit]

*See also: Lung cancer staging*

Lung cancer staging is an assessment of the degree of spread of the cancer from its original source.[71] It is one of the factors affecting the prognosis and potential treatment of lung cancer.[6][71]

The evaluation of non-small-cell lung carcinoma (NSCLC) staging uses the TNM classification. This is based on the size of the primary **t**umor, lymph **n**ode involvement, and distant **m**etastasis.[6]

**TNM classification in lung cancer**[6][72]

| T: Primary tumor | | |
|---|---|---|
| TX | Any of: | Primary tumor cannot be assessed |
| | | Tumor cells present in sputum or bronchial washing, but tumor not seen with imaging or bronchoscopy |
| T0 | No evidence of primary tumor | |
| Tis | Carcinoma in situ | |
| T1 | Tumor size less than or equal to 3 cm across, surrounded by lung or visceral pleura, without invasion proximal to the lobar bronchus | |
| T1a | Tumor size less than or equal to 2 cm across | |
| T1b | Tumor size more than 2 cm but less than or equal to 3 cm across | |
| T2 | Any of: | Tumor size more than 3 cm but less than or equal to 7 cm across |
| | | Involvement of the main bronchus at least 2 cm distal to the carina |
| | | Invasion of visceral pleura |
| | | Atelectasis/obstructive pneumonitis extending to the hilum but not involving the whole lung |
| T2a | Tumor size more than 3 cm but less than or equal to 5 cm across | |
| T2b | Tumor size more than 5 cm but less than or equal to 7 cm across | |
| T3 | Any of: | Tumor size more than 7 cm across |
| | | Invasion into the chest wall, diaphragm, phrenic nerve, mediastinal pleura or parietal pericardium |
| | | Tumor less than 2 cm distal to the carina, but not involving the carina |
| | | Atelectasis/obstructive pneumonitis of the whole lung |
| | | Separate tumor nodule in the same lobe |
| T4 | Any of: | Invasion of the mediastinum, heart, great vessels, trachea, carina, recurrent laryngeal nerve, esophagus, or vertebra |
| | | Separate tumor nodule in a different lobe of the same lung |

| N: Lymph nodes | | |
|---|---|---|
| NX | Regional lymph nodes cannot be assessed | |
| N0 | No regional lymph node metastasis | |
| N1 | Metastasis to ipsilateral peribronchial and/or hilar lymph nodes | |
| N2 | Metastasis to ipsilateral mediastinal and/or subcarinal lymph nodes | |
| N3 | Any of: | Metastasis to scalene or supraclavicular lymph nodes |
| | | Metastasis to contralateral hilar or mediastinal lymph nodes |

| M: Metastasis | | |
|---|---|---|
| MX | Distant metastasis cannot be assessed | |
| M0 | No distant metastasis | |
| M1a | Any of: | Separate tumor nodule in the other lung |
| | | Tumor with pleural nodules |
| | | Malignant pleural or pericardial effusion |
| M1b | Distant metastasis | |

Using the TNM descriptors, a group is assigned, ranging from occult cancer, through stages 0, IA (one-A),

IB, IIA, IIB, IIIA, IIIB and IV (four). This stage group assists with the choice of treatment and estimation of prognosis.[73]

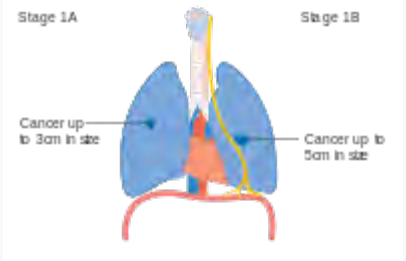
**Stage group according to TNM classification in lung cancer**[6]

| TNM | Stage group |
|---|---|
| T1a–T1b N0 M0 | IA |
| T2a N0 M0 | IB |
| T1a–T2a N1 M0 | IIA |
| T2b N0 M0 | |
| T2b N1 M0 | IIB |
| T3 N0 M0 | |
| T1a–T3 N2 M0 | IIIA |
| T3 N1 M0 | |
| T4 N0–N1 M0 | |
| N3 M0 | IIIB |
| T4 N2 M0 | |
| M1 | IV |

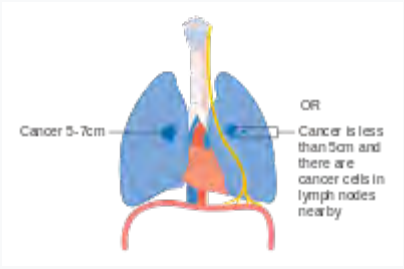
Small-cell lung carcinoma (SCLC) has traditionally been classified as "limited stage" (confined to one-half of the chest and within the scope of a single tolerable radiotherapy field) or "extensive stage" (more widespread disease).[6] However, the TNM classification and grouping are useful in estimating prognosis.[73]

For both NSCLC and SCLC, the two general types of staging evaluations are clinical staging and surgical staging. Clinical staging is performed prior to definitive surgery. It is based on the results of imaging studies (such as CT scans and PET scans) and biopsy results. Surgical staging is evaluated either during or after the operation and is based on the combined results of surgical and clinical findings, including surgical sampling of thoracic lymph nodes.[12]

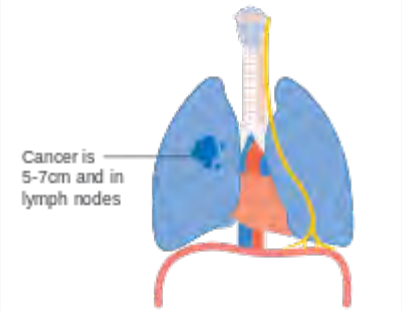
**Diagrams of main features of staging**



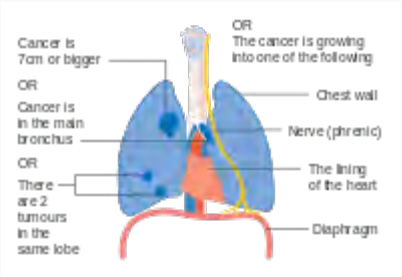
Stage IA and IB lung cancer



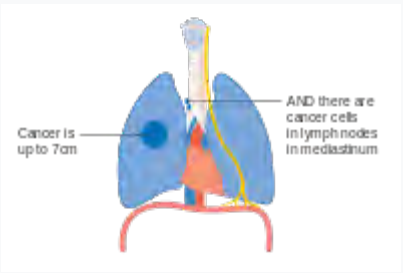
Stage IIA lung cancer



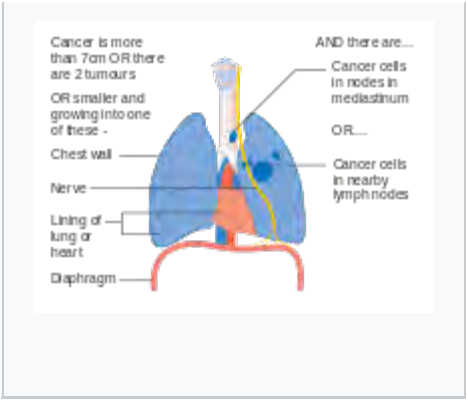
Stage IIB lung cancer



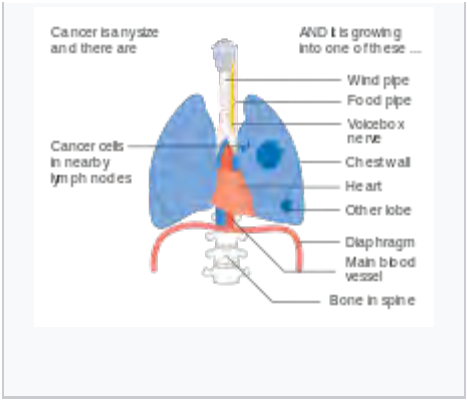
One option for stage IIB lung cancer, with T2b; but if tumor is within 2 cm of the carina, this is stage 3



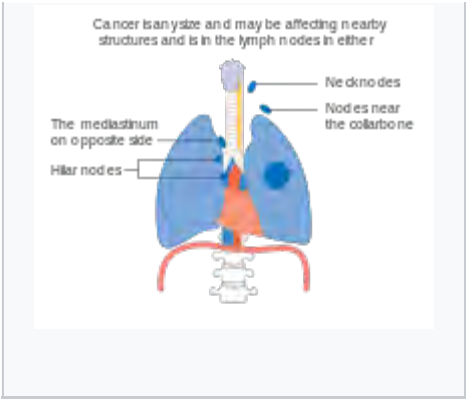
Stage IIIA lung cancer



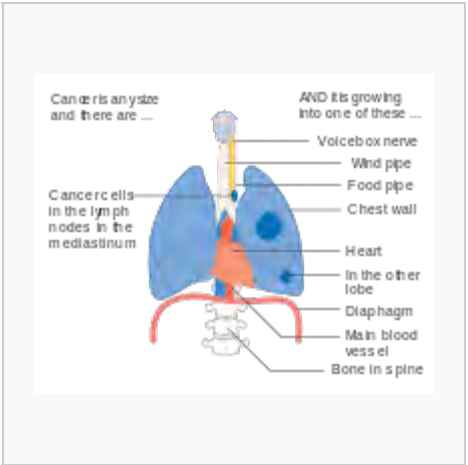
Stage IIIA lung cancer, if there is one feature from the list on each side



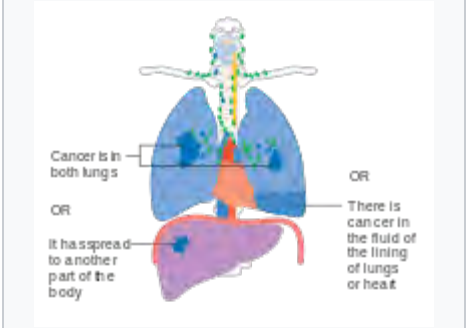
Stage IIIA lung cancer



Stage IIIB lung cancer



Stage IIIB lung cancer



Stage IV lung cancer

# Prevention [edit]

Smoking prevention and smoking cessation are effective ways of preventing the development of lung cancer.[74]

## Smoking ban [edit]

*See also: Smoking ban*

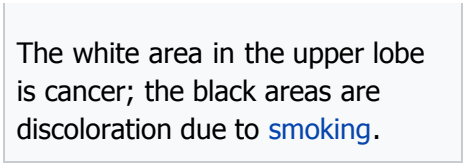
While in most countries industrial and domestic carcinogens have been identified and banned, tobacco smoking is still widespread. Eliminating tobacco smoking is a primary goal in the prevention of lung cancer, and smoking cessation is an important preventive tool in this process.[75]

Policy interventions to decrease passive smoking in public areas such as restaurants and workplaces have become more common in many Western countries.[76] Bhutan has had a complete smoking ban since 2005[77] while India introduced a ban on smoking in public in October 2008.[78] The World Health Organization has called for governments to institute a total ban on tobacco advertising to prevent young people from taking up smoking. They assess that such bans have reduced tobacco consumption by 16% where instituted.[79]

Cross section of a human lung:

## Screening [edit]

*Main article: Lung cancer screening*



The white area in the upper lobe is cancer; the black areas are discoloration due to smoking.

Cancer screening uses medical tests to detect disease in large groups of people who have no symptoms.[80] For individuals with high risk of developing lung cancer, computed tomography (CT) screening can detect cancer and give a person options to respond to it in a way that prolongs life.[63][81] This form of screening reduces the chance of death from lung cancer by an absolute amount of 0.3% (relative amount of 20%).[82][83] High risk people are those age 55–74 who have smoked equivalent amount of a pack of cigarettes daily for 30 years including time within the past 15 years.[63]

CT screening is associated with a high rate of falsely positive tests which may result in unneeded treatment.[84] For each true positive scan there are about 19 falsely positives scans.[85] Other concerns include radiation exposure[84] and the cost of testing along with follow up.[63] Research has not found two other available tests—sputum cytology or chest radiograph (CXR) screening tests—to have any benefit.[81][86]

The United States Preventive Services Task Force (USPSTF) recommends yearly screening using low-dose computed tomography in those who have a total smoking history of 30 pack-years and are between 55 and 80 years old until a person has not been smoking for more than 15 years.[87] Screening should not be done in those with other health problems that would make treatment of lung cancer if found not an option.[87] The English National Health Service was in 2014 re-examining the evidence for screening.[88]

## Other prevention strategies [edit]

The long-term use of supplemental vitamin A,[89][90] vitamin C,[89] vitamin D[91] or vitamin E[89] does not reduce the risk of lung cancer. Some studies suggest that people who eat diets with a higher proportion of vegetables and fruit tend to have a lower risk,[28][92] but this may be due to confounding—with the lower risk actually due to the association of a high fruit/vegetables diet with less smoking.[93] More rigorous studies have not demonstrated a clear association between diet and lung cancer risk.[6][92]

# Management [edit]

*Main article: Treatment of lung cancer*

Treatment for lung cancer depends on the cancer's specific cell type, how far it has spread, and the person's performance status. Common treatments include palliative care,[94] surgery, chemotherapy, and radiation therapy.[6] Targeted therapy of lung cancer is growing in importance for advanced lung cancer.

## Surgery [edit]

*Main article: Lung cancer surgery*

If investigations confirm NSCLC, the stage is assessed to determine whether the disease is localized and amenable to surgery or if it has spread to the point where it cannot be cured surgically. CT scan and positron emission tomography are used for this determination.[6] If mediastinal lymph node involvement is suspected, the nodes may be sampled to assist staging. Techniques used for this include transthoracic needle aspiration, transbronchial needle aspiration (with or without endobronchial ultrasound), endoscopic ultrasound with needle aspiration, mediastinoscopy, and thoracoscopy.[95] Blood tests and pulmonary function testing are used to assess whether a person is well enough for surgery.[13] If pulmonary function tests reveal poor respiratory reserve,
[6]

Pneumonectomy specimen containing a squamous-cell carcinoma, seen as a white area near the bronchi

surgery may not be possible.

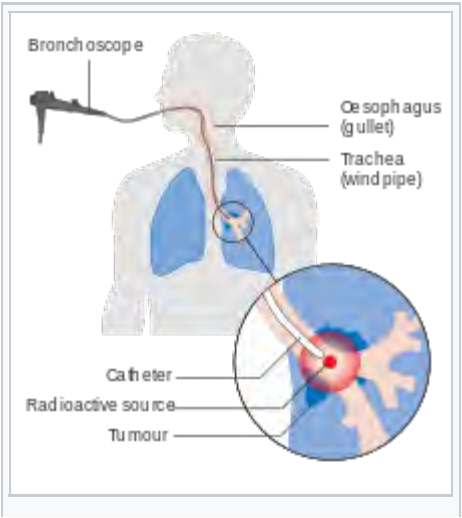
In most cases of early-stage NSCLC, removal of a lobe of lung (lobectomy) is the surgical treatment of choice. In people who are unfit for a full lobectomy, a smaller sublobar excision (wedge resection) may be performed. However, wedge resection has a higher risk of recurrence than lobectomy. Radioactive iodine brachytherapy at the margins of wedge excision may reduce the risk of recurrence. Rarely, removal of a whole lung (pneumonectomy) is performed.[96] Video-assisted thoracoscopic surgery (VATS) and VATS lobectomy use a minimally invasive approach to lung cancer surgery.[97] VATS lobectomy is equally effective compared to conventional open lobectomy, with less postoperative illness.[98]

In SCLC, chemotherapy and/or radiotherapy is typically used.[99] However the role of surgery in SCLC is being reconsidered. Surgery might improve outcomes when added to chemotherapy and radiation in early stage SCLC.[100]

## Radiotherapy [edit]

Radiotherapy is often given together with chemotherapy, and may be used with curative intent in people with NSCLC who are not eligible for surgery. This form of high-intensity radiotherapy is called radical radiotherapy.[101] A refinement of this technique is continuous hyperfractionated accelerated radiotherapy (CHART), in which a high dose of radiotherapy is given in a short time period.[102] Postoperative thoracic radiotherapy generally should not be used after curative intent surgery for NSCLC.[103] Some people with mediastinal N2 lymph node involvement might benefit from post-operative radiotherapy.[104]

For potentially curable SCLC cases, chest radiotherapy is often recommended in addition to chemotherapy.[12]



If cancer growth blocks a short section of bronchus, brachytherapy (localized radiotherapy) may be given directly inside the airway to open the passage. Compared to external beam radiotherapy, brachytherapy allows a reduction in treatment time and reduced radiation exposure to healthcare staff.[105] Evidence for brachytherapy, however, is less than that for external beam radiotherapy.[106]

Prophylactic cranial irradiation (PCI) is a type of radiotherapy to the brain, used to reduce the risk of metastasis. PCI is most useful in SCLC. In limited-stage disease, PCI increases three-year survival from 15% to 20%; in extensive disease, one-year survival increases from 13% to 27%.[107]

Recent improvements in targeting and imaging have led to the development of stereotactic radiation in the treatment of early-stage lung cancer. In this form of radiotherapy, high doses are delivered over

Internal radiotherapy for lung cancer given via the airway.

a number of sessions using stereotactic targeting techniques. Its use is primarily in patients who are not surgical candidates due to medical comorbidities.[108]

For both NSCLC and SCLC patients, smaller doses of radiation to the chest may be used for symptom control (palliative radiotherapy).[109]

## Chemotherapy [edit]

The chemotherapy regimen depends on the tumor type.[12] Small-cell lung carcinoma (SCLC), even relatively early stage disease, is treated primarily with chemotherapy and radiation.[110] In SCLC, cisplatin and etoposide are most commonly used.[111] Combinations with carboplatin, gemcitabine, paclitaxel, vinorelbine, topotecan, and irinotecan are also used.[112][113] In advanced non-small cell lung carcinoma (NSCLC), chemotherapy improves survival and is used as first-line treatment, provided the person is well enough for the treatment.[114] Typically, two drugs are used, of which one is often platinum-based (either cisplatin or carboplatin). Other commonly used drugs are gemcitabine, paclitaxel, docetaxel,[115][116] pemetrexed,[117] etoposide or vinorelbine.[116]

Adjuvant chemotherapy refers to the use of chemotherapy after apparently curative surgery to improve the outcome. In NSCLC, samples are taken of nearby lymph nodes during surgery to assist staging. If stage II or III disease is confirmed, adjuvant chemotherapy improves survival by 5% at five years.[118][119] The combination of vinorelbine and cisplatin is more effective than older regimens.[119] Adjuvant chemotherapy for people with stage IB cancer is controversial, as clinical trials have not clearly demonstrated a survival benefit.[120][121] Chemotherapy before surgery in NSCLC that can be removed surgically also appears to improve outcomes.[122]

Chemotherapy may be combined with palliative care in the treatment of the NSCLC. In advanced cases, appropriate chemotherapy improves average survival over supportive care alone, as well as improving quality of life.[123] With adequate physical fitness maintaining chemotherapy during lung cancer palliation offers 1.5 to 3 months of prolongation of survival, symptomatic relief, and an improvement in quality of life, with better results seen with modern agents.[124][125] The NSCLC Meta-Analyses Collaborative Group recommends if the recipient wants and can tolerate treatment, then chemotherapy should be considered in advanced NSCLC.[114][126]

## Targeted therapy [edit]

Several drugs that target molecular pathways in lung cancer are available, especially for the treatment of advanced disease. Erlotinib, gefitinib and afatinib inhibit tyrosine kinase at the epidermal growth factor receptor. Denosumab is a monoclonal antibody directed against receptor activator of nuclear factor kappa-B ligand. It may be useful in the treatment of bone metastases.[127]

## Bronchoscopy [edit]

Several treatments can be administered via bronchoscopy for the management of airway obstruction or bleeding. If an airway becomes obstructed by cancer growth, options include rigid bronchoscopy, balloon bronchoplasty, stenting, and microdebridement.[128] Laser photosection involves the delivery of laser light inside the airway via a bronchoscope to remove the obstructing tumor.[129]

## Palliative care [edit]

Palliative care when added to usual cancer care benefits people even when they are still receiving chemotherapy.[130] These approaches allow additional discussion of treatment options and provide opportunities to arrive at well-considered decisions.[131][132] Palliative care may avoid unhelpful but expensive care not only at the end of life, but also throughout the course of the illness. For individuals who [13][132]

have more advanced disease, hospice care may also be appropriate.

## Prognosis [edit]

Of all people with lung cancer in the US, 16.8% survive for at least five years after diagnosis.[17][133] In England and Wales, between 2010 and 2011, overall five-year survival for lung cancer was estimated at 9.5%.[134] Outcomes are generally worse in the developing world.[18] Stage is often advanced at the time of diagnosis. At presentation, 30–40% of cases of NSCLC are stage IV, and 60% of SCLC are stage IV.[12] Survival for lung cancer falls as the stage at diagnosis becomes more advanced: the English data suggest that around 70% of patients survive at least a year when diagnosed at the earliest stage, but this falls to just 14% for those diagnosed with the most advanced disease.[135]

**Outcomes in lung cancer according to clinical stage**[73]

| Clinical stage | Five-year survival (%) | |
|---|---|---|
| | Non-small-cell lung carcinoma | Small-cell lung carcinoma |
| IA | 50 | 38 |
| IB | 47 | 21 |
| IIA | 36 | 38 |
| IIB | 26 | 18 |
| IIIA | 19 | 13 |
| IIIB | 7 | 9 |
| IV | 2 | 1 |

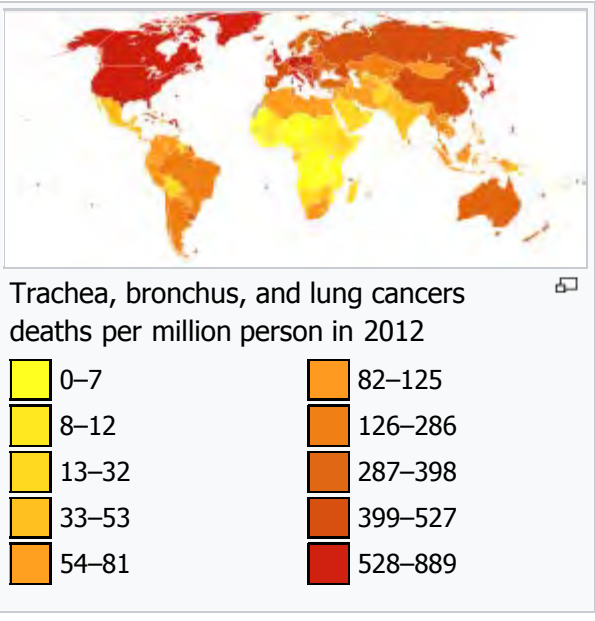
Prognostic factors in NSCLC include presence of pulmonary symptoms, large tumor size (>3 cm), nonsquamous cell type (histology), degree of spread (stage) and metastases to multiple lymph nodes, and vascular invasion. For people with inoperable disease, outcomes are worse in those with poor performance status and weight loss of more than 10%.[136] Prognostic factors in small cell lung cancer include performance status, gender, stage of disease, and involvement of the central nervous system or liver at the time of diagnosis.[137]

For NSCLC, the best prognosis is achieved with complete surgical resection of stage IA disease, with up to 70% five-year survival.[138] People with extensive-stage SCLC have an average five-year survival rate of less than 1%. The average survival time for limited-stage disease is 20 months, with a five-year survival rate of 20%.[1]

According to data provided by the National Cancer Institute, the median age at diagnosis of lung cancer in the United States is 70 years,[139] and the median age at death is 72 years.[140] In the US, people with medical insurance are more likely to have a better outcome.[141]

## Epidemiology [edit]

Worldwide, lung cancer is the most common cancer among men in terms of both incidence and mortality, and among women has the third highest incidence, and is second after breast cancer in mortality. In 2012, there were 1.82 million new cases globally, and 1.56 million deaths due to lung cancer, representing 19.4% of all deaths from cancer.[16] The highest rates are in North America, Europe and East Asia, with over a third of new cases in 2012 in China. Rates in Africa and South Asia are much lower.[142]



The population segment most likely to develop lung cancer is people aged over 50 who have a history of smoking. In contrast to the mortality rate in men, which began declining more than 20 years ago, women's lung cancer mortality rates have been rising over the last decades, and are just recently beginning to stabilize.[143] In the USA, the lifetime risk of developing lung cancer is 8% in men and 6% in women.[6]

For every 3–4 million cigarettes smoked, one lung cancer death occurs.[144] The influence of "Big Tobacco" plays a

significant role in the smoking culture.[145] Young nonsmokers who see tobacco advertisements are more likely to take up smoking.[146] The role of passive smoking is increasingly being recognized as a risk factor for lung cancer,[31] leading to policy interventions to decrease undesired exposure of nonsmokers to others' tobacco smoke.[147]

In the United States, black men and women have a higher incidence.[148] Lung cancer rates are currently lower in developing countries.[149] With increased smoking in developing countries, the rates are expected to increase in the next few years, notably in China[150] and India.[151]

In the United States military veterans have a 25–50% higher rate of lung cancer primarily due to higher rates of smoking.[152] During World War Two and the Korean War asbestos also played a part and Agent Orange may have caused some problems during the Vietnam War.[153]

Lung cancer is the third most common cancer in the UK (around 46,400 people were diagnosed with the disease in 2014),[154] and it is the most common cause of cancer death (around 35,900 people died in 2014).[155]

From the 1960s, the rates of lung adenocarcinoma started to rise relative to other types of lung cancer. This is partly due to the introduction of filter cigarettes. The use of filters removes larger particles from tobacco smoke, thus reducing deposition in larger airways. However, the smoker has to inhale more deeply to receive the same amount of nicotine, increasing particle deposition in small airways where adenocarcinoma tends to arise.[156] The incidence of lung adenocarcinoma continues to rise.[157]

## History [edit]

*See also: Timeline of lung cancer*

Lung cancer was uncommon before the advent of cigarette smoking; it was not even recognized as a distinct disease until 1761.[158] Different aspects of lung cancer were described further in 1810.[159] Malignant lung tumors made up only 1% of all cancers seen at autopsy in 1878, but had risen to 10–15% by the early 1900s.[160] Case reports in the medical literature numbered only 374 worldwide in 1912,[161] but a review of autopsies showed the incidence of lung cancer had increased from 0.3% in 1852 to 5.66% in 1952.[162] In Germany in 1929, physician Fritz Lickint recognized the link between smoking and lung cancer,[160] which led to an aggressive antismoking campaign.[163] The British Doctors' Study, published in the 1950s, was the first solid epidemiological evidence of the link between lung cancer and smoking.[164] As a result, in 1964 the Surgeon General of the United States recommended smokers should stop smoking.[165]

The connection with radon gas was first recognized among miners in the Ore Mountains near Schneeberg, Saxony. Silver has been mined there since 1470, and these mines are rich in uranium, with its accompanying radium and radon gas.[166] Miners developed a disproportionate amount of lung disease, eventually recognized as lung cancer in the 1870s.[167] Despite this discovery, mining continued into the 1950s, due to

the USSR's demand for uranium.[166] Radon was confirmed as a cause of lung cancer in the 1960s.[168]

The first successful pneumonectomy for lung cancer was performed in 1933.[169] Palliative radiotherapy has been used since the 1940s.[170] Radical radiotherapy, initially used in the 1950s, was an attempt to use larger radiation doses in patients with relatively early-stage lung cancer, but who were otherwise unfit for surgery.[171] In 1997, continuous hyperfractionated accelerated radiotherapy was seen as an improvement over conventional radical radiotherapy.[172] With small-cell lung carcinoma, initial attempts in the 1960s at surgical resection[173] and radical radiotherapy[174] were unsuccessful. In the 1970s, successful chemotherapy regimens were developed.[175]

## Research directions [edit]

Current research directions for lung cancer treatment include immunotherapy,[176] which encourages the body's immune system to attack the tumor cells, epigenetics, and new combinations of chemotherapy and radiotherapy, both on their own and together. Many of these new treatments work through immune checkpoint blockade, disrupting cancer's ability to evade the immune system.[176]

Ipilimumab blocks signaling through a receptor on T cells known as CTLA-4 which dampens down the immune system. It has been approved by the U.S. Food and Drug Administration (FDA) for treatment of melanoma and is undergoing clinical trials for both non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC).[176]

Other immunotherapy treatments interfere with the binding of programmed cell death 1 (PD-1) protein with its ligand PD-1 ligand 1 (PD-L1). Signaling through PD-1 inactivates T cells. Some cancer cells appear to exploit this by expressing PD-L1 in order to switch off T cells that might recognise them as a threat. Monoclonal antibodies targeting both PD-1 and PD-L1, such as pembrolizumab and nivolumab[177] are currently in clinical trials for treatment for lung cancer.[176]

Epigenetics is the study of small, usually heritable, molecular modifications—or "tags"—that bind DNA and modify gene expression levels. Targeting these tags with drugs can kill cancer cells. Early-stage research in NSCLC using drugs aimed at epigenetic modifications shows that blocking more than one of these tags can kill cancer cells with fewer side effects.[178] Studies also show that giving patients these drugs before standard treatment can improve its effectiveness. Clinical trials are underway to evaluate how well these drugs kill lung cancer cells in humans.[178] Several drugs that target epigenetic mechanisms are in development. Histone deacetylase inhibitors in development include valproic acid, vorinostat, belinostat, panobinostat, entinostat, and romidepsin. DNA methyltransferase inhibitors in development include decitabine, azacytidine, and hydralazine.[58]

The TRACERx project is looking at how NSCLC develops and evolves, and how these tumors become resistant to treatment.[179] The project will look at tumor samples from 850 NSCLC patients at various stages including diagnosis, after first treatment, post-treatment, and relapse.[180] By studying samples at different points of tumor development, the researchers hope to identify the changes that drive tumor growth and resistance to treatment. The results of this project will help scientists and doctors gain a better understanding of NSCLC and potentially lead to the development of new treatments for the disease.[179]

For lung cancer cases that develop resistance to epidermal growth factor receptor (EGFR) and anaplastic lymphoma kinase (ALK) tyrosine kinase inhibitors, new drugs are in development. New EGFR inhibitors include afatinib and dacomitinib. An alternative signaling pathway, c-Met, can be inhibited by tivantinib and onartuzumab. New ALK inhibitors include crizotinib and ceritinib.[181]

# Lymphoma

From Wikipedia, the free encyclopedia

**Lymphoma** is a group of blood cell tumors that develop from lymphocytes (a type of white blood cell). The name often refers to just the cancerous ones rather than all such tumors.[1] Signs and symptoms may include enlarged lymph nodes, fever, drenching sweats, unintended weight loss, itching, and constantly feeling tired.[2][3] The enlarged lymph nodes are usually painless.[2] The sweats are most common at night.[2][3]

There are dozens of subtypes of lymphomas.[4] The two main categories of lymphomas are Hodgkin's lymphomas (HL) and the non-Hodgkin lymphomas (NHL).[5] The World Health Organization (WHO) includes two other categories as types of lymphoma: multiple myeloma and immunoproliferative diseases.[6] About 90% of lymphomas are non-Hodgkin lymphomas.[3][7] Lymphomas and leukemias are a part of the broader group of tumors of the hematopoietic and lymphoid tissues.[8]

Risk factors for Hodgkin lymphoma include infection with Epstein–Barr virus and a history of the disease in the family.[2] Risk factors for common types of non-Hodgkin lymphomas include autoimmune diseases, HIV/AIDS, infection with human T-lymphotropic virus, immunosuppressant medications, and some pesticides.[3] Eating large amounts of red meat and tobacco smoking may also increase the risk.[9][10][11] Diagnosis, if enlarged lymph nodes are present, is usually by lymph node biopsy.[2][3] Blood, urine, and bone marrow testing may also be useful in the diagnosis.[3] Medical imaging may then be done to determine if and where the cancer has spread.[2][3] Lymphoma most often spreads to the lungs, liver, and/or brain.[2][3]

Treatment may involve one or more of the following: chemotherapy, radiation therapy, targeted therapy, and surgery.[2][3] In some non-Hodgkin lymphomas, an increased amount of protein produced by the lymphoma cells causes the blood to become so thick that plasmapheresis is performed to remove the protein.[3] Watchful waiting may be appropriate for certain types.[3] The outcome depends on the subtype with some being curable and treatment prolonging survival in most.[5] The five-year survival rate in the United States for all Hodgkin lymphoma subtypes is 85%,[12] while that for non-Hodgkin lymphomas is 69%.[13] Worldwide, lymphomas developed in 566,000 people in 2012 and caused 305,000 deaths.[6] They make up 3–4% of all cancers, making them as a group the seventh-most common form.[6][14] In children, they are the third-most common cancer.[15] They occur more often in the developed world than the developing world.[6]

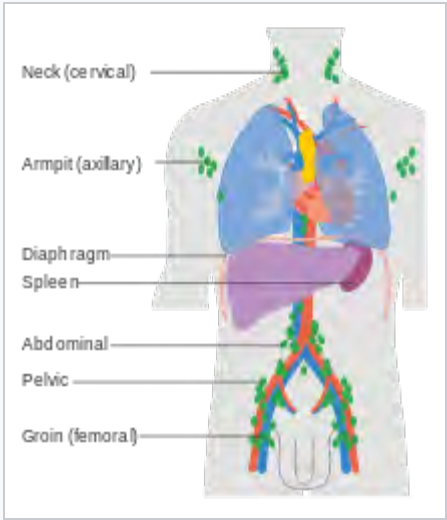
Contents

# Signs and symptoms [edit]

Lymphoma may present with certain nonspecific symptoms; if the symptoms are persistent, an evaluation to determine their cause, including possible lymphoma, should be undertaken.

- Lymphadenopathy[16][17] or swelling of lymph nodes, is the primary presentation in lymphoma.
- B symptoms (systemic symptoms) – can be associated with both Hodgkin lymphoma and non-Hodgkin lymphoma. They consist of:
  - Fever[16][17]
  - Night sweats[16][17]
  - Weight loss[16][17]
- Other symptoms:
  - Loss of appetite or anorexia[17]
  - Fatigue[16][17]
  - Respiratory distress or dyspnea[17]
  - Itching[16][17]

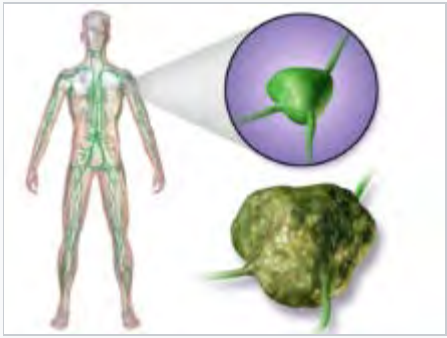


The lymph nodes where lymphoma most commonly develops

# Diagnosis [edit]

Lymphoma is definitively diagnosed by a lymph node biopsy, meaning a partial or total excision of a lymph node examined under the microscope.[18] This examination reveals histopathological features that may indicate lymphoma. After lymphoma is diagnosed, a variety of tests may be carried out to look for specific features characteristic of different types of lymphoma. These include:

- Immunophenotyping
- Flow cytometry
- Fluorescence *in situ* hybridization testing

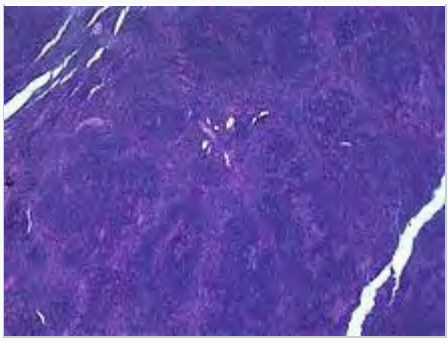


Lymphoma and lymphatic system

## Classification [edit]

Lymphomas *sensu stricto* are any neoplasms of the lymphatic tissues (*lympho-* + *-oma*) .[19] The main classes are malignant neoplasms (that

is, cancers) of the lymphocytes, a type of white blood cell that belongs to both the lymph and the blood and pervades both. Thus, lymphomas and leukemias are both tumors of the hematopoietic and lymphoid tissues, and as lymphoproliferative disorders, lymphomas and lymphoid leukemias are closely related, to the point that some of them are unitary disease entities that can be called by either name (for example, adult T-cell leukemia/lymphoma).



Lymph node with mantle cell lymphoma (low-power view, H&E)

Several classification systems have existed for lymphoma, which use histological and other findings to divide lymphoma into different categories. The classification of a lymphoma can affect treatment and prognosis. Classification systems generally classify lymphoma according to:

- Whether or not it is a Hodgkin lymphoma
- Whether the cell that is replicating is a T cell or B cell
- The site from which the cell arises

Lymphoma can also spread to the central nervous system, often around the brain in the meninges, known as lymphomatous meningitis (LM).[20]

## Hodgkin lymphoma [edit]

*Main article: Hodgkin lymphoma*

Hodgkin lymphoma is one of the most commonly known types of lymphoma,[*citation needed*] and differs from other forms of lymphoma in its prognosis and several pathological characteristics. A division into Hodgkin and non-Hodgkin lymphomas is used in several of the older classification systems. A Hodgkin lymphoma is marked by the presence of a type of cell called the Reed–Sternberg cell.[21][22]

## Non-Hodgkin lymphomas [edit]

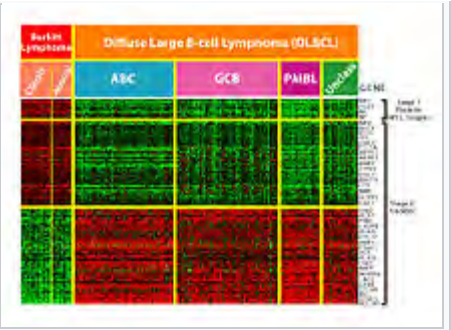
Non-Hodgkin lymphomas, which are defined as being all lymphomas except Hodgkin lymphoma, are more common than Hodgkin lymphoma. A wide variety of lymphomas are in this class, and the causes, the types of cells involved, and the prognosis vary by type. The incidence of non-Hodgkin lymphoma increases with age. It is further divided into several subtypes.

## WHO classification [edit]

The WHO classification, published in 2001 and updated in 2008,[23][24] is based upon the foundations laid within the "revised European-American lymphoma classification" (REAL). This system groups lymphomas by cell type (i.e. the normal cell type that most resembles the tumor) and defining phenotypic, molecular, or cytogenetic characteristics. The five groups are shown in the table. Hodgkin lymphoma is considered separately within the WHO and preceding classifications, although it is recognized as being a tumor of, albeit markedly abnormal, lymphocytes of mature B cell lineage.

Of the many forms of lymphoma, some are categorized as indolent (e.g. small lymphocytic lymphoma), compatible with a long life even without treatment, whereas other forms are aggressive (e.g. Burkitt's lymphoma), causing rapid deterioration and death. However, most of the aggressive lymphomas respond well to treatment and are curable. The prognosis, therefore, depends on the correct diagnosis and classification of the disease, which is established after examination of a biopsy by a pathologist (usually a hematopathologist).[25]

| Lymphoma subtypes (WHO 2008) |
| --- |
| **Mature B cell neoplasms** |
| ▪ B-cell chronic lymphocytic leukemia/small cell lymphoma<br>3 to 4% of lymphomas in adults<br>Small resting lymphocytes mixed with variable numbers of large |



DNA-microarray analysis of Burkitt's lymphoma and diffuse large B-cell lymphoma (DLBCL) showing differences in gene expression patterns. Colors indicate levels of expression; green indicates genes that are underexpressed in lymphoma cells (as compared to normal cells), whereas red indicates genes that are overexpressed in lymphoma cells.

activated cells, lymph nodes diffusely effaced
CD5, surface immunoglobulin
50%.[26]
Occurs in older adults, usually involves lymph nodes, bone marrow and spleen, most patients have peripheral blood involvement, indolent

- B-cell prolymphocytic leukemia
- Lymphoplasmacytic lymphoma (such as Waldenström macroglobulinemia)
- Splenic marginal zone lymphoma
- Hairy cell leukemia
- Plasma cell neoplasms:
  - Plasma cell myeloma (also known as multiple myeloma)
  - Plasmacytoma
  - Monoclonal immunoglobulin deposition diseases
  - Heavy chain diseases
- Extranodal marginal zone B cell lymphoma, also called MALT lymphoma

  About 5% of lymphomas in adults
  Variable cell size and differentiation, 40% show plasma cell differentiation, homing of B cells to epithelium creates lymphoepithelial lesions.
  CD5, CD10, surface Ig
  Frequently occurs outside lymph nodes, very indolent, may be cured by local excision
- Nodal marginal zone B cell lymphoma
- Follicular lymphoma

  About 40% of lymphomas in adults
  Small "cleaved" cells (centrocytes) mixed with large activated cells (centroblasts), usually nodular ("follicular") growth pattern
  CD10, surface Ig
  72–77%[27]
  Occurs in older adults, usually involves lymph nodes, bone marrow and spleen, associated with t(14;18) translocation overexpressing Bcl-2, indolent
- Primary cutaneous follicle center lymphoma
- Mantle cell lymphoma

  3 to 4% of lymphomas in adults
  Lymphocytes of small to intermediate size growing in diffuse pattern
  CD5
  50%[28] to 70%[28]
  Occurs mainly in adult males, usually involves lymph nodes, bone marrow, spleen and GI tract, associated with t(11;14) translocation overexpressing cyclin D1, moderately aggressive
- Diffuse large B cell lymphoma, not otherwise specified

  About 40 to 50% of lymphomas in adults
  Variable, most resemble B cells of large germinal centers, diffuse growth pattern
  Variable expression of CD10 and surface Ig
  5-year survival 60%[29]
  Occurs in all ages, but most commonly in older adults, may occur outside lymph nodes, aggressive
- Diffuse large B-cell lymphoma associated with chronic inflammation
- Epstein–Barr virus-positive DLBCL of the elderly
- Lymphomatoid granulomatosis
- Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma

ALK+ large B-cell lymphoma
- Plasmablastic lymphoma
- Primary effusion lymphoma
- Large B-cell lymphoma arising in HHV8-associated multicentric Castleman's disease
- Burkitt lymphoma/leukemia

  < 1% of lymphomas in the United States
  Round lymphoid cells of intermediate size with several nucleoli, starry-sky appearance by diffuse spread with interspersed apoptosis
  CD10, surface Ig
  5-year survival 50%[30]
  Endemic in Africa, sporadic elsewhere, more common in immunocompromised and children, often visceral involvement, highly aggressive

**Mature T cell and natural killer (NK) cell neoplasms**

- T-cell prolymphocytic leukemia
- T-cell large granular lymphocyte leukemia
- Aggressive NK cell leukemia
- Adult T-cell leukemia/lymphoma
- Extranodal NK/T-cell lymphoma, nasal type
- Enteropathy-associated T-cell lymphoma
- Hepatosplenic T-cell lymphoma
- Blastic NK cell lymphoma
- Mycosis fungoides / Sezary syndrome

  Most common cutaneous lymphoid malignancy
  Usually small lymphoid cells with convoluted nuclei that often infiltrate the epidermis, creating Pautrier microabscesseses
  CD4
  5-year survival 75%[31]
  Localized or more generalized skin symptoms, generally indolent, in a more aggressive variant, Sézary's disease, skin erythema and peripheral blood involvement
- Primary cutaneous CD30-positive T cell lymphoproliferative disorders
  - Primary cutaneous anaplastic large cell lymphoma
  - Lymphomatoid papulosis
- Peripheral T-cell lymphoma not otherwise specified

  Most common T cell lymphoma
  Variable, usually a mix small to large lymphoid cells with irregular nuclear contours
  CD3
  Probably consists of several rare tumor types, often disseminated and generally aggressive
- Angioimmunoblastic T cell lymphoma
- Anaplastic large cell lymphoma

**Precursor lymphoid neoplasms**

- B-lymphoblastic leukemia/lymphoma not otherwise specified
- B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities
- T-lymphoblastic leukemia/lymphoma

  15% of childhood acute lymphoblastic leukemia and 90% of lymphoblastic lymphoma.[23]:635
  Lymphoblasts with irregular nuclear contours, condensed chromatin, small nucleoli and scant cytoplasm without granules
  TdT, CD2, CD7
  It often presents as a mediastinal mass because of involvement of the thymus. It is highly associated with *NOTCH1* mutations, and is most common in adolescent males.

**Hodgkin lymphoma**

- Classical Hodgkin lymphomas:
  - Nodular sclerosis form of Hodgkin lymphoma
    Most common type of Hodgkin lymphoma
    Reed-Sternberg cell variants and inflammation, usually broad sclerotic bands that consist of collagen
    CD15, CD30
    Most common in young adults, often arises in the mediastinum or cervical lymph nodes
  - Mixed cellularity Hodgkin lymphoma
    Second-most common form of Hodgkin lymphoma
    Many classic Reed-Sternberg cells and inflammation
    CD15, CD30
    Most common in men, more likely to be diagnosed at advanced stages than the nodular sclerosis form
    Epstein-Barr virus involved in 70% of cases
  - Lymphocyte-rich
  - Lymphocyte depleted or not depleted
- Nodular lymphocyte-predominant Hodgkin lymphoma

**Immunodeficiency-associated lymphoproliferative disorders**

- Associated with a primary immune disorder
- Associated with the human immunodeficiency virus (HIV)
- Post-transplant
- Associated with methotrexate therapy
- Primary central nervous system lymphoma occurs most often in immunocompromised patients, in particular those with AIDS, but it can occur in the immunocompetent, as well. It has a poor prognosis, particularly in those with AIDS. Treatment can consist of corticosteroids, radiotherapy, and chemotherapy, often with methotrexate.

## Previous classifications [edit]

Several previous classifications have been used, including Rappaport 1956, Lennert / Kiel 1974, BNLI, Working formulation (1982), and REAL (1994).

The Working formulation of 1982 was a classification of non-Hodgkin lymphoma. It excluded the Hodgkin lymphomas and divided the remaining lymphomas into four grades (low, intermediate, high, and miscellaneous) related to prognosis, with some further subdivisions based on the size and shape of affected cells. This purely histological classification included no information about cell surface markers, or genetics, and it made no distinction between T-cell lymphomas and B-cell lymphomas. It was widely accepted at the time of its publication, but is now obsolete.[32] It is still used by some cancer agencies for compilation of lymphoma statistics and historical rate comparisons.[*citation needed*]

In 1994, the Revised European-American Lymphoma (REAL) classification applied immunophenotypic and genetic features in identifying distinct clinicopathologic entities among all the lymphomas except Hodgkin lymphoma.[33] For coding purposes, the ICD-O (codes 9590–9999)[34] and ICD-10 (codes C81-C96)[35] are available.

## Staging [edit]

After a diagnosis and before treatment, a cancer is staged. This refers to determining if the cancer has spread, and if so, whether locally or to distant sites. Staging is reported as a grade between I (confined) and IV (spread). Staging is carried out because the stage of a cancer impacts its prognosis and treatment.[*citation needed*]

The Ann Arbor staging system is routinely used for staging of both HL and NHL. In this staging system, I represents a localized disease contained within a lymph node, II represents the presence of lymphoma

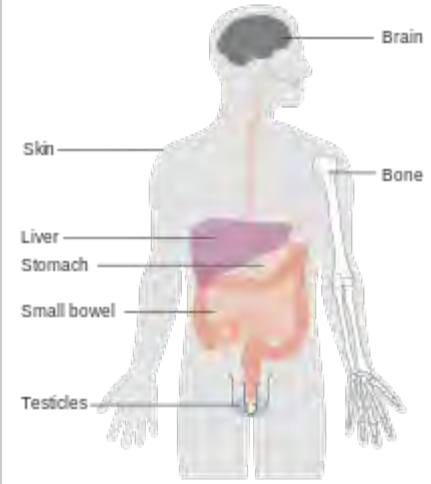


Diagram showing common sites where lymphoma spreads

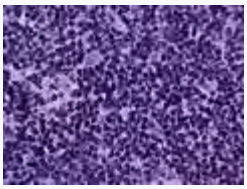
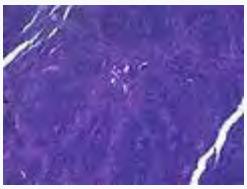
in two or more lymph nodes, III represents spread of the lymphoma to both sides of the diaphragm, and IV indicates tissue outside a lymph node.[*citation needed*]

CT scan or PET scan imaging modalities are used to stage a cancer.[*citation needed*]

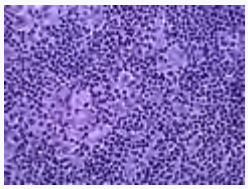
Age and poor performance status are established poor prognostic factors, as well.[36]



Mantle cell lymphoma: Notice the irregular nuclear contours of the medium-sized lymphoma cells and the presence of a pink histiocyte. By immunohistochemistry, the lymphoma cells expressed CD20, CD5, and Cyclin D1 (high-power view, H&E)



Hodgkin lymphoma, nodular lymphocyte predominant (low-power view): Notice the nodular architecture and the areas of "mottling".(H&E)



Hodgkin lymphoma, nodular lymphocyte predominant (high-power view): Notice the presence of L&H cells, also known as "popcorn cells". (H&E)

## Treatment [edit]

Prognoses and treatments are different for HL and between all the different forms of NHL,[37] and also depend on the grade of tumour, referring to how quickly a cancer replicates. Paradoxically, high-grade lymphomas are more readily treated and have better prognoses:[*citation needed*] Burkitt lymphoma, for example, is a high-grade tumour known to double within days, and is highly responsive to treatment. Lymphomas may be curable if detected in early stages with modern treatment.

### Low-grade lymphomas [edit]

Many low-grade lymphomas remain indolent for many years. Treatment of the nonsymptomatic patient is often avoided. In these forms of lymphoma, such as follicular lymphoma, watchful waiting is often the initial course of action. This is carried out because the harms and risks of treatment outweigh the benefits.[38] If a low-grade lymphoma is becoming symptomatic, radiotherapy or chemotherapy are the treatments of

choice; although they do not cure the lymphoma, they can alleviate the symptoms, particularly painful lymphadenopathy. Patients with these types of lymphoma can live near-normal lifespans, but the disease is incurable. Some centers advocate the use of single agent rituximab in the treatment of follicular lymphoma rather than the wait and watch approach. Watchful waiting is not a good strategy for all patients, as it leads to significant distress and anxiety in some patients. It has been equated with watch and worry.[39]

### High-grade lymphomas [edit]

Treatment of some other, more aggressive, forms of lymphoma[*which?*] can result in a cure in the majority of cases, but the prognosis for patients with a poor response to therapy is worse.[40] Treatment for these types of lymphoma typically consists of aggressive chemotherapy, including the CHOP or R-CHOP regimen. A number of people are cured with first-line chemotherapy. Most relapses occur within the first two years, and the relapse risk drops significantly thereafter.[41] For people who relapse, high-dose chemotherapy followed by autologous stem cell transplantation is a proven approach.[42]

### Hodgkin lymphoma [edit]

Hodgkin lymphoma typically is treated with radiotherapy alone, as long as it is localized.[43]

Advanced Hodgkin disease requires systemic chemotherapy, sometimes combined with radiotherapy.[44] Chemotherapy used includes the ABVD regimen, which is commonly used in the United States. Other regimens used in the management of Hodgkin lymphoma include BEACOPP and Stanford V. Considerable controversy exists regarding the use of ABVD or BEACOPP. Briefly, both regimens are effective, but BEACOPP is associated with more toxicity. Encouragingly, a significant number of people who relapse after ABVD can still be salvaged by stem cell transplant.[45]

### Palliative care [edit]

Palliative care, a specialized medical care focused on the symptoms, pain, and stress of a serious illness, is recommended by multiple national cancer treatment guidelines as an accompaniment to curative treatments for people suffering from lymphoma.[46][47] It is used to address both the direct symptoms of lymphoma and many unwanted side effects that arise from treatments.[48][49] Palliative care can be especially helpful for children who develop lymphoma, helping both children and their families deal with the physical and emotional symptoms of the disease.[48][50][51][52] For these reasons, palliative care is especially important for patients requiring bone marrow transplants.[53][54]

## Prognosis [edit]

| Five-year relative survival by stage at diagnosis[55] | | |
|---|---|---|
| Stage at diagnosis | Five-year relative survival (%) | Percentage of cases (%) |
| Localized (confined to primary site) | 82.3 | 26 |
| Regional (spread to regional lymph nodes) | 78.3 | 19 |
| Distant (cancer has metastasized) | 62.7 | 47 |
| Unknown (unstaged) | 68.6 | 8 |

## Epidemiology [edit]

Lymphoma is the most common form of hematological malignancy, or "blood cancer", in the developed world.

Taken together, lymphomas represent 5.3% of all cancers (excluding simple basal cell and squamous cell skin cancers) in the United States and 55.6% of all blood cancers.[56]

According to the U.S. National Institutes of Health, lymphomas account for about 5%, and Hodgkin lymphoma in particular accounts for less than 1% of all cases of cancer in the United States.

Because the whole system is part of the body's immune system, patients with a weakened immune system such as from HIV infection or from certain drugs or medication also have a higher incidence of lymphoma.[57]

Deaths from lymphomas and multiple myeloma per million persons in 2012

| | | |
|---|---|---|
| 0-13 | 23-28 | 43-57 |
| 14-18 | 29-34 | 58-88 |
| 19-22 | 35-42 | 89-121 |
| | | 122-184 |

## History [edit]

*See also: Timeline of lymphoma*

Thomas Hodgkin published the first description of lymphoma in 1832, specifically of the form named after him.[58] Since then, many other forms of lymphoma have been described.

## Research [edit]

The two types of lymphoma research are clinical or translational research and basic research. Clinical/translational research focuses on studying the disease in a defined and generally immediately patient-applicable way, such as testing a new drug in patients. Studies may focus on effective means of treatment, better ways of treating the disease, improving the quality of life for patients, or appropriate care in remission or after cures. Hundreds of clinical trials are being planned or conducted at any given time.[59]

Basic science research studies the disease process at a distance, such as seeing whether a suspected carcinogen can cause healthy cells to turn into lymphoma cells in the laboratory or how the DNA changes inside lymphoma cells as the disease progresses. The results from basic research studies are generally less immediately useful to patients with the disease,[60] but can improve scientists' understanding of lymphoma and form the foundation for future, more effective treatments.

# Melanoma

From Wikipedia, the free encyclopedia

**Melanoma**, also known as **malignant melanoma**, is a type of cancer that develops from the pigment-containing cells known as melanocytes.[1] Melanomas typically occur in the skin but may rarely occur in the mouth, intestines, or eye.[1][2] In women they most commonly occur on the legs, while in men they are most common on the back.[2] Sometimes they develop from a mole with concerning changes including an increase in size, irregular edges, change in color, itchiness, or skin breakdown.[1]

The primary cause of melanoma is ultraviolet light (UV) exposure in those with low levels of skin pigment.[2][3] The UV light may be from either the sun or from other sources, such as tanning devices. About 25% develop from moles.[2] Those with many moles, a history of affected family members, and who have poor immune function are at greater risk.[1] A number of rare genetic defects such as xeroderma pigmentosum also increase risk.[4] Diagnosis is by biopsy of any concerning skin lesion.[1]

Using sunscreen and avoiding UV light may prevent melanoma.[2] Treatment is typically removal by surgery. In those with slightly larger cancers, nearby lymph nodes may be tested for spread. Most people are cured if spread has not occurred. For those in whom melanoma has spread, immunotherapy, biologic therapy, radiation therapy, or chemotherapy may improve survival.[1] With treatment the five-year survival rates in the United States is 98% among those with localized disease and 17% among those in whom spread has occurred.[5] The likelihood that it will come back or spread depends how thick the melanoma is, how fast the cells are dividing, and whether or not the overlying skin has broken down.[2]

Melanoma is the most dangerous type of skin cancer. Globally, in 2012, it occurred in 232,000 people and resulted in 55,000 deaths. Australia and New Zealand have the highest rates of melanoma in the world. There are also high rates in Europe and North America while it is less common in Asia, Africa, and Latin America.[2] Melanoma is more common in men than women.[4] Melanoma has become more common since the 1960s in areas that are mostly Caucasian.[2][4]

Contents

## Signs and symptoms [edit]

Early signs of melanoma are changes to the shape or color of existing moles or, in the case of nodular melanoma, the appearance of a new lump anywhere on the skin. At later stages, the mole may itch, ulcerate or bleed.[6] Early signs of melanoma are summarized by the mnemonic "ABCDE":

- **A**symmetry
- **B**orders (irregular with edges and corners)
- **C**olor (variegated)
- **D**iameter (greater than 6 mm (0.24 in), about the size of a pencil eraser)
- **E**volving over time

These classifications do not, however, apply to the most dangerous form of melanoma, nodular melanoma, which has its own classifications:

- **E**levated above the skin surface
- **F**irm to the touch
- **G**rowing

Metastatic melanoma may cause nonspecific paraneoplastic symptoms, including loss of appetite, nausea, vomiting and fatigue. Metastasis of early melanoma is possible, but relatively rare: less than a fifth of melanomas diagnosed early become metastatic. Brain metastases are particularly common in patients with metastatic melanoma.[7] It can also spread to the liver, bones, abdomen or distant lymph nodes.

## Cause [edit]

Melanomas are usually caused by DNA damage resulting from exposure to ultraviolet (UV) light from the sun. Genetics also play a role.

### UV radiation [edit]

The ultraviolet radiation from tanning beds increases the risk of melanoma.[8] The International Agency for Research on Cancer finds that tanning beds are "carcinogenic to humans" and that people who begin using tanning devices before age 30 are 75% more likely to develop melanoma.[9]

Those who work in airplanes also appear to have an increased risk, believed to be due to greater exposure to UV.[10]

Ultraviolet UVB light (wavelengths between 315 – 280 nm) from the sun is absorbed by skin cell DNA and results in a type of direct DNA damage called cyclobutane pyrimidine dimers (CPDs). Thymine-thymine, cytosine-cytosine or cytosine-thymine dimers are formed by the joining of two adjacent pyrimidine bases within a DNA strand. Somewhat similarly to UVB, UVA light (longer wavelengths between 400 – 315 nm) from the sun or from tanning beds can also be directly absorbed by skin DNA (at about 100 to 1000 fold lower efficiency than UVB is absorbed).[11]

Studies suggest that exposure to ultraviolet radiation (UVA[12] and UVB) is one of the major contributors to the development of melanoma. Occasional extreme sun exposure (resulting in "sunburn") is causally related to melanoma.[13] Melanoma is most common on the back in men and on legs in women (areas of intermittent sun exposure). The risk appears to be strongly influenced by socio-economic conditions rather than indoor versus outdoor occupations; it is more common in professional and administrative workers than unskilled workers.[14][15] Other factors are mutations in or total loss of tumor suppressor genes. Use of sunbeds (with deeply penetrating UVA rays) has been linked to the development of skin cancers, including melanoma.[16]

Possible significant elements in determining risk include the intensity and duration of sun exposure, the age at which sun exposure occurs, and the degree of skin pigmentation. Melanoma rates tend to be highest in countries settled by migrants from northern Europe that have a large amount of direct, intense sunlight that the skin of the settlers is not adapted to, most notably Australia. Exposure during childhood is a more important risk factor than exposure in adulthood. This is seen in migration studies in Australia.[17]

### Genetics [edit]

A number of rare mutations, which often run in families, greatly increase melanoma susceptibility. Several genes increase risks. Some rare genes have a relatively high risk of causing melanoma; some more common genes, such as a gene called MC1R that causes red hair, have a relatively lower elevated risk. Genetic testing can be used to search for the mutations.

One class of mutations affects the gene CDKN2A. An alternative reading frame mutation in this gene leads to the destabilization of p53, a transcription factor involved in apoptosis and in fifty percent of human cancers. Another mutation in the same gene results in a nonfunctional inhibitor of CDK4, a cyclin-dependent kinase that promotes cell division. Mutations that cause the skin condition xeroderma pigmentosum (XP) also increase melanoma susceptibility. Scattered throughout the genome, these mutations reduce a cell's ability to repair DNA. Both CDKN2A and XP mutations are highly penetrant (the chances of a carrier to express the phenotype is high).

Familial melanoma is genetically heterogeneous,[18] and loci for familial melanoma appear on the chromosome arms 1p, 9p and 12q. Multiple genetic events have been related to melanoma's pathogenesis (disease development).[19] The multiple tumor suppressor 1 (CDKN2A/MTS1) gene encodes p16INK4a – a low-molecular weight protein inhibitor of cyclin-dependent protein kinases (CDKs) – which has been localised to the p21 region of human chromosome 9.[20]

Other mutations confer lower risk, but are more common in the population. People with mutations in the MC1R gene, for example, are two to four times more likely to develop melanoma than those with two wild-type (typical unaffected type) copies. MC1R mutations are very common; in fact, all red-haired people have a mutated copy. Mutation of the MDM2 SNP309 gene is associated with increased risks for younger women.[21]

Fair- and red-haired people, persons with multiple atypical nevi or dysplastic nevi and persons born with giant congenital melanocytic nevi are at increased risk.[22]

A family history of melanoma greatly increases a person's risk because mutations in several genes have been found in melanoma-prone families.[23] People with a history of one melanoma are at increased risk of developing a second primary tumor.[24]

## Pathophysiology [edit]

The earliest stage of melanoma starts when melanocytes begin out-of-control growth. Melanocytes are found between the outer layer of the skin (the epidermis) and the next layer (the dermis). This early stage of the disease is called the radial growth phase, when the tumor is less than 1 mm thick. Because the cancer cells have not yet reached the blood vessels deeper in the skin, it is very unlikely that this early-stage melanoma will spread to other parts of the body. If the melanoma is detected at this stage, then it can usually be completely removed with surgery.

When the tumor cells start to move in a different direction — vertically up into the epidermis and into the papillary dermis — cell behaviour changes dramatically.[25]

The next step in the evolution is the invasive radial growth phase, which is a confusing term; however, it explains the process of the radial growth, in which individual cells start to acquire invasive potential. From this point on the melanoma is capable of spreading. The Breslow's depth of the lesion is usually less than 1 mm (0.04 in), while the Clark level is usually 2.

The vertical growth phase (VGP) following is the invasive melanoma. The tumor becomes able to grow into the surrounding tissue and can spread around the body through blood or lymph vessels. The tumor thickness is usually more than 1 mm (0.04 in), and the tumor involves the deeper parts of the dermis.

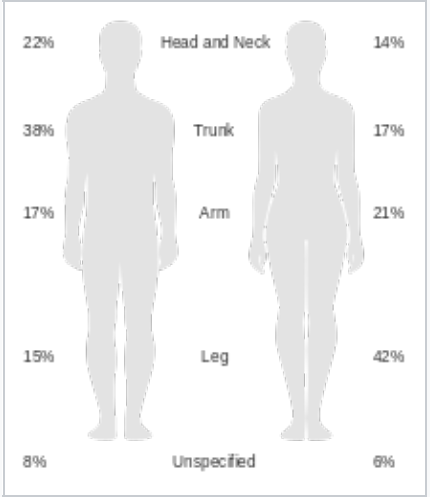
The host elicits an immunological reaction against the tumor during the VGP,[26] which is judged by the presence and activity of the tumor infiltrating lymphocytes (TILs). These cells sometimes completely destroy the primary tumor; this is called regression, which is the latest stage of development. In certain cases, the primary tumor is completely destroyed and only the metastatic tumor is discovered. About 40% of human melanomas contain activating mutations affecting the structure of the B-Raf protein, resulting in constitutive signaling through the Raf to MAP kinase pathway.[27]

In general, cancers are caused by damage to DNA.[28] UVA light mainly causes thymine-thymine dimers.[29] UVA also produces reactive oxygen species and these inflict other DNA damage, primarily single-strand breaks, oxidized pyrimidines and the oxidized purine 8-oxoguanine (a mutagenic DNA change) at 1/10th, 1/10th and 1/3rd the frequencies of UVA-induced thymine-thymine dimers, respectively.

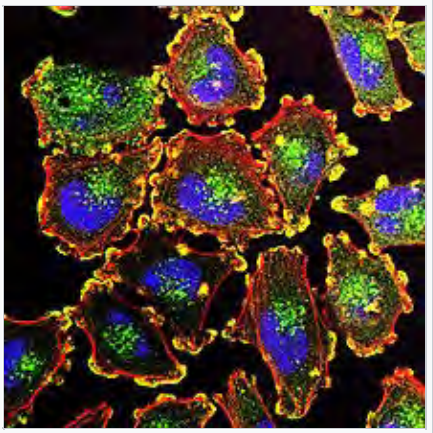
If unrepaired, CPD photoproducts can lead to mutations by inaccurate translesion synthesis during DNA replication or repair. The most frequent mutations due to inaccurate synthesis past CPDs are cytosine to thymine (C>T) or CC>TT transition mutations. These are commonly referred to as UV fingerprint mutations, as they are the most specific mutation caused by UV, being frequently found in sun-exposed skin but rarely found in internal organs.[30] Errors in DNA repair of UV photoproducts, or inaccurate synthesis past these photoproducts, can also lead to deletions, insertions and chromosomal translocations.

The entire genomes of 25 melanomas were sequenced.[31] On average, about 80,000 mutated bases (mostly C>T transitions) and about 100 structural rearragements were found per melanoma genome. This is much higher than the approximately 70 mutations across generations (parent to child).[32][33] Among the 25 melanomas, about 6,000 protein-coding genes had missense, nonsense or splice site mutations.

UV radiation causes damage to the DNA of cells, typically thymine dimerization, which when unrepaired can create mutations in the cell's genes. When the cell divides, these mutations are propagated to new generations of cells. If the mutations occur in protooncogenes or tumor suppressor genes, the rate of mitosis in the mutation-bearing cells can become uncontrolled, leading to the formation of a tumor. Data from patients suggest that aberrant levels of activating transcription factor in the nucleus of melanoma cells are associated with increased metastatic activity of melanoma cells;[34][35][36] studies from mice on skin cancer tend to confirm a role for activating transcription factor-2 in cancer progression.[37][38]



Where melanoma is most likely to develop

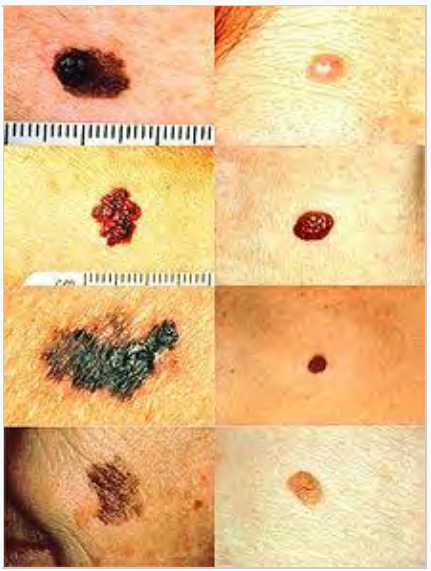


Molecular basis for melanoma cell motility: actin-rich podosomes (yellow), along with cell nuclei (blue), actin (red), and an actin regulator (green).

Cancer stem cells may also be involved.[39]

## Diagnosis [edit]

Visual inspection is the most common diagnostic technique.[40] Moles that are irregular in color or shape are typically treated as candidates. To detect melanomas (and increase survival rates), it is recommended to learn to recognize them (see "ABCDE" mnemonic above), to regularly examine moles for changes (shape, size, color, itching or bleeding) and to consult a qualified physician when a candidate appears.[41][42]



ABCD rule illustration: On the left side from top to bottom: melanomas showing (A) Asymmetry, (B) a border that is uneven, ragged, or notched, (C) coloring of different shades of brown, black, or tan and (D) diameter that had changed in size. The normal moles on the right side do not have abnormal characteristics (no asymmetry, even border, even color, no change in diameter).

### ABCDE [edit]

A popular method for remembering the signs and symptoms of melanoma is the mnemonic "ABCDE":

- **A**symmetrical skin lesion.
- **B**order of the lesion is irregular.
- **C**olor: melanomas usually have multiple colors.
- **D**iameter: moles greater than 6 mm are more likely to be melanomas than smaller moles.
- **E**nlarging: Enlarging or evolving

However, many melanomas present as lesions smaller than 6 mm in diameter; and all melanomas are malignant when they first appear as a small dot. Physicians typically examine all moles, including those less than 6 mm in diameter. Seborrheic keratosis may meet some or all of the ABCD criteria, and can lead to false alarms. Doctors can generally distinguish seborrheic keratosis from melanoma upon examination, or with dermatoscopy.

Some advocate replacing enlarging with evolution. Certainly moles that change and evolve will be a concern. Alternatively, some practitioners prefer elevation. Elevation can help identify a melanoma, but lack of elevation does not mean that the lesion is not a melanoma. Most melanomas in the US are detected before they become elevated. By the time elevation is visible, they may have progressed to the more dangerous invasive stage.

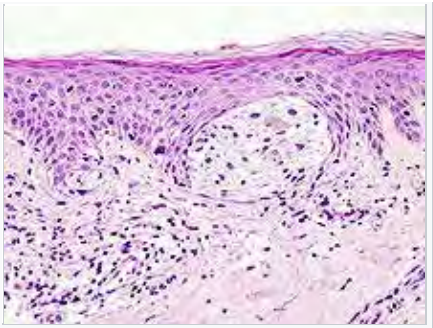
Nodular melanomas do not fulfill these criteria, having their own mnemonic, "EFG":

- **E**levated: the lesion is raised above the surrounding skin.
- **F**irm: the nodule is solid to the touch.
- **G**rowing: the nodule is increasing in size.

A dermatoscope

### Ugly duckling [edit]

A recent and novel method is the "ugly duckling sign".[43] It is simple, easy to teach, and highly effective. Correlation of common lesion characteristics is made. Lesions that greatly deviate from the common characteristics are labeled an "Ugly Duckling", and a further professional exam is required. The "Little Red Riding Hood" sign[43] suggests that individuals with fair skin and light-colored hair might have difficult-to-diagnose amelanotic melanomas. Extra care is required when examining such individuals, as they might have multiple melanomas and severely dysplastic nevi. A dermatoscope must be used to detect "ugly ducklings", as many melanomas in these individuals resemble non-melanomas or are considered to be "wolves in sheep's clothing".[44] These fair-skinned individuals often have lightly pigmented or amelanotic melanomas that do not present easy-to-observe color changes and variations. Their borders are often indistinct, complicating visual identification without a dermatoscope.



Melanoma in skin biopsy with H&E stain — this case may represent superficial spreading melanoma.

Amelanotic melanomas and melanomas arising in fair-skinned individuals are very difficult to detect, as they fail to show many of the characteristics in the ABCD rule, break the "Ugly Duckling" sign and are hard to distinguish from acne scarring, insect bites, dermatofibromas, or lentigines.

## Biopsy [edit]

Following a visual examination and a dermatoscopic exam,[44] or *in vivo* diagnostic tools such as a confocal microscope, the doctor may biopsy the suspicious mole. A skin biopsy performed under local anesthesia is often required to assist in making or confirming the diagnosis and in defining severity. Elliptical excisional biopsies may remove the tumor, followed by histological analysis and Breslow scoring. Punch biopsies are contraindicated in suspected melanomas, for fear of seeding tumor cells and hastening the spread of malignant cells.

Total body photography, which involves photographic documentation of as much body surface as possible, is often used during follow-up for high-risk patients. The technique has been reported to enable early detection and provides a cost-effective approach (with any digital camera), but its efficacy has been questioned due to its inability to detect macroscopic changes.[40] The diagnosis method should be used in conjunction with (and not as a replacement for) dermoscopic imaging, with a combination of both methods appearing to give extremely high rates of detection.

Lymph node with almost complete replacement by metastatic melanoma. The brown pigment is focal deposition of melanin.

## Classification [edit]

Melanoma is divided into the following types:[45]

- Lentigo maligna
- Lentigo maligna melanoma
- Superficial spreading melanoma
- Acral lentiginous melanoma
- Mucosal melanoma
- Nodular melanoma
- Polypoid melanoma
- Desmoplastic melanoma
- Amelanotic melanoma
- Soft-tissue melanoma

- Uveal melanoma

## Laboratory [edit]

Lactate dehydrogenase (LDH) tests are often used to screen for metastases, although many patients with metastases (even end-stage) have a normal LDH; extraordinarily high LDH often indicates metastatic spread of the disease to the liver.

It is common for patients diagnosed with melanoma to have chest X-rays and an LDH test, and in some cases CT, MRI, PET and/or PET/CT scans. Although controversial, sentinel lymph node biopsies and examination of the lymph nodes are also performed in patients to assess spread to the lymph nodes. A diagnosis of melanoma is

supported by the presence of the S-100 protein marker.

HMB-45 is a monoclonal antibody that reacts against an antigen present in melanocytic tumors such as melanomas. It is used in anatomic pathology as a marker for such tumors. The antibody was generated to an extract of melanoma. It reacts positively against melanocytic tumors but not other tumors, thus demonstrating specificity and sensitivity. The antibody also reacts positively against junctional nevus cells but not intradermal nevi, and against fetal melanocytes but not normal adult melanocytes.

HMB-45 is nonreactive with almost all non-melanoma human malignancies, with the exception of rare tumors showing evidence of melanogenesis (e.g., pigmented schwannoma, clear cell sarcoma) or tumors associated with tuberous sclerosis complex (angiomyolipoma and lymphangiomyoma).

## Staging [edit]

*Further context on cancer staging is available at TNM.*

Also of importance are the "Clark level" and "Breslow's depth", which refer to the microscopic depth of tumor invasion.[47]

Melanoma stages:[48] 5 year survival rates:

**Stage 0**: Melanoma *in situ* (Clark Level I), 99.9% survival

**Stage I / II**: Invasive melanoma, 89–95% survival

- T1a: Less than 1.0 mm primary tumor thickness, without ulceration, and mitosis < 1/mm2
- T1b: Less than 1.0 mm primary tumor thickness, with ulceration or mitoses ≥ 1/mm2
- T2a: 1.01–2.0 mm primary tumor thickness, without ulceration

**Stage II**: High risk melanoma, 45–79% survival

- T2b: 1.01–2.0 mm primary tumor thickness, with ulceration
- T3a: 2.01–4.0 mm primary tumor thickness, without ulceration
- T3b: 2.01–4.0 mm primary tumor thickness, with ulceration
- T4a: Greater than 4.0 mm primary tumor thickness, without ulceration
- T4b: Greater than 4.0 mm primary tumor thickness, with ulceration

**Stage III**: Regional metastasis, 24–70% survival

- N1: Single positive lymph node
- N2: Two to three positive lymph nodes *or* regional skin/in-transit metastasis
- N3: Four positive lymph nodes *or* one lymph node and regional skin/in-transit metastases

**Stage IV**: Distant metastasis, 7–19% survival

- M1a: Distant skin metastasis, normal LDH
- M1b: Lung metastasis, normal LDH
- M1c: Other distant metastasis *or* any distant metastasis with elevated LDH

*Based upon AJCC five-year survival from initial melanoma diagnosis with proper treatment.*

# Prevention [edit]

## Avoiding ultraviolet radiation [edit]

Minimizing exposure to sources of ultraviolet radiation (the sun and sunbeds),[49] following sun protection measures and wearing sun protective clothing (long-sleeved shirts, long trousers, and broad-brimmed hats) can offer protection.

Using artificial light for tanning was once believed to help prevent skin cancers, but it can actually lead to an [50]

increased incidence of melanomas. Even though tanning beds emit mostly UVA, which causes tanning, it by itself might be enough to induce melanomas.

To decrease ultraviolet light exposure it is recommended to avoid the sun between the hours of 9 a.m. and 3 p.m. or avoid the sun when one's shadow is shorter than one's height.

### Sunscreen [edit]

Sunscreen appears to be effective in preventing melanoma.[2][51] In the past, use of sunscreens with a sun protection factor (SPF) rating of 50 or higher on exposed areas were recommended; as older sunscreens more effectively blocked UVA with higher SPF.[52] Currently, newer sunscreen ingredients (avobenzone, zinc oxide, and titanium dioxide) effectively block both UVA and UVB even at lower SPFs. Sunscreen also protects against squamous cell carcinoma, another skin cancer.[53]

## Treatment [edit]

Confirmation of the clinical diagnosis is done with a skin biopsy. This is usually followed up with a wider excision of the scar or tumor. Depending on the stage, a sentinel lymph node biopsy is done, as well, although controversy exists around trial evidence for this procedure.[54] Treatment of advanced malignant melanoma is performed from a multidisciplinary approach.

Extensive malignant melanoma on a person's chest

### Surgery [edit]

Excisional biopsies may remove the tumor, but further surgery is often necessary to reduce the risk of recurrence. Complete surgical excision with adequate surgical margins and assessment for the presence of detectable metastatic disease along with short- and long-term followup is standard. Often this is done by a wide local excision (WLE) with 1 to 2 cm margins. Melanoma-in-situ and lentigo malignas are treated with narrower surgical margins, usually 0.2 to 0.5 cm. Many surgeons consider 0.5 cm the standard of care for standard excision of melanoma-in-situ,[55] but 0.2 cm margin might be acceptable for margin controlled surgery (Mohs surgery, or the double-bladed technique with margin control). The wide excision aims to reduce the rate of tumor recurrence at the site of the original lesion. This is a common pattern of treatment failure in melanoma. Considerable research has aimed to elucidate appropriate margins for excision with a general trend toward less aggressive treatment during the last decades.[56]

Mohs surgery has been reported with cure rate as low as 77%[57] and as high as 98.0% for melanoma-in-situ.[58] CCPDMA and the "double scalpel" peripheral margin controlled surgery is equivalent to Mohs surgery in effectiveness on this "intra-epithelial" type of melanoma.

Melanomas that spread usually do so to the lymph nodes in the area of the tumor before spreading elsewhere. Attempts to improve survival by removing lymph nodes surgically (lymphadenectomy) were associated with many complications, but no overall survival benefit. Recently, the technique of sentinel lymph node biopsy has been developed to reduce the complications of lymph node surgery while allowing assessment of the involvement of nodes with tumor.[59]

Biopsy of sentinel lymph nodes is a widely used procedure when treating cutaneous melanoma.[60][61]

Neither sentinel lymph node biopsy nor other diagnostic tests should be performed to evaluate early, thin melanoma, including melanoma in situ, T1a melanoma or T1b melanoma ≤ 0.5mm.[62] People with these conditions are unlikely to have the cancer spread to their lymph nodes or anywhere else and already have a 97% 5-year survival rate.[62] Because of these things, sentinel lymph node biopsy is unnecessary health care for them.[62] Furthermore, baseline blood tests and radiographic studies should not be performed only based on identifying this kind of melanoma, as there are more accurate tests for detecting cancer and these tests have high false-positive rates.[62]

Sentinel lymph node biopsy is often performed, especially for T1b/T2+ tumors, mucosal tumors, ocular

melanoma and tumors of the limbs.[*citation needed*] A process called lymphoscintigraphy is performed in which a radioactive tracer is injected at the tumor site to localize the sentinel node(s). Further precision is provided using a blue tracer dye, and surgery is performed to biopsy the node(s). Routine hematoxylin and eosin (H&E) and immunoperoxidase staining will be adequate to rule out node involvement. Polymerase chain reaction (PCR) tests on nodes, usually performed to test for entry into clinical trials, now demonstrate that many patients with a negative sentinel lymph node actually had a small number of positive cells in their nodes. Alternatively, a fine-needle aspiration biopsy may be performed and is often used to test masses.

If a lymph node is positive, depending on the extent of lymph node spread, a radical lymph node dissection will often be performed. If the disease is completely resected, the patient will be considered for adjuvant therapy. Excisional skin biopsy is the management of choice. Here, the suspect lesion is totally removed with an adequate (but minimal, usually 1 or 2 mm) ellipse of surrounding skin and tissue.[63] To avoid disruption of the local lymphatic drainage, the preferred surgical margin for the initial biopsy should be narrow (1 mm). The biopsy should include the epidermal, dermal, and subcutaneous layers of the skin. This enables the histopathologist to determine the thickness of the melanoma by microscopic examination. This is described by Breslow's thickness (measured in millimeters). However, for large lesions, such as suspected lentigo maligna, or for lesions in surgically difficult areas (face, toes, fingers, eyelids), a small punch biopsy in representative areas will give adequate information and will not disrupt the final staging or depth determination. In no circumstances should the initial biopsy include the final surgical margin (0.5 cm, 1.0 cm, or 2 cm), as a misdiagnosis can result in excessive scarring and morbidity from the procedure. A large initial excision will disrupt the local lymphatic drainage and can affect further lymphangiogram-directed lymphnode dissection. A small punch biopsy can be used at any time where for logistical and personal reasons a patient refuses more invasive excisional biopsy. Small punch biopsies are minimally invasive and heal quickly, usually without noticeable scarring.

## Add on treatment [edit]

High-risk melanomas may require adjuvant treatment, although attitudes to this vary in different countries. In the United States, most patients in otherwise good health will begin up to a year of high-dose interferon treatment, which has severe side effects, but may improve the patient's prognosis slightly.[64] However British Association of Dermatologist guidelines on melanoma state that interferon is not recommended as a standard adjuvant treatment for melanoma.[65] A 2011 meta-analysis showed that interferon could lengthen the time before a melanoma comes back but increased survival by only 3% at 5 years. The unpleasant side effects also greatly decrease quality of life.[66]

In Europe, interferon is usually not used outside the scope of clinical trials.[67][68]

Metastatic melanomas can be detected by X-rays, CT scans, MRIs, PET and PET/CTs, ultrasound, LDH testing and photoacoustic detection.[69]

## Chemotherapy and immunotherapy [edit]

Various chemotherapy agents, including temozolomide, dacarbazine (also termed DTIC), immunotherapy (with interleukin-2 (IL-2) or interferon (IFN)), as well as local perfusion, are used by different centers. The overall success in metastatic melanoma is quite limited.[70]

IL-2 (Proleukin) was the first new therapy approved (1990 Europe, 1992 USA) for the treatment of metastatic melanoma in 20 years. Studies have demonstrated that IL-2 offers the possibility of a complete and long-lasting remission in this disease, although only in a small percentage of patients.[71] Intralesional IL-2 for in-transit metastases has a high complete response rate ranging from 40 to 100%.[72]

By 2005 a number of new agents and novel approaches were under evaluation and showed promise.[73]

In 2009 Clinical trial participation was considered the standard of care for metastatic melanoma.[74]

Therapies for metastatic melanoma include biologic immunotherapy agents ipilimumab, pembrolizumab, and nivolumab; BRAF inhibitors, such as vemurafenib and dabrafenib; and a MEK inhibitor trametinib.[72]

Ongoing research is looking at treatment by adoptive cell transfer.[75] For this purpose, application of prestimulated or modified T cells [76] or dendritic cells is possible.[77]

## Lentigo maligna [edit]

Standard excision is still being done by most surgeons. Unfortunately, the recurrence rate is exceedingly high (up to 50%). This is due to the ill-defined visible surgical margin, and the facial location of the lesions (often forcing the surgeon to use a narrow surgical margin). The narrow surgical margin used, combined with the limitation of the standard "bread-loafing" technique of fixed tissue histology — result in a high "false negative" error rate, and frequent recurrences. Margin control (peripheral margins) is necessary to eliminate the false negative errors. If bread loafing is used, distances from sections should approach 0.1 mm to assure that the method approaches complete margin control.

Mohs surgery has been done with cure rate reported to be as low as 77%,[57] and as high as 95% by another author.[58] The "double scalpel" peripheral margin controlled excision method approximates the Mohs method in margin control, but requires a pathologist intimately familiar with the complexity of managing the vertical margin on the thin peripheral sections and staining methods.[78]

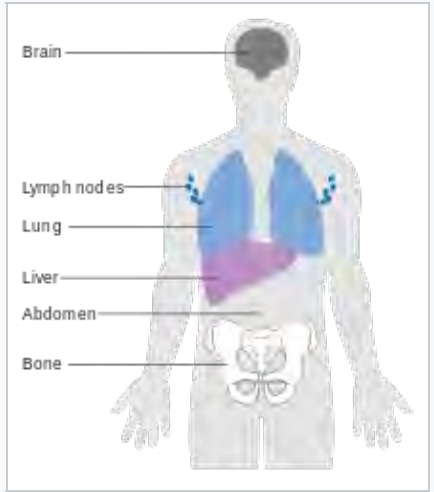
Some melanocytic nevi, and melanoma-in-situ (lentigo maligna) have resolved with an experimental treatment, imiquimod (Aldara) topical cream, an immune enhancing agent. Some dermasurgeons are combining the 2 methods: surgically excising the cancer and then treating the area with Aldara cream postoperatively for three months.

### Radiation therapy [edit]

Radiation therapy is often used after surgical resection for patients with locally or regionally advanced melanoma or for patients with unresectable distant metastases. Kilovoltage x-ray beams are often used for these treatments and have the property of the maximum radiation dose occurring close to the skin surface.[79] It may reduce the rate of local recurrence but does not prolong survival.[80] Radioimmunotherapy of metastatic melanoma is currently under investigation. Radiotherapy has a role in the palliation of metastatic melanoma.[81]

## Prognosis [edit]

Features that affect prognosis are tumor thickness in millimeters (Breslow's depth), depth related to skin structures (Clark level), type of melanoma, presence of ulceration, presence of lymphatic/perineural invasion, presence of tumor-infiltrating lymphocytes (if present, prognosis is better), location of lesion, presence of satellite lesions, and presence of regional or distant metastasis.[82] Certain types of melanoma have worse prognoses but this is explained by their thickness. Interestingly, less invasive melanomas even with lymph node metastases carry a better prognosis than deep melanomas without regional metastasis at time of staging. Local recurrences tend to behave similarly to a primary unless they are at the site of a wide local excision (as opposed to a staged excision or punch/shave excision) since these recurrences tend to indicate lymphatic invasion.



A diagram showing the most common sites for melanoma to spread

When melanomas have spread to the lymph nodes, one of the most important factors is the number of nodes with malignancy. Extent of malignancy within a node is also important; micrometastases in which malignancy is only microscopic have a more favorable prognosis than macrometastases. In some cases micrometastases may only be detected by special staining, and if malignancy is only detectable by a rarely employed test known as the polymerase chain reaction (PCR), the prognosis is better. Macrometastases in which malignancy is clinically apparent (in some cases cancer completely replaces a node) have a far worse prognosis, and if nodes are matted or if there is extracapsular extension, the prognosis is worse still.

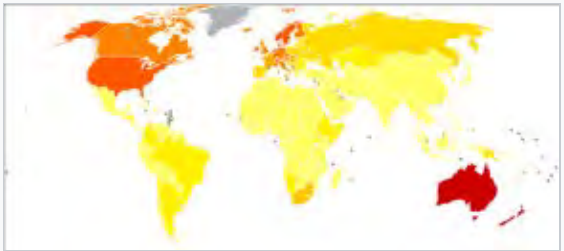
When there is distant metastasis, the cancer is generally considered incurable. The five-year survival rate is less than 10%.[48] The median survival is 6–12 months. Treatment is palliative, focusing on life extension and quality of life. In some cases, patients may live many months or even years with metastatic melanoma (depending on the aggressiveness of the treatment). Metastases to skin and lungs have a better prognosis. Metastases to brain, bone and liver are associated with a worse prognosis. Survival is better with metastasis in which the location of the primary tumor is unknown.[83]

There is not enough definitive evidence to adequately stage, and thus give a prognosis for, ocular melanoma and melanoma of soft parts, or mucosal melanoma (e.g. rectal melanoma), although these tend to metastasize more easily. Even though regression may increase survival, when a melanoma has regressed, it is impossible to know its original size and thus the original tumor is often worse than a pathology report might indicate.

## Epidemiology [edit]

Globally, in 2012, melanoma occurred in 232,000 people and resulted in 55,000 deaths.[2] Australia and New Zealand have the highest rates of melanoma in the world.[2] It has become more common in the last 20 years in areas that are mostly Caucasian.[2]

The rate of melanoma has increased in the recent years, but it is not clear to what extent changes in behavior, in the environment, or in early detection are involved.[85]



Age-standardized new cases per year of melanoma of the skin per 100,000 inhabitants in 2008.[84]

| 3-5 | 9-9 | 19-37 |
| 6-6 | 10-13 | 38-51 |
| | | 52-114 |

### Australia [edit]

Australia has a very high - and increasing - rate of melanoma. In 2012, deaths from melanoma occurred in 7.3-9.8 per 100,000 population. In Australia, melanoma is the third most common cancer in either sex; indeed, its incidence is higher than for lung cancer, although the latter accounts for more deaths. It is estimated that in 2012, more than 12,000 Australians were diagnosed with melanoma: given Australia's modest population, this is better expressed as 59.6 new cases per 100,000 population per year; >1 in 10 of all new cancer cases were melanomas.[86] Melanoma incidence in Australia is matter of significance, for the following reasons:

- Australian melanoma incidence has increased by more than 30 per cent between 1991 and 2009.
- Australian melanoma age-standardised incidence rates were, as of 2008, at least 12 times higher than the world average.
- Australian melanoma incidence is, by some margin, the highest in the world.
- Overall age-standardised cancer incidence in Australia is the highest in the world, and this is attributable to melanoma alone. Age-standardised overall cancer incidence is similar to New Zealand, but there is a statistically-significant difference between Australia and all other parts of the developed world including North America, Western Europe, and the Mediterranean.

### United States [edit]

In the United States about 9,000 people die from melanoma a year.[87] In 2011 it affected 19.7 per 100,000, and resulted in death in 2.7 per 100,000.[87]

## History [edit]

*See also: Timeline of melanoma*

Although melanoma is not a new disease, evidence for its occurrence in antiquity is rather scarce. However, one example lies in a 1960s examination of nine Peruvian mummies, radiocarbon dated to be approximately 2400 years old, which showed apparent signs of melanoma: melanotic masses in the skin and diffuse metastases to the bones.[88]

John Hunter is reported to be the first to operate on metastatic melanoma in 1787. Although not knowing precisely what it was, he described it as a "cancerous fungous excrescence". The excised tumor was preserved in the Hunterian Museum of the Royal College of Surgeons of England. It was not until 1968 that microscopic examination of the specimen revealed it to be an example of metastatic melanoma.[89]

The French physician René Laennec was the first to describe melanoma as a disease entity. His report was initially presented during a lecture for the Faculté de Médecine de Paris in 1804 and then published as a bulletin in 1806.[90] The first English language report of melanoma was presented by an English general practitioner from Stourbridge, William Norris in 1820.[91] In his later work in 1857 he remarked that there is a familial predisposition for development of melanoma (*Eight Cases of Melanosis with Pathological and Therapeutical Remarks on That Disease*). Norris was also a pioneer in suggesting a link between nevi and melanoma and the possibility of a relationship between melanoma and environmental exposures, by observing that most of his patients had pale complexions.[92] He also described that melanomas could be amelanotic and later showed the metastatic nature of melanoma by observing that they can disseminate to other visceral organs.

The first formal acknowledgment of advanced melanoma as untreatable came from Samuel Cooper in 1840. He stated that the only chance for a cure depends upon the early removal of the disease (i.e., early excision of the malignant mole) ...'[93] More than one and a half centuries later this situation remains largely unchanged.

The world melanoma is from the Greek μέλας *melas* meaning "dark".[94]

## Research [edit]

Pharmacotherapy research for unresectable or metastatic malignant melanoma offers new treatment possibilities.[95] In addition to the advances with recently approved agents, ongoing research into combination therapy, such as dabrafenib and trametinib, may reveal a more effective and better-tolerated option for patients with metastatic melanoma. One important pathway in melanin synthesis involves the transcription factor MITF. The MITF gene is highly conserved and is found in people, mice, birds, and even fish. MITF production is regulated via a fairly straightforward pathway. UV radiation causes increased expression of transcription factor p53 in keratinocytes, and p53 causes these cells to produce melanocyte-stimulating hormone (MSH), which binds to melanocortin 1 receptors (MC1R) on melanocytes. Ligand-binding at MC1R receptors activates adenylate cyclases, which produce cAMP, which activates CREB, which promote MITF expression. The targets of MITF include p16 (a CDK inhibitor) and Bcl2, a gene essential to melanocyte survival. It is often difficult to design drugs that interfere with transcription factors, but perhaps new drugs will be discovered that can impede some reaction in the pathway upstream of MITF.

Studies of chromatin structure also promise to shed light on transcriptional regulation in melanoma cells.[96] It has long been assumed that nucleosomes are positioned randomly on DNA, but murine studies of genes involved in melanin production now suggest that nucleosomes are stereotypically positioned on DNA. When a gene is undergoing transcription, its transcription start site is almost always nucleosome-free. When the gene is silent, however, nucleosomes often block the transcriptional start site, suggesting that nucleosome position may play a role in gene regulation. In addition to genetic mutations, evidence demonstrates that epigenetic events (e.g. loss of DNA hydroxymethylation 5-hydroxymethylcytosine) also play roles in melanoma tumorigenesis.[97]

Finally, given the fact that melanin helps protect skin cells from UV-induced damage, new melanoma prevention strategies could involve attempts to induce melanin synthesis in individuals who would otherwise get sunburns. Redheads, for example, do not tan because they have MC1R mutations. In mice, it has been shown that the melanin production pathway can be rescued downstream of MC1R.[*citation needed*]

### Targeted therapies [edit]

In clinical research setting other therapies, such as adoptive cell therapy or gene therapy, are being tested.[98]

Two kinds of experimental treatments developed at the National Cancer Institute (NCI), have been used in metastatic melanoma with tentative success.[25]

The first treatment involves adoptive cell therapy (ACT) using TILs immune cells (tumor infiltrating lymphocytes) isolated from a person's own melanoma tumor.[72] These cells are grown in large numbers in a laboratory and returned to the patient after a treatment that temporarily reduces normal T cells in the patient's body. TIL therapy following lymphodepletion can result in durable complete response in a variety of setups.[99][100]

The second treatment, adoptive transfer of genetically altered autologous lymphocytes, depends on delivering genes that encode so called T cell receptors (TCRs), into patient's lymphocytes.[72] After that manipulation lymphocytes recognize and bind to certain molecules found on the surface of melanoma cells and kill them.[101]

A vaccine to train the immune system to fight cancer showed modest benefit in late-stage testing in 2009 against melanoma.[102][103]

## BRAF inhibitors [edit]

About 60% of melanomas contain a mutation in the B-Raf gene. Early clinical trials suggested that B-Raf inhibitors including Plexxicon's vemurafenib could lead to substantial tumor regression in a majority of patients if their tumor contain the B-Raf mutation.[104] In June 2011, a large clinical trial confirmed the positive findings from those earlier trials.[105][106]

In August 2011 Vemurafenib received FDA approval for the treatment of late-stage melanoma. In May 2013 the US FDA approved dabrafenib as a single agent treatment for patients with BRAF V600E mutation-positive advanced melanoma.[107]

Some researchers believe that combination therapies that simultaneously block multiple pathways may improve efficacy by making it more difficult for the tumor cells to mutate before being destroyed. In October 2012 a study reported that combining Dabrafenib with a MEK inhibitor trametinib led to even better outcomes. Compared to Dabrafenib alone, progression-free survival was increased to 41% from 9%, and the median progression-free survival increased to 9.4 months versus 5.8 months. Some side effects were, however, increased in the combined study. [108][109]

In January 2014, the FDA approved the combination of dabrafenib and trametinib for the treatment of patients with BRAF V600E/K-mutant metastatic melanoma.[110]

Eventual resistance to BRAF and MEK inhibitors may be due to a cell surface protein known as EphA2 which is now being investigated.[111]

## Ipilimumab [edit]

At the American Society of Clinical Oncology Conference in June 2010, the Bristol-Myers Squibb pharmaceutical company reported the clinical findings of their drug ipilimumab. The study found an increase in median survival from 6.4 to 10 months in patients with advanced melanomas treated with the monoclonal ipilimumab, versus an experimental vaccine. It also found a one-year survival rate of 25% in the control group using the vaccine, 44% in the vaccine and ipilimumab group, and 46% in the group treated with ipilimumab alone.[112] However, some have raised concerns about this study for its use of the unconventional control arm, rather than comparing the drug against a placebo or standard treatment.[113][114] The criticism was that although Ipilimumab performed better than the vaccine, the vaccine has not been tested before and may be causing toxicity, making the drug appear better by comparison.

Ipilimumab was approved by the FDA in March 2011 to treat patients with late-stage melanoma that has spread or cannot be removed by surgery.[115][116][117]

In June 2011, a clinical trial of ipilimumab plus dacarbazine combined this immune system booster with the standard chemotherapy drug that targets cell division. It showed an increase in median survival for these late stage patients to 11 months instead of the 9 months normally seen. Researchers were also hopeful that perhaps 10–20% of patients could live a long time. Some serious side-effects of revving up the immune system were seen in some patients. A course of treatment costs $120,000. The drug's brandname is Yervoy.[105][118]

## Surveillance methods [edit]

Advances in high resolution ultrasound scanning have enabled surveillance of metastatic burden to the sentinel lymph nodes.[119] The Screening and Surveillance of Ultrasound in Melanoma trial (SUNMEL) is evaluating ultrasound as an alternative to invasive surgical methods.[120]

## Oncolytic virotherapy [edit]

In some countries oncolytic virotherapy methods are studied and used to treat melanoma. Oncolytic virotherapy is a promising branch of virotherapy, where oncolytic viruses are used to treat diseases; viruses can increase metabolism, reduce anti-tumor immunity and disorganize vasculature.[121] Talimogene laherparepvec (T-VEC) (which is a herpes simplex virus type 1–derived oncolytic immunotherapy), was shown to be useful against metastatic melanoma in 2015 with an increased survival of 4.4 months.[122]

# Mesothelioma

From Wikipedia, the free encyclopedia

**Mesothelioma** is a type of cancer that develops from the thin layer of tissue that covers many of the internal organs (known as the mesothelium).[1] The most common area affected is the lining of the lungs and chest wall.[2][3] Less commonly the lining of the abdomen and rarely the sac surrounding the heart,[4] or the sac surrounding the testis may be affected.[2][5] Signs and symptoms of mesothelioma may include shortness of breath due to fluid around the lung, a swollen abdomen, chest wall pain, cough, feeling tired, and weight loss.[2] These symptoms typically come on slowly.[6]

Greater than 80% of mesothelioma cases are caused by exposure to asbestos. The greater the exposure the greater the risk.[3] As of 2013 about 125 million people have been exposed to asbestos at work.[7] High rates of disease occur in people who mine asbestos, produce products from asbestos, work with asbestos products, live with asbestos workers, or work in buildings containing asbestos. Often it is around 40 years between exposure and the cancer starting.[3] Washing the clothing of someone who worked with asbestos also increases the risk.[3] Other risk factors include genetics and infection with the simian virus 40.[3] The diagnosis may be suspected based on chest X-ray and CT scan findings, and is confirmed by either examining fluid produced by the cancer or by a tissue biopsy of the cancer.[6]

Prevention centers around reducing exposure to asbestos.[8] Treatment often includes surgery, radiation therapy, and chemotherapy. A procedure known as pleurodesis, which involves using substances such as talc to scar together the pleura, may be used to prevent more fluid from building up around the lungs.[9] Chemotherapy often includes the medications cisplatin and pemetrexed.[6] The percentage of people that survive five years following diagnosis is on average 8% in the United States.[10]

In 2013 about 50,000 people had mesothelioma and 34,000 died from the disease.[11][12] Rates of mesothelioma vary in different areas of the world. Rates are higher in Australia, the United Kingdom, and lower in Japan.[3] It occurs in about 3,000 people per year in the United States.[13] It occurs more often in males than females. Rates of disease have increased since the 1950s. Diagnosis typically occurs after the age of 65 and most deaths occur around 70 years old. The disease was rare before the commercial use of asbestos.[3]

## Signs and symptoms [edit]

### Pleural mesothelioma [edit]

Symptoms or signs of mesothelioma may not appear until 20 to 50 years (or more) after exposure to asbestos. Shortness of breath, cough, and pain in the chest due to an accumulation of fluid in the pleural space (pleural effusion) are often symptoms of pleural mesothelioma.[14]

Mesothelioma that affects the pleura can cause these signs and symptoms:[14]

- Chest wall pain
- Pleural effusion, or fluid surrounding the lung
- Shortness of breath
- Fatigue or anemia
- Wheezing, hoarseness, or a cough
- Blood in the sputum (fluid) coughed up (hemoptysis)

In severe cases, the person may have many tumor masses. The individual may develop a pneumothorax, or collapse of the lung. The disease may metastasize, or spread to other parts of the body.

### Peritoneal mesothelioma [edit]

The most common symptoms of peritoneal mesothelioma are abdominal swelling and pain due to ascites (a buildup of fluid in the abdominal cavity). Other features may include weight loss, fever, night sweats, poor appetite, vomiting, constipation, and umbilical hernia.[15] If the cancer has spread beyond the mesothelium to other parts of the body, symptoms may include pain, trouble swallowing, or swelling of the neck or face.[*citation needed*] These symptoms may be caused by mesothelioma or by other, less serious conditions.

Tumors that affect the abdominal cavity often do not cause symptoms until they are at a late stage. Symptoms include:[*citation needed*]

- Abdominal pain
- Ascites, or an abnormal buildup of fluid in the abdomen
- A mass in the abdomen
- Problems with bowel function
- Weight loss

A mesothelioma does not usually spread to the bone, brain, or adrenal glands. Pleural tumors are usually found only on one side of the lungs.[*citation needed*]

### Pericardial mesothelioma [edit]

Pericardial mesothelioma is not well characterized, but observed cases have included cardiac symptoms, specifically constrictive pericarditis, heart failure, pulmonary embolism, and cardiac tamponade. They have also included nonspecific symptoms, including substernal chest pain, orthopnea (shortness of breath when lying flat), and cough. These symptoms are caused by the tumor encasing or infiltrating the heart.[4]

### End stage mesothelioma [edit]

In severe cases of the disease, the following signs and symptoms may be present:[*citation needed*]

- Blood clots in the veins, which may cause thrombophlebitis
- Disseminated intravascular coagulation, a disorder causing severe bleeding in many body organs
- Jaundice, or yellowing of the eyes and skin
- Low blood sugar level
- Pleural effusion
- Pulmonary emboli, or blood clots in the arteries of the lungs
- Severe ascites

## Cause [edit]

Working with asbestos is the most common risk factor for mesothelioma.[16] In the United States, asbestos is considered the major cause of malignant mesothelioma[17] and has been considered "indisputably"[18] associated with the development of mesothelioma. Indeed, the relationship between asbestos and mesothelioma is so strong that many consider mesothelioma a "signal" or "sentinel" tumor.[19][20][21][22] A history of asbestos exposure exists in most cases. However, mesothelioma has been reported in some individuals without any known exposure to asbestos. In rare cases, mesothelioma has also been associated with irradiation of the chest or abdomen, intrapleural thorium dioxide (thorotrast) as a contrast medium, and inhalation of other fibrous silicates, such as erionite or talc.[5][23] Some studies suggest that simian virus 40 (SV40) may act as a cofactor in the development of mesothelioma.[23] This has been confirmed in animal studies,[24][25] but studies in humans are inconclusive.[24][26][27] Pericardial mesothelioma may not be associated with asbestos exposure.[4]

Asbestos was known in antiquity, but it was not mined and widely used commercially until the late 19th century. Its use greatly increased during World War II. Since the early 1940s, millions of American workers have been exposed to asbestos dust. Initially, the risks associated with asbestos exposure were not publicly known. However, an increased risk of developing mesothelioma was later found among naval personnel (e.g., Navy, Marine Corps, and Coast Guard), shipyard workers, people who work in asbestos mines and mills, producers of asbestos products, workers in the heating and construction industries, and other tradespeople. Today, the official position of the U.S. Occupational Safety and Health Administration (OSHA) and the U.S. EPA is that protections and "permissible exposure limits" required by U.S. regulations, while adequate to prevent most asbestos-related non-malignant disease, are *not* adequate to prevent or protect against asbestos-related cancers such as mesothelioma.[28] Likewise, the British Government's Health and Safety Executive (HSE) states formally that any threshold for exposure to asbestos must be at a very low level and it is widely agreed that if any such threshold does exist at all, then it cannot currently be quantified. For practical purposes, therefore, HSE assumes that no such "safe" threshold exists. Others have noted as well that there is no evidence of a threshold level below which there is no risk of mesothelioma.[29] There appears to be a linear, dose-response relationship, with increasing dose producing increasing disease.[30] Nevertheless, mesothelioma may be related to brief, low level or indirect exposures to asbestos.[18] The dose necessary for effect appears to be lower for asbestos-induced mesothelioma than for pulmonary asbestosis or lung cancer.[18] Again, there

is no known safe level of exposure to asbestos as it relates to increased risk of mesothelioma.

The duration of exposure to asbestos causing mesothelioma can be short. For example, cases of mesothelioma have been documented with only 1–3 months of exposure.[31][32] People who work with asbestos wear personal protective equipment to lower their risk of exposure.[*citation needed*]

Latency, the time from first exposure to manifestation of disease, is prolonged in the case of mesothelioma. It is virtually never less than fifteen years and peaks at 30–40 years.[18] In a review of occupationally related mesothelioma cases, the median latency was 32 years.[33] Based upon the data from Peto *et al.*, the risk of mesothelioma appears to increase to the third or fourth power from first exposure.[30]

## Environmental exposures [edit]

The incidence of mesothelioma has been found to be higher in populations living near naturally occurring asbestos. People can be exposed to naturally occurring asbestos in areas where mining or road construction is occurring, or when the asbestos-containing rock is naturally weathered. Another common route of exposure is through asbestos-containing soil, which is used to whitewash, plaster, and roof houses in Greece.[7] In central Cappadocia, Turkey, mesothelioma was causing 50% of all deaths in three small villages—Tuzköy, Karain, and Sarıhıdır. Initially, this was attributed to erionite. Environmental exposure to asbestos has caused mesothelioma in places other than Turkey, including Corsica, Greece, Cyprus, China, and California.[7][34][35] In Metsovo, this exposure had resulted in mesothelioma incidence around 300 times more than expected in asbestos free populations and was associated with very frequent pleural calcification known as "Metsovo Lung".[36][37]

The documented presence of asbestos fibers in water supplies and food products has fostered concerns about the possible impact of long-term and, as yet, unknown exposure of the general population to these fibers.[*citation needed*]

Exposure to talc is also a risk factor for mesothelioma; exposure can affect those who live near talc mines, work in talc mines, or work in talc mills.[23]

## Occupational [edit]

Exposure to asbestos fibers has been recognized as an occupational health hazard since the early 20th century. Numerous epidemiological studies have associated occupational exposure to asbestos with the development of pleural plaques, diffuse pleural thickening, asbestosis, carcinoma of the lung and larynx, gastrointestinal tumors, and diffuse malignant mesothelioma of the pleura and peritoneum. Asbestos has been widely used in many industrial products, including cement, brake linings, gaskets, roof shingles, flooring products, textiles, and insulation.[38]

Commercial asbestos mining at Wittenoom, Western Australia, took place from 1937 to 1966. The first case of mesothelioma in the town occurred in 1960. The second case was in 1969, and new cases began to appear more frequently thereafter. The lag time between initial exposure to asbestos and the development of mesothelioma varied from 12 years 9 months up to 58 years.[39] A cohort study of miners employed at the mine reported that 85 deaths attributable to mesothelioma had occurred by 1985. By 1994, 539 reported deaths due to mesothelioma had been reported in Western Australia.[*citation needed*]

Occupational exposure to asbestos in the United States mainly occurs when people are maintaining buildings that already have asbestos. Approximately 1.3 million US workers are exposed to asbestos annually; in 2002, an estimated 44,000 miners were potentially exposed to asbestos.[23]

## Paraoccupational secondary exposure [edit]

Family members and others living with asbestos workers have an increased risk of developing mesothelioma, and possibly other asbestos-related diseases.[5][40][41] This risk may be the result of exposure to asbestos dust brought home on the clothing and hair of asbestos workers via washing a worker's clothes or coming into contact with asbestos-contaminated work clothing.[7][23] To reduce the chance of exposing family members to asbestos fibres, asbestos workers are usually required to shower and change their clothing before leaving the workplace.[*citation needed*]

## Asbestos in buildings [edit]

Many building materials used in both public and domestic premises prior to the banning of asbestos may contain asbestos. Those performing renovation works or DIY activities may expose themselves to asbestos dust. In the UK use of Chrysotile asbestos was banned at the end of 1999. Brown and blue asbestos was banned in the UK around 1985. Buildings built or renovated prior to these dates may contain asbestos materials.[*citation needed*]

## Genetic disposition [edit]

In a recent research carried on white American population in 2012, it was found that people with a germline mutation in their BAP1 gene are at higher risk of developing mesothelioma and uveal melanoma.[42]

## Erionite [edit]

Erionite is a zeolite mineral with similar properties to asbestos and is known to cause mesothelioma.[5] Detailed epidemiological investigation has shown that erionite causes mesothelioma mostly in families with a genetic predisposition.[7][34][35] Erionite is found in deposits in the Western United States, where it is used in gravel for road surfacing, and in Turkey, where it is used to construct homes. In Turkey, the United States, and Mexico, erionite has been associated with mesothelioma and has thus been designated a "known human carcinogen" by the US National Toxicology Program.[35]

# Pathophysiology [edit]

The mesothelium consists of a single layer of flattened to cuboidal cells forming the epithelial lining of the serous cavities of the body including the peritoneal, pericardial and pleural cavities. Deposition of asbestos fibers in the parenchyma of the lung may result in the penetration of the visceral pleura from where the fiber can then be carried to the pleural surface, thus leading to the development of malignant mesothelial plaques. The processes leading to the development of peritoneal mesothelioma remain unresolved, although it has been proposed that asbestos fibers from the lung are transported to the abdomen and associated organs via the lymphatic system. Additionally, asbestos fibers may be deposited in the gut after ingestion of sputum contaminated with asbestos fibers.[*citation needed*]

Diffuse pleural mesothelioma with extensive involvement of the pericardium.

Pleural contamination with asbestos or other mineral fibers has been shown to cause cancer. Long thin asbestos fibers (blue asbestos, amphibole fibers) are more potent carcinogens than "feathery fibers" (chrysotile or white asbestos fibers).[18] However, there is now evidence that smaller particles may be more dangerous than the larger fibers. They remain suspended in the air where they can be inhaled, and may penetrate more easily and deeper into the lungs. "We probably will find out a lot more about the health aspects of asbestos from [the World Trade Center attack], unfortunately," said Dr. Alan Fein, chief of pulmonary and critical-care medicine at North Shore-Long Island Jewish Health System.[43]

Mesothelioma development in rats has been demonstrated following intra-pleural inoculation of phosphorylated chrysotile fibers. It has been suggested that in humans, transport of fibers to the pleura is critical to the pathogenesis of mesothelioma. This is supported by the observed recruitment of significant numbers of macrophages and other cells of the immune system to localized lesions of accumulated asbestos fibers in the pleural and peritoneal cavities of rats. These lesions continued to attract and accumulate macrophages as the disease progressed, and cellular changes within the lesion culminated in a morphologically malignant tumor.[*citation needed*]

Experimental evidence suggests that asbestos acts as a complete carcinogen with the development of mesothelioma occurring in sequential stages of initiation and promotion. The molecular mechanisms underlying the malignant transformation of normal mesothelial cells by asbestos fibers remain unclear despite the demonstration of its oncogenic capabilities (see next-but-one paragraph). However, complete in vitro transformation of normal human mesothelial cells to malignant phenotype following exposure to asbestos fibers has not yet been achieved. In general, asbestos fibers are thought to act through direct physical interactions with the cells of the mesothelium in conjunction with indirect effects following interaction with inflammatory cells such as macrophages.[*citation needed*]

Analysis of the interactions between asbestos fibers and DNA has shown that phagocytosed fibers are able to make contact with chromosomes, often adhering to the chromatin fibers or becoming entangled within the chromosome. This contact between the asbestos fiber and the chromosomes or structural proteins of the spindle apparatus can induce complex abnormalities. The most common abnormality is monosomy of chromosome 22. Other frequent abnormalities include structural rearrangement of 1p, 3p, 9p and 6q chromosome arms.[*citation needed*]

Common gene abnormalities in mesothelioma cell lines include deletion of the tumor suppressor genes:[*citation needed*]

- Neurofibromatosis type 2 at 22q12
- $P16^{INK4A}$ [44]
- $P14^{ARF}$

Asbestos has also been shown to mediate the entry of foreign DNA into target cells. Incorporation of this foreign DNA may lead to mutations and oncogenesis by several possible mechanisms:

- Inactivation of tumor suppressor genes
- Activation of oncogenes
- Activation of proto-oncogenes due to incorporation of foreign DNA containing a promoter region
- Activation of DNA repair enzymes, which may be prone to error
- Activation of telomerase
- Prevention of apoptosis

Several genes are commonly mutated in mesothelioma, and may be prognostic factors. These include epidermal growth factor receptor (EGFR) and C-Met, receptor tyrosine kinasesoverexpressed in many mesotheliomas. Some association has been found with EGFR and epithelioid histology but no clear association has been found between EGFR overexpression and overall survival. Expression of AXL receptor tyrosine kinase is a negative prognostic factor. Expression of PDGFRB is a positive prognostic factor.[45] In general, mesothelioma is characterized by loss of function in tumor suppressor genes, rather than by an overexpression or gain of function in oncogenes.[46]

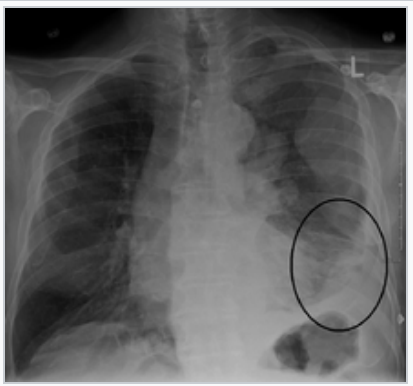
Asbestos fibers have been shown to alter the function and secretory properties of macrophages, ultimately creating conditions which favour the development of mesothelioma. Following asbestos phagocytosis, macrophages generate increased amounts of hydroxyl radicals, which are normal by-products of cellular anaerobic metabolism. However, these free radicals are also known clastogenic and membrane-active agents thought to promote asbestos carcinogenicity. These oxidants can participate in the oncogenic process by directly and indirectly interacting with DNA, modifying membrane-associated cellular events, including oncogene activation and perturbation of cellular antioxidant defences.[*citation needed*]

Asbestos also may possess immunosuppressive properties. For example, chrysotile fibres have been shown to depress the in vitro proliferation of phytohemagglutinin-stimulated peripheral blood lymphocytes, suppress natural killer cell lysis and significantly reduce lymphokine-activated killer cell viability and recovery. Furthermore, genetic alterations in asbestos-activated macrophages may result in the release of potent mesothelial cell mitogens such as platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β) which in turn, may induce the chronic stimulation and proliferation of mesothelial cells after injury by asbestos fibres.[*citation needed*]

As an environmentally triggered malignancy, mesothelioma tumors have been found to be polyclonal in origin by performing a X-inactivation based assay on epitheloid and biphasic tumors obtained from female patients.[47] These results suggest that an environmental factor, e.g. asbestos exposure, may damage and transform a group of cells in the tissue, therefore result in a population of tumor cells that are, albeit slightly, genetically different.[*citation needed*]

## Diagnosis [edit]

Diagnosis of mesothelioma can be suspected with imaging but is confirmed with biopsy. It must be clinically and histologically differentiated from other pleural and pulmonary malignancies, including reactive pleural disease, primary lung carcinoma, pleural metastases of other cancers, and other primary pleural cancers.[5] Primary pericardial mesothelioma is often diagnosed after it has metastasized to lymph nodes or the lungs.[4]



CXR demonstrating a mesothelioma

### Imaging [edit]

Diagnosing mesothelioma is often difficult because the symptoms are similar to those of a number of other conditions. Diagnosis begins with a review of the patient's medical history. A history of exposure to asbestos may increase clinical suspicion for mesothelioma. A physical examination is performed, followed by chest X-ray and often lung function tests. The X-ray may reveal pleural thickening commonly seen after asbestos exposure and increases suspicion of mesothelioma.[14] A CT (or CAT) scan or an MRI is usually performed. If a large amount of fluid is present, abnormal cells may be detected by cytopathology if this fluid is aspirated with a syringe.[4] For pleural fluid, this is done by thoracentesis or tube thoracostomy (chest tube); for ascites, with paracentesis or ascitic drain; and for pericardial effusion with pericardiocentesis. While absence of malignant cells on cytology does not completely exclude mesothelioma, it makes it much more unlikely, especially if an alternative diagnosis can be made (e.g. tuberculosis, heart failure).[*citation needed*] However, with primary pericardial mesothelioma, pericardial

fluid may not contain malignant cells and a tissue biopsy is more useful in diagnosis.[4] Using conventional cytology diagnosis of malignant mesothelioma is difficult, but immunocytochemistry has greatly enhanced the accuracy of cytology.[*citation needed*]

## Biopsy [edit]

Generally, a biopsy is needed to confirm a diagnosis of malignant mesothelioma. A doctor removes a sample of tissue for examination under a microscope by a pathologist. A biopsy may be done in different ways, depending on where the abnormal area is located. If the cancer is in the chest, the doctor may perform a thoracoscopy. In this procedure, the doctor makes a small cut through the chest wall and puts a thin, lighted tube called a thoracoscope into the chest between two ribs. Thoracoscopy allows the doctor to look inside the chest and obtain tissue samples. Alternatively, the chest surgeon might directly open the chest (thoracotomy). If the cancer is in the abdomen, the doctor may perform a laparoscopy. To obtain tissue for examination, the doctor makes a small incision in the abdomen and inserts a special instrument into the abdominal cavity. If these procedures do not yield enough tissue, more extensive diagnostic surgery may be necessary.[*citation needed*]

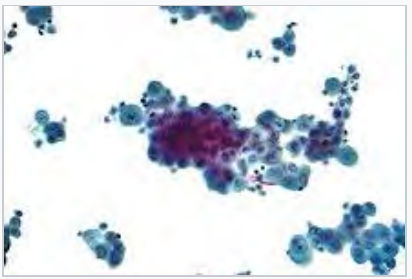
## Immunochemistry [edit]

Immunohistochemical studies play an important role for the pathologist in differentiating malignant mesothelioma from neoplastic mimics, such as breast or lung cancer that has metastasized to the pleura. There are numerous tests and panels available, but no single test is perfect for distinguishing mesothelioma from carcinoma or even benign versus malignant. The positive markers indicate that mesothelioma is present; if other markers are positive it may indicate another type of cancer, such as breast or lung adenocarcinoma. Calretinin is a particularly important marker in distinguishing mesothelioma from metastatic breast or lung cancer.[5]

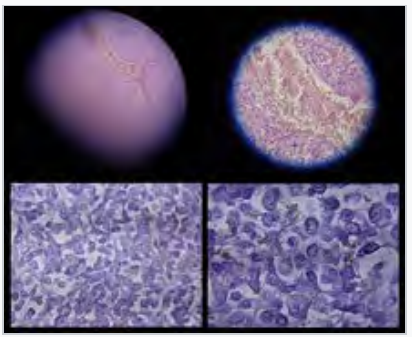
**Typical immunohistochemistry results**

| Positive | Negative |
|---|---|
| EMA (epithelial membrane antigen) in a membranous distribution | CEA (carcinoembryonic antigen)[5] |
| WT1 (Wilms' tumour 1)[5] | B72.3 |
| Calretinin[5] | MOC-3 1 |
| Mesothelin[5] | CD15 |
| Cytokeratin 5[5] | Ber-EP4 |
| HBME-1 (human mesothelial cell 1) | TTF-1 (thyroid transcription factor-1)[5] |
| Podoplanin (PDPN)[5] | Claudin-4[5] |
| Osteopontin[5] | Epithelial cell adhesion molecule (EpCAM)[5] |
| | Estrogen receptor alpha[5] |
| | Mammaglobin[5] |

CT scan of a patient with mesothelioma, coronal section (the section follows the plane that divides the body in a front and a back half). The mesothelioma is indicated by yellow arrows, the central pleural effusion (fluid collection) is marked with a yellow star. Red numbers: (1) right lung, (2) spine, (3) left lung, (4) ribs, (5) descending part of the aorta, (6) spleen, (7) left kidney, (8) right kidney, (9) liver.



Micrograph of a pleural fluid cytopathology specimen showing mesothelioma.



Micrographs showing mesothelioma in a core biopsy.

## Subtypes [edit]

There are three main histological subtypes of malignant mesothelioma: epithelioid, sarcomatous, and biphasic. Epithelioid and biphasic mesothelioma make up approximately 75-95% of mesotheliomas and have been well characterized histologically, whereas sarcomatous mesothelioma has not been studied extensively. Most mesotheliomas express high levels of cytokeratin 5 regardless of subtype.[5]

Epithelioid mesothelioma is characterized by high levels of calretinin.[5]

Sarcomatous mesothelioma does not express high levels of calretinin.[5]

Other morphological subtypes have been described:

- Desmoplastic
- Clear cell
- Deciduoid
- Adenomatoid
- Glandular
- Mucohyaline
- Cartilaginous and osseous metaplasia
- Lymphohistiocytic

## Differential diagnosis [edit]

- Metastatic adenocarcinoma
- Pleural sarcoma
- Synovial sarcoma
- Thymoma
- Metastatic clear cell renal cell carcinoma
- Metastatic osteosarcoma

## Staging [edit]

Staging of mesothelioma is based on the recommendation by the International Mesothelioma Interest Group.[48] TNM classification of the primary tumor, lymph node involvement, and distant metastasis is performed. Mesothelioma is staged Ia–IV (one-A to four) based on the TNM status.[48][49]

# Prevention [edit]

Mesothelioma can be prevented in most cases by preventing exposure to asbestos. The US National Institute for Occupational Safety and Health maintains a recommended exposure limit of 0.1 asbestos fiber per cubic centimeter.[23]

# Screening [edit]

There is no universally agreed protocol for screening people who have been exposed to asbestos. Screening tests might diagnose mesothelioma earlier than conventional methods thus improving the survival prospects for patients. The serum osteopontin level might be useful in screening asbestos-exposed people for mesothelioma. The level of soluble mesothelin-related protein is elevated in the serum of about 75% of patients at diagnosis and it has been suggested that it may be useful for screening.[50] Doctors have begun testing the Mesomark assay which measures levels of soluble mesothelin-related proteins (SMRPs) released by diseased mesothelioma cells.[51]

# Treatment [edit]

Mesothelioma is generally resistant to radiation and chemotherapy treatment. Long-term survival and cures are exceedingly rare.[5] Treatment of malignant mesothelioma at earlier stages has a better prognosis. Clinical behavior of the malignancy is affected by several factors including the continuous mesothelial surface of the pleural cavity which favors local metastasis via exfoliated cells, invasion to underlying tissue and other organs within the pleural cavity, and the extremely long latency period between asbestos exposure and development of the disease. The histological subtype and the patient's age and health status also help predict prognosis. The epithelioid histology responds better

to treatment and has a survival advantage over sarcomatoid histology.[52]

## Surgery [edit]

Surgery, by itself, has proved disappointing. In one large series, the median survival with surgery (including extrapleural pneumonectomy) was only 11.7 months.[53] However, research indicates varied success when used in combination with radiation and chemotherapy (Duke, 2008), or with one of the latter. A pleurectomy/decortication is the most common surgery, in which the lining of the chest is removed. Less common is an extrapleural pneumonectomy (EPP), in which the lung, lining of the inside of the chest, the hemi-diaphragm and the pericardium are removed.[*citation needed*] In localized pericardial mesothelioma, pericardectomy can be curative; when the tumor has metastasized, pericardectomy is a palliative care option. The entire tumor is not often able to be removed.[4]

## Radiation [edit]

For patients with localized disease, and who can tolerate a radical surgery, radiation can be given post-operatively as a consolidative treatment. The entire hemithorax is treated with radiation therapy, often given simultaneously with chemotherapy. Delivering radiation and chemotherapy after a radical surgery have led to extended life expectancy in selected patient populations. It can also induce severe side-effects, including fatal pneumonitis.[54] As part of a curative approach to mesothelioma, radiotherapy is commonly applied to the sites of chest drain insertion, in order to prevent growth of the tumor along the track in the chest wall.[*citation needed*]

Although mesothelioma is generally resistant to curative treatment with radiotherapy alone, palliative treatment regimens are sometimes used to relieve symptoms arising from tumor growth, such as obstruction of a major blood vessel. Radiation therapy, when given alone with curative intent, has never been shown to improve survival from mesothelioma. The necessary radiation dose to treat mesothelioma that has not been surgically removed would be very toxic.[*citation needed*] Radiotherapy is of some use in pericardial mesothelioma.[4]

## Chemotherapy [edit]

Chemotherapy is the only treatment for mesothelioma that has been proven to improve survival in randomised and controlled trials. The landmark study published in 2003 by Vogelzang and colleagues compared cisplatin chemotherapy alone with a combination of cisplatin and pemetrexed (brand name Alimta) chemotherapy in patients who had not received chemotherapy for malignant pleural mesothelioma[55] previously and were not candidates for more aggressive "curative" surgery.[56] This trial was the first to report a survival advantage from chemotherapy in malignant pleural mesothelioma, showing a statistically significant improvement in median survival from 10 months in the patients treated with cisplatin alone to 13.3 months in the group of patients treated with cisplatin in the combination with pemetrexed and who also received supplementation with folate and vitamin $B_{12}$. Vitamin supplementation was given to most patients in the trial and pemetrexed related side effects were significantly less in patients receiving pemetrexed when they also received daily oral folate 500mcg and intramuscular vitamin $B_{12}$ 1000mcg every 9 weeks compared with patients receiving pemetrexed without vitamin supplementation. The objective response rate increased from 20% in the cisplatin group to 46% in the combination pemetrexed group. Some side effects such as nausea and vomiting, stomatitis, and diarrhoea were more common in the combination pemetrexed group but only affected a minority of patients and overall the combination of pemetrexed and cisplatin was well tolerated when patients received vitamin supplementation; both quality of life and lung function tests improved in the combination pemetrexed group. In February 2004, the United States Food and Drug Administration approved pemetrexed for treatment of malignant pleural mesothelioma. However, there are still unanswered questions about the optimal use of chemotherapy, including when to start treatment, and the optimal number of cycles to give.[*citation needed*] Cisplatin and pemetrexed together give patients a median survival of 12.1 months.[5]

Cisplatin in combination with raltitrexed has shown an improvement in survival similar to that reported for pemetrexed in combination with cisplatin, but raltitrexed is no longer commercially available for this indication. For patients unable to tolerate pemetrexed, cisplatin in combination with gemcitabine or vinorelbine is an alternative, or vinorelbine on its own, although a survival benefit has not been shown for these drugs. For patients in whom cisplatin cannot be used, carboplatin can be substituted but non-randomised data have shown lower response rates and high rates of haematological toxicity for carboplatin-based combinations, albeit with similar survival figures to patients receiving cisplatin.[57]

In January 2009, the United States FDA approved using conventional therapies such as surgery in combination with radiation and or chemotherapy on stage I or II Mesothelioma after research conducted by a nationwide study by Duke University concluded an almost 50 point increase in remission rates.[*citation needed*]

In pericardial mesothelioma, chemotherapy - typically adriamycin and/or cisplatin - is primarily used to shrink the

tumor and is not curative.[4]

### Immunotherapy [edit]

Treatment regimens involving immunotherapy have yielded variable results. For example, intrapleural inoculation of Bacillus Calmette-Guérin (BCG) in an attempt to boost the immune response, was found to be of no benefit to the patient (while it may benefit patients with bladder cancer). Mesothelioma cells proved susceptible to in vitro lysis by LAK cells following activation by interleukin-2 (IL-2), but patients undergoing this particular therapy experienced major side effects. Indeed, this trial was suspended in view of the unacceptably high levels of IL-2 toxicity and the severity of side effects such as fever and cachexia. Nonetheless, other trials involving interferon alpha have proved more encouraging with 20% of patients experiencing a greater than 50% reduction in tumor mass combined with minimal side effects.[*citation needed*]

### Heated intraoperative intraperitoneal chemotherapy [edit]

This technique is used in conjunction with surgery,[58] including in patients with malignant pleural mesothelioma.[59] The surgeon removes as much of the tumor as possible followed by the direct administration of a chemotherapy agent, heated to between 40 and 48 °C, in the abdomen. The fluid is perfused for 60 to 120 minutes and then drained. High concentrations of selected drugs are then administered into the abdominal and pelvic surfaces. Heating the chemotherapy treatment increases the penetration of the drugs into tissues. Also, heating itself damages the malignant cells more than the normal cells.[*citation needed*]

### Multimodality therapy [edit]

All of the standard approaches to treating solid tumors—radiation, chemotherapy, and surgery—have been investigated in patients with malignant pleural mesothelioma. Although surgery, by itself, is not very effective, surgery combined with adjuvant chemotherapy and radiation (trimodality therapy) has produced significant survival extension (3–14 years) among patients with favorable prognostic factors.[60] However, other large series of examining multimodality treatment have only demonstrated modest improvement in survival (median survival 14.5 months and only 29.6% surviving 2 years).[53] Reducing the bulk of the tumor with cytoreductive surgery is key to extending survival. Two surgeries have been developed: extrapleural pneumonectomy and pleurectomy/decortication. The indications for performing these operations are unique. The choice of operation namely depends on the size of the patient's tumor. This is an important consideration because tumor volume has been identified as a prognostic factor in mesothelioma.[61] Pleurectomy/decortication spares the underlying lung and is performed in patients with early stage disease when the intention is to remove all gross visible tumor (macroscopic complete resection), not simply palliation.[62] Extrapleural pneumonectomy is a more extensive operation that involves resection of the parietal and visceral pleurae, underlying lung, ipsilateral (same side) diaphragm, and ipsilateral pericardium. This operation is indicated for a subset of patients with more advanced tumors, who can tolerate a pneumonectomy.[63]

## Prognosis [edit]

Mesothelioma often has a poor prognosis. Typical survival despite surgery is between 12 and 21 months depending on the stage of disease at diagnosis with about 7.5% of people surviving for 5 years.[64]

Women, young people, people with low-stage cancers, and people with epithelioid cancers have better prognoses.[5] Negative prognostic factors include sarcomatoid or biphasic histology, high platelet counts (above 400,000), age over 50 years, white blood cell counts above 15.5, low glucose levels in the pleural fluid, low albumin levels, and high fibrinogen levels. Several markers are under investigation as prognostic factors, including nuclear grade, and serum c-reactive protein. Long-term survival is rare.[45]

Pericardial mesothelioma has a 10-month median survival time.[4]

In peritoneal mesothelioma, high expression of WT-1 protein indicates a worse prognosis.[5]

## Epidemiology [edit]

Although reported incidence rates have increased in the past 20 years, mesothelioma is still a relatively rare cancer. The incidence rate varies from one country to another, from a low rate of less than 1 per 1,000,000 in Tunisia and Morocco, to the highest rate in Britain, Australia and Belgium: 30 per 1,000,000 per year.[65] For comparison, populations with high levels of smoking can have a lung cancer incidence of over 1,000 per 1,000,000. Incidence of

malignant mesothelioma currently ranges from about 7 to 40 per 1,000,000 in industrialized Western nations, depending on the amount of asbestos exposure of the populations during the past several decades.[66] Worldwide incidence is estimated at 1-6 per 1,000,000.[5] Incidence of mesothelioma lags behind that of asbestosis due to the longer time it takes to develop; due to the cessation of asbestos use in developed countries, mesothelioma incidence is expected to decrease.[23] Incidence is expected to continue increasing in developing countries due to continuing use of asbestos.[5] Mesothelioma occurs more often in men than in women and risk increases with age, but this disease can appear in either men or women at any age. Approximately one fifth to one third of all mesotheliomas are peritoneal.[*citation needed*] Less than 5% of mesotheliomas are pericardial. The prevalence of pericardial mesothelioma is less than 0.002%; it is more common in men than women. It typically occurs in a person's 50s-70s.[4][67]

Between 1940 and 1979, approximately 27.5 million people were occupationally exposed to asbestos in the United States.[68] Between 1973 and 1984, the incidence of pleural mesothelioma among Caucasian males increased 300%. From 1980 to the late 1990s, the death rate from mesothelioma in the USA increased from 2,000 per year to 3,000, with men four times more likely to acquire it than women.[*citation needed*] More than 80% of mesotheliomas are caused by asbestos exposure.[5]

The incidence of peritoneal mesothelioma is 0.5–3.0 per million per year in men, and 0.2–2.0 per million per year in women.[69]

### UK [edit]

Mesothelioma accounts for less than 1% of all cancers diagnosed in the UK, (around 2,600 people were diagnosed with the disease in 2011), and it is the seventeenth most common cause of cancer death (around 2,400 people died in 2012).[70]

## History [edit]

The connection between asbestos exposure and mesothelioma was discovered in the 1970s. In the United States, asbestos manufacture stopped in 2002. Asbestos exposure thus shifted from workers in asbestos textile mills, friction product manufacturing, cement pipe fabrication, and insulation manufacture and installation to maintenance workers in asbestos-containing buildings.[23]

## Society and culture [edit]

### Notable cases [edit]

Mesothelioma, though rare, has had a number of notable patients:

- Bernie Banton, an Australian workers' rights activist, fought a long battle for compensation from James Hardie after he contracted mesothelioma after working for that company. He claimed James Hardie knew of the dangers of asbestos before he began work with the substance making insulation for power stations. Mesothelioma eventually took his life along with his brothers' and hundreds of James Hardie workers'. James Hardie made an undisclosed settlement with Banton only when his mesothelioma had reached its final stages and he was expected to have no more than 48 hours to live. Australian Prime Minister Kevin Rudd mentioned Banton's extended struggle in his acceptance speech after winning the 2007 Australian federal election.
- Steve McQueen, American actor, was diagnosed with peritoneal mesothelioma on December 22, 1979. He was not offered surgery or chemotherapy because doctors felt the cancer was too advanced. McQueen subsequently sought alternative treatments at clinics in Mexico. He died of a heart attack on November 7, 1980, in Juárez, Mexico, following cancer surgery. He may have been exposed to asbestos while serving with the U.S. Marines as a young adult—asbestos was then commonly used to insulate ships' piping—or from its use as an insulating material in automobile racing suits (McQueen was an avid racing driver and fan).[71]
- Cynthia Stelljes, oboist and founding member of the Canadian classical quartet Quartetto Gelato, died from the disease on December 29, 2006.[*citation needed*]
- Bill Tait, the husband of early anti-asbestos campaigner Nancy Tait, died of the condition in 1968, sparking his wife's subsequent activism.
- Bruce Vento, U.S. Congressman, died of mesothelioma in 2000. The Bruce Vento Hopebuilder award is given yearly by his wife at the MARF Symposium to persons or organizations who have done the most to support mesothelioma research and advocacy.
- Warren Zevon, an American rock singer-songwriter, was diagnosed with inoperable peritoneal mesothelioma in

2002. Zevon refused treatments due to concerns that they would serve to only incapacitate him, and instead opted to record his final album. He died on September 7, 2003, at the age of 56, in his Los Angeles home. His album, The Wind, was nominated for several Grammy awards, winning two.

Although life expectancy with this disease is typically limited, there are notable survivors. In July 1982, Stephen Jay Gould, a well-regarded paleontologist, was diagnosed with peritoneal mesothelioma. After his diagnosis, Gould wrote "The Median Isn't the Message",[72] in which he argued that statistics such as median survival are useful abstractions, not destiny. Gould lived for another 20 years, eventually succumbing to cancer not linked to his mesothelioma.

Paul Kraus, diagnosed in 1997, is considered the longest currently living (as of 2016) mesothelioma survivor in the world.[73]

## Legal issues [edit]

*Main article: Asbestos and the law*

Some people who were exposed to asbestos have collected damages for an asbestos-related disease, including mesothelioma. Compensation via asbestos funds or class action lawsuits is an important issue in law practices regarding mesothelioma.[*citation needed*]

The first lawsuits against asbestos manufacturers were in 1929. Since then, many lawsuits have been filed against asbestos manufacturers and employers, for neglecting to implement safety measures after the links between asbestos, asbestosis, and mesothelioma became known (some reports seem to place this as early as 1898). The liability resulting from the sheer number of lawsuits and people affected has reached billions of dollars.[74] The amounts and method of allocating compensation have been the source of many court cases, reaching up to the United States Supreme Court, and government attempts at resolution of existing and future cases. However, to date, the US Congress has not stepped in and there are no federal laws governing asbestos compensation.[75] In 2013, the "Furthering Asbestos Claim Transparency (FACT) Act of 2013" passed the US House of representatives and was sent to the US Senate, where it was referred to the Senate Judiciary Committee.[76] As the Senate did not vote on it before the end of the 113th Congress, it died in committee. It was revived in the 114th Congress, where it has not yet been brought before the House for a vote.[77]

### History

The first lawsuit against asbestos manufacturers was brought in 1929. The parties settled that lawsuit, and as part of the agreement, the attorneys agreed not to pursue further cases. In 1960, an article published by Wagner et al. was seminal in establishing mesothelioma as a disease arising from exposure to asbestos.[78] The article referred to over 30 case studies of people who had suffered from mesothelioma in South Africa. Some exposures were transient and some were mine workers. Prior to the use of advanced microscopy techniques, malignant mesothelioma was often diagnosed as a variant form of lung cancer.[79] In 1962 McNulty reported the first diagnosed case of malignant mesothelioma in an Australian asbestos worker.[80] The worker had worked in the mill at the asbestos mine in Wittenoom from 1948 to 1950.[*citation needed*]

In the town of Wittenoom, asbestos-containing mine waste was used to cover schoolyards and playgrounds. In 1965 an article in the British Journal of Industrial Medicine established that people who lived in the neighbourhoods of asbestos factories and mines, but did not work in them, had contracted mesothelioma.[*citation needed*]

Despite proof that the dust associated with asbestos mining and milling causes asbestos-related disease, mining began at Wittenoom in 1943 and continued until 1966. In 1974 the first public warnings of the dangers of blue asbestos were published in a cover story called "Is this Killer in Your Home?" in Australia's *Bulletin* magazine. In 1978 the Western Australian Government decided to phase out the town of Wittenoom, following the publication of a Health Dept. booklet, "The Health Hazard at Wittenoom", containing the results of air sampling and an appraisal of worldwide medical information.[*citation needed*]

By 1979 the first writs for negligence related to Wittenoom were issued against CSR and its subsidiary ABA, and the Asbestos Diseases Society was formed to represent the Wittenoom victims.[*citation needed*]

In Leeds, England the Armley asbestos disaster involved several court cases against Turner & Newall where local residents who contracted mesothelioma claimed compensation because of the asbestos pollution from the company's factory. One notable case was that of June Hancock, who contracted the disease in 1993 and died in 1997.[81]

# Research [edit]

*See also: Mesothelioma Applied Research Foundation*

The WT-1 protein is overexpressed in mesothelioma and is being researched as a potential target for drugs.[5]

# Ovarian cancer

From Wikipedia, the free encyclopedia

**Ovarian cancer** is a cancer that forms in an ovary.[1] It results in abnormal cells that have the ability to invade or spread to other parts of the body.[2] When this process begins, there may be no or only vague symptoms. Symptoms become more noticeable as the cancer progresses.[3][4] These symptoms may include bloating, pelvic pain, abdominal swelling, and loss of appetite, among others.[3] Common areas to which the cancer may spread include the lining of the abdomen, lining of the bowel and bladder, lymph nodes, lungs, and liver.[5][6]

The risk of ovarian cancer increases in women who have ovulated more over their lifetime. This includes those who have never had children, those who begin ovulation at a younger age or reach menopause at an older age.[7] Other risk factors include hormone therapy after menopause, fertility medication, and obesity.[1][8] Factors that decrease risk include hormonal birth control, tubal ligation, and breast feeding.[8] About 10% of cases are related to inherited genetic risk; women with mutations in the genes *BRCA1* or *BRCA2* have about a 50% chance of developing the disease. The most common type of ovarian cancer, comprising more than 95% of cases, is ovarian carcinoma. There are five main subtypes of ovarian carcinoma, of which high-grade serous carcinoma is the most common. These tumors are believed to start in the cells covering the ovaries,[7] though some may form at the Fallopian tubes.[9] Less common types of ovarian cancer include germ cell tumors and sex cord stromal tumors.[7] A diagnosis of ovarian cancer is confirmed through a biopsy of tissue, usually removed during surgery.[3]

Screening is not recommended in women who are at average risk, as evidence does not support a reduction in death and the high rate of false positive tests may lead to unneeded surgery, which is accompanied by its own risks.[10] Those at very high risk may have their ovaries removed as a preventive measure.[1] If caught and treated in an early stage, ovarian cancer may be curable. Treatment usually includes some combination of surgery, radiation therapy, and chemotherapy.[3] Outcomes depend on the extent of the disease and the subtype of the cancer present.[7] The overall five-year survival rate in the United States is 45%.[11] Outcomes are worse in the developing world.[7]

In 2012, ovarian cancer occurred in 239,000 women and resulted in 152,000 deaths worldwide. This makes it, among women, the seventh-most common cancer and the eighth-most common cause of death from cancer.[7] The typical age of diagnosis is 63.[12] Death from ovarian cancer is more common in North [7]

## Signs and symptoms [edit]

Signs and symptoms of ovarian cancer are frequently absent in early stages; even when they do exist, they may be subtle. In most cases, symptoms exist for several months before being recognized and diagnosed, or they may initially be misdiagnosed as a condition such as irritable bowel syndrome.[13] The early stages of ovarian cancer tend to be painless unless the growing mass causes ovarian torsion.[14] Early symptoms can include bloating, abdominopelvic pain, and pain in the side.[15] The most typical symptoms of ovarian cancer include bloating, abdominal or pelvic pain or discomfort, back pain, irregular menstruation or postmenopausal vaginal bleeding, pain or bleeding after or during sexual intercourse, difficulty eating, loss of appetite, fatigue, diarrhea, indigestion, heartburn, constipation, nausea, early satiety, and possibly urinary symptoms (including frequent urination and urgent urination); typically these symptoms are caused by a mass pressing on the other abdominopelvic organs or from metastases.[14][15][16] If these symptoms start to occur more often or more severely than usual, especially after no significant history of such symptoms, ovarian cancer should be considered.[14][17][18] Metastases may cause a Sister Mary Joseph nodule.[16]

In adolescents or children with ovarian tumors, the presenting symptoms can include severe abdominal pain, irritation of the peritoneum, or bleeding.[19] As the cancer becomes more advanced, it can cause an

accumulation of fluid in the abdomen. If the malignancy has not been diagnosed by the time it causes ascites, it is typically diagnosed shortly thereafter.[14] Advanced cancers can also cause abdominal masses, lymph node masses, or pleural effusion.[16]

Ovarian cancer symptoms can vary based on the subtype.[14] Low malignant potential (LMP) tumors, also known as borderline tumors, do not cause an increase in CA125 levels and are not identifiable with an ultrasound. The typical symptoms of a LMP tumor can include abdominal distension or pelvic pain. Particularly large masses tend to be benign or borderline.[18] Rarely, teratomas can cause growing teratoma syndrome or peritoneal gliomatosis.[16] The symptoms of sex cord-stromal tumors belie their ability to produce hormones. In prepubertal children, early puberty is the main symptom; abdominal pain and distension are also common. Rather than early puberty, adolescents with sex cord-stromal tumors may experience amenorrhea. Adults instead experience menometrorrhagia and abnormal vaginal bleeding after menopause in most cases. Other common symptoms include hirsutism, abdominal pain, virilization, and an adnexal mass.[20]

## Risk factors [edit]

Most of the risk for ovarian cancer is related to the amount of time spent in ovulation. Thus not having children is a risk factor for ovarian cancer, likely because ovulation is not suppressed via pregnancy. Both obesity and hormone replacement therapy also raise the risk.[14]

Things that halt ovulation: breast feeding, oral contraceptive use with estrogen/progesterone combination meds, multiple pregnancies, and pregnancy at an early age, all decrease risk of ovarian cancer. These conditions decrease the overall time during one's lifetime spent ovulating. A positive family history of ovarian cancer is a risk factor for ovarian cancer. People with hereditary nonpolyposis colon cancer (Lynch Syndrome), and those with BRCA-1 and BRCA-2 genetic abnormalities are at increased risk.

### Hormones [edit]

Use of fertility medication may contribute to borderline ovarian tumor formation, but the link between the two is disputed and difficult to study.[13] Fertility drugs may be associated with a higher risk of borderline tumors.[16] Those who have been treated for infertility but remain nulliparous are at higher risk for epithelial ovarian cancer; however, those who are successfully treated for infertility and subsequently give birth are at no higher risk. This may be due to shedding of precancerous cells during pregnancy but the cause remains unclear.[18] The risk factor may instead be infertility itself, not the treatment.[21]

Hormonal conditions such as polycystic ovary syndrome and endometriosis are associated with ovarian cancer, but the link is not completely confirmed.[13] Postmenopausal hormone replacement therapy (HRT) with estrogen likely increases the risk of ovarian cancer. The association has not been confirmed in a large-scale study,[18][22] but notable studies including the Million Women Study have supported this link. Postmenopausal HRT with combined estrogen and progesterone may increase contemporaneous risk if used for over 5 years, but this risk returns to normal after cessation of therapy.[21] Estrogen HRT with or without progestins increases the risk of endometrioid and serous tumors but lowers the risk of mucinous tumors. Higher doses of estrogen increase this risk.[16]

Long periods of continuous ovulation are thought to be the main non-genetic cause of epithelial ovarian cancer. This is because during the cells are constantly stimulated to divide while ovulatory cycles continue. Therefore, people who have not borne children are at twice the risk of ovarian cancer than those who have. A longer period of ovulation caused by early first menstruation or late menopause is also a risk factor.[18][21][23]

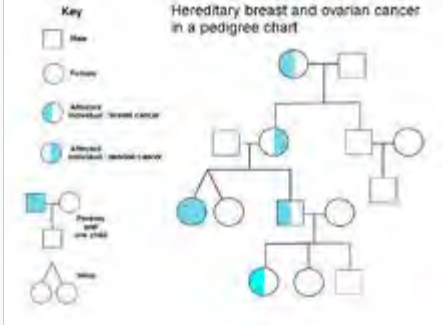
Endometriosis is another risk factor for ovarian cancer,[21] as is pain with menstruation. Endometriosis is associated with clear-cell and endometrioid subtypes, low-grade serous tumors, stage I and II tumors, grade 1 tumors, and lower mortality.[16]

Before menopause, obesity can increase a person's risk of ovarian cancer, but this risk is not present after

menopause. This risk is also relevant in those who are both obese and have never used HRT. A similar association with ovarian cancer appears in taller people.[21]

## Genetics [edit]

*Further information: Hereditary breast–ovarian cancer syndrome*



Ovarian and breast cancer patients in a pedigree chart of a family

In general, a family history of ovarian cancer can indicate a predisposition to developing it. The major genetic risk factor for ovarian cancer is a mutation in *BRCA1* or *BRCA2* DNA mismatch repair genes, which is present in 10% of ovarian cancer cases. Only one allele need be mutated to place a person at high risk, because the risky mutations are autosomal dominant. The gene can be inherited through either the maternal or paternal line, but has variable penetrance.[14][18] Though mutations in these genes are usually associated with increased risk of breast cancer, they also carry a substantial lifetime risk of ovarian cancer, a risk that peaks in a person's 40s and 50s. The lowest risk cited is 30% and the highest 60%.[13][14][18] Mutations in BRCA1 have a lifetime risk of developing ovarian cancer of 15–45%.[16] Mutations in *BRCA2* are less risky than those with *BRCA1*, with a lifetime risk of 10% (lowest risk cited) to 40% (highest risk cited).[14][16] On average, BRCA-associated cancers develop 15 years before their sporadic counterparts, because people who inherit the mutations on one copy of their gene only need one mutation to start the process of carcinogenesis, whereas people with two normal genes would need to acquire two mutations.[18]

In the United States, five of 100 women with a first-degree relative with ovarian cancer will eventually get ovarian cancer themselves, placing those with affected family members at triple the risk of women with unaffected family members. Seven of 100 women with two or more relatives with ovarian cancer will eventually get ovarian cancer.[18][24] In general, 5–10% of ovarian cancer cases have a genetic cause.[18] BRCA mutations are associated with high-grade serous nonmucinous epithelial ovarian cancer.[16]

A strong family history of endometrial cancer, colon cancer, or other gastrointestinal cancers may indicate the presence of a syndrome known as hereditary nonpolyposis colorectal cancer (also known as Lynch syndrome), which confers a higher risk for developing a number of cancers, including ovarian cancer. Lynch syndrome is caused by mutations in mismatch repair genes, including *MSH2*, *MLH1*, *MLH6*, *PMS1*, and *PMS2*.[14] The risk of ovarian cancer for an individual with Lynch syndrome is between 10 and 12 percent.[14][18] People of Icelandic descent, European Jewish descent/Ashkenazi Jewish descent, and Hungarian descent are at higher risk for epithelial ovarian cancer.[18] Estrogen receptor beta gene (ESR2) seems to be a key to pathogenesis and response to therapy.[25] Other genes that have been associated with ovarian cancer are *BRIP1*, *MSH6*, *RAD51C* and *RAD51D*.[26] *CDH1*, *CHEK2*, *PALB2* and *RAD50* have also been associated with ovarian cancer.[27]

Several rare genetic disorders are associated with specific subtypes of ovarian cancer. Peutz–Jeghers syndrome, a rare genetic disorder, also predisposes people to sex cord tumour with annular tubules.[13][14] Ollier disease and Maffucci syndrome are associated with granulosa cell tumors in children and may also be associated with Sertoli-Leydig tumors. Benign fibromas are associated with nevoid basal cell carcinoma syndrome.[14]

## Environmental factors [edit]

Industrialized nations, with the exception of Japan, have high rates of epithelial ovarian cancer, which may be due to diet in those countries. White people are at a 30–40% higher risk for ovarian cancer when compared to Black and Hispanic people, likely due to socioeconomic factors; white women tend to have fewer children and different rates of gynecologic surgeries that affect risk for ovarian cancer.[18]

Cohort studies have found a correlation between dairy consumption and ovarian cancer, but case-control studies do not show this correlation. There is mixed evidence regarding the effect of red meat and processed meat in ovarian cancer.[16]

Tentative evidence suggests that talc, pesticides, and herbicides increase the risk of ovarian cancer.[28] The American Cancer Society notes that as of now, no study has been able to accurately link any single chemical in the environment, or in the human diet, directly to mutations that cause ovarian cancer.[29]

## Other [edit]

Alcohol consumption does not appear to be related to ovarian cancer.[16][30] Other factors that have been investigated, such as smoking, low levels of vitamin D in the blood,[31] presence of inclusion ovarian cysts, and infection with human papilloma virus (the cause of some cases of cervical cancer), have been disproven as risk factors for ovarian cancer.[13][16] The carcinogenicity of perineal talc is controversial, because it can act as an irritant if it travels through the reproductive tract to the ovaries.[16][18][21] Case-control studies have shown that use of perineal talc does increase the risk of ovarian cancer, but using talc more often does not create a greater risk.[16] Use of talc elsewhere on the body is unrelated to ovarian cancer.[21] Sitting regularly for prolonged periods is associated with higher mortality from epithelial ovarian cancer. The risk is not negated by regular exercise, though it is lowered.[32]

Increased age (up to the 70s) is a risk factor for epithelial ovarian cancer because more mutations in cells can accumulate and eventually cause cancer. Those over 80 are at slightly lower risk.[18]

Smoking tobacco is associated with a higher risk of mucinous ovarian cancer; after smoking cessation, the risk eventually returns to normal.A diet high in animal fats may be associated with ovarian cancer, but the connection is unclear. Diet seems to play a very small role, if any, in ovarian cancer risk.[21]

Trans men who have ovaries may be at higher risk of ovarian cancer, but the reason for this is unknown. Potential factors include testosterone therapy and lower rates of protective factors.[33]

Higher levels of C-reactive protein are associated with a higher risk of developing ovarian cancer.[16]

## Protective factors [edit]

Suppression of ovulation, which would otherwise cause damage to the ovarian epithelium and, consequently, inflammation, is generally protective. This effect can be achieved by having children, taking combined oral contraceptives, and breast feeding, all of which are protective factors.[14] A longer period of breastfeeding correlates with a larger decrease in the risk of ovarian cancer.[21] Each birth decreases risk of ovarian cancer more, and this effect is seen with up to five births. Combined oral contraceptives reduce the risk of ovarian cancer by up to 50%, and the protective effect of combined oral contraceptives can last 25–30 years after they are discontinued.[18][21] Regular use of aspirin or acetaminophen (paracetamol) may be associated with a lower risk of ovarian cancer; other NSAIDs do not seem to have a similar protective effect.[16]

Tubal ligation is protective because carcinogens are unable to reach the ovary and fimbriae via the vagina, uterus, and Fallopian tubes.[14] Tubal ligation is also protective in women with the BRCA1 mutation, but not the BRCA2 mutation.[16] Hysterectomy reduces the risk, and removal of both Fallopian tubes and ovaries (bilateral salpingo-oophorectomy) dramatically reduces the risk of not only ovarian cancer, but breast cancer as well.[13] This is still a topic of research, as the link between hysterectomy and lower ovarian cancer risk is controversial. The reasons that hysterectomy may be protective have not been elucidated as of 2015.[21]

A diet that includes large amounts of carotene, fiber, and vitamins with low amounts of fat—specifically, a diet with non-starchy vegetables (e.g. broccoli and onions)—may be protective,[18] though research is still ongoing in this area.[21] Higher caffeine intake and consumption of more than two cups of tea a day have both been associated with lower ovarian cancer risk.[16] Smoking tobacco is protective for sex cord-stromal

tumors.[20]

## Pathophysiology [edit]

Ovarian cancer forms when errors in normal ovarian cell growth occur. Usually, when cells grow old or get damaged, they die, and new cells take their place. Cancer starts when new cells form unneeded, and old or damaged cells do not die as they should. The buildup of extra cells often forms a mass of tissue called a growth or tumor. These abnormal cancer cells have many genetic abnormalities that cause them to grow excessively.[36] When an ovary releases an egg, the egg follicle bursts open and becomes the corpus luteum. This structure needs to be repaired by dividing cells in the ovary.[21] Continuous ovulation for a long time means more repair of the ovary by dividing cells, which can acquire mutations in each division.[18]

Overall, the most common gene mutations in ovarian cancer occur in *NF1*, *BRCA1*, *BRCA2*, and *CDK12*. Type I ovarian cancers, which tend to be less aggressive, tend to have microsatellite instability in several genes, including both oncogenes (most notably *BRAF* and *KRAS*) and tumor suppressors (most notably *PTEN*).[13] The most common mutations in Type I cancers are *KRAS*, *BRAF*, *ERBB2*, *PTEN*, *PIK3CA*, and *ARID1A*.[16] Type II cancers, the more aggressive type, have different genes mutated, including *p53*, *BRCA1*, and *BRCA2*.[13] Low-grade cancers tend to have mutations in KRAS, whereas cancers of any grade that develop from low malignant potential tumors tend to have mutations in p53.[18] Type I cancers tend to develop from precursor lesions, whereas Type II cancers can develop from a serous tubal intraepithelial carcinoma.[16] Serous cancers that have BRCA

**Mutations found in ovarian cancer subtypes**[13][16][34]

| Gene mutated | Mutation type | Subtype | Prevalence |

mutations also inevitably have p53 mutations, indicating that the removal of both functional genes is important for cancer to develop.[18]

In 50% of high-grade serous cancers, homologous recombination DNA repair is dysfunctional, as are the notch and FOXM1 signaling pathways. They also almost always have p53 mutations. Other than this, mutations in high-grade serous carcinoma are hard to characterize beyond their high degree of genomic instability. *BRCA1* and *BRCA2* are essential for homologous recombination DNA repair, and germline mutations in these genes are found in about 15% of people with ovarian cancer.[13] The most common mutations in BRCA1 and BRCA2 are the frameshift mutations that originated in a small founding population of Ashkenazi Jews.[18]

Autophagy regulator beclin-1 has been implicated in ovarian cancer tumorigenesis and tumor progression; it has one copy deleted in many ovarian tumors.[35]

Almost 100% of rare mucinous carcinomas have mutations in *KRAS* and amplifications of *ERBB2* (also known as *Her2/neu*).[13] Overall, 20% of ovarian cancers have mutations in *Her2/neu*.[14]

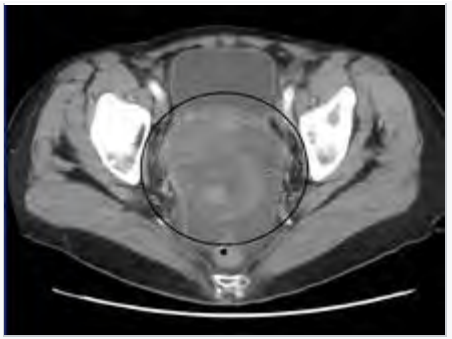
Serous carcinomas may develop from serous tubal intraepithelial carcinoma, rather than developing spontaneously from ovarian tissue. Other carcinomas develop from cortical inclusion cysts, which are groups of epithelial ovarian cells inside the stroma.[18]

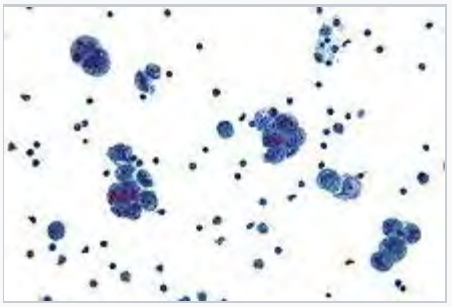
# Diagnosis [edit]

## Examination [edit]

Diagnosis of ovarian cancer starts with a physical examination (including a pelvic examination), a blood test (for CA-125 and sometimes other markers), and transvaginal ultrasound.[14] Sometimes a rectovaginal examination is used to help plan a surgery.[18] The diagnosis must be confirmed with surgery to inspect the abdominal cavity, take biopsies (tissue samples for microscopic analysis), and look for cancer cells in the abdominal fluid. This helps to determine if an ovarian mass is benign or malignant.[14]



A very large ovarian cancer as seen on CT



Micrograph of serous carcinoma, a type of ovarian cancer, diagnosed in peritoneal fluid

Ovarian cancer's early stages (I/II) are difficult to diagnose because most symptoms are nonspecific and thus of little use in diagnosis; as a result, it is rarely diagnosed until it spreads and advances to later stages (III/IV).[37] Additionally, symptoms of ovarian cancer may appear similar to irritable bowel syndrome. In patients in whom pregnancy is a possibility, BHCG level should be measured during the diagnosis process. Serum alpha-fetoprotein, neuron-specific enolase, and lactate dehydrogenase should be measured in young girls and adolescents with suspected ovarian tumors as younger patients are more likely to have malignant germ cell tumors.[14][16]

A physical examination, including a pelvic examination, and a pelvic ultrasound (transvaginal or otherwise) are both essential for diagnosis: physical examination may reveal increased abdominal girth and/or ascites (fluid within the abdominal cavity), while pelvic examination may reveal an ovarian or abdominal mass.[13] An adnexal mass is a significant finding that often indicates ovarian cancer, especially if it is fixed, nodular, irregular, solid, and/or bilateral. 13–21% of adnexal masses are caused by malignancy; however, there are other benign causes of adnexal masses, including ovarian follicular cyst, leiomyoma, endometriosis, ectopic pregnancy, hydrosalpinx, tuboovarian abscess, ovarian torsion, dermoid cyst, cystadenoma (serous or mucinous), diverticular or appendiceal abscess, nerve sheath tumor, pelvic kidney, ureteral or bladder diverticulum, benign cystic mesothelioma of the peritoneum, peritoneal tuberculosis, or paraovarian cyst. Ovaries that can be felt are also a sign of ovarian cancer in postmenopausal women. Other parts of a physical examination for suspected ovarian cancer can include a breast examination and a digital rectal exam. Palpation of the supraclavicular, axillary, and inguinal lymph nodes may reveal lymphadenopathy, which can be indicative of metastasis. Another indicator may be the presence of a pleural effusion, which can be noted on auscultation.[16]

When an ovarian malignancy is included in a list of diagnostic possibilities, a limited number of laboratory tests are indicated. A complete blood count and serum electrolyte test should be obtained in all patients;[38] when an ovarian cancer is present, these tests often show a high number of platelets (20–25% of people) and low blood sodium levels due to chemical signals secreted by the tumor.[18] A positive test for inhibin A and inhibin B can indicate a granulosa cell tumor.[16]

A blood test for a marker molecule called CA-125 is useful in differential diagnosis and in follow up of the disease, but it by itself has not been shown to be an effective method to screen for early-stage ovarian cancer due to its unacceptable low sensitivity and specificity.[38] CA-125 levels in premenopausal people over 200 U/mL may indicate ovarian cancer, as may any elevation in CA-125 above 35 U/mL in post-menopausal people. CA-125 levels are not accurate in early stage ovarian cancer, as fully half of stage I ovarian cancer patients have a normal CA-125 level.[16][18] CA-125 may also be elevated in benign (non-cancerous) conditions, including endometriosis, pregnancy, uterine fibroids, menstruation, ovarian cysts, systemic lupus erythematosus, liver disease, inflammatory bowel disease, pelvic inflammatory disease, and leiomyoma.[16][39] HE4 is another candidate for ovarian cancer testing, though it has not been extensively tested. Other tumor markers for ovarian cancer include CA19-9, CA72-4, CA15-3, immunosuppressive acidic protein, haptoglobin-alpha, OVX1, mesothelin, lysophosphatidic acid, osteopontin, and fibroblast growth factor 23.[16]

Use of blood test panels may help in diagnosis.[16][38] The OVA1 panel includes CA-125, beta-2 microglobulin, transferrin, apolipoprotein A1, and transthyretin. OVA1 above 5.0 in premenopausal people and 4.4 in postmenopausal people indicates a high risk for cancer.[18] A different set of laboratory tests is used for detecting sex cord-stromal tumors. High levels of testosterone or dehydroepiandrosterone sulfate, combined with other symptoms and high levels of inhibin A and inhibin B can be indicative of an SCST of any type.[20]

Current research is looking at ways to consider tumor marker proteomics in combination with other indicators of disease (i.e. radiology and/or symptoms) to improve diagnostic accuracy. The challenge in such an approach is that the disparate prevalence of ovarian cancer means that even testing with very high sensitivity and specificity will still lead to a number of false positive results, which in turn may lead to issues such as performing surgical procedures in which cancer is not found intraoperatively.[40] Genomics approaches have not yet been developed for ovarian cancer.[16]

CT scanning is preferred to assess the extent of the tumor in the abdominopelvic cavity, though magnetic resonance imaging can also be used.[13] CT scanning can also be useful for finding omental caking or differentiating fluid from solid tumor in the abdomen, especially in low malignant potential tumors. However, it may not detect smaller tumors. Sometimes, a chest x-ray is used to detect metastases in the chest or pleural effusion. Another test for metastatic disease, though it is infrequently used, is a barium enema, which can show if the rectosigmoid colon is involved in the disease. Positron emission tomography, bone scans, and paracentesis are of limited use; in fact, paracentesis can cause metastases to form at the needle insertion site and may not provide useful results.[18] However, paracentesis can be used in cases where there is no pelvic mass and ascites is still present.[18] A physician suspecting ovarian cancer may also perform mammography or an endometrial biopsy (in the case of abnormal bleeding) to assess the possibility of breast malignancies and endometrial malignancy, respectively. Vaginal ultrasonography is often the first-line imaging study performed when an adnexal mass is found. Several characteristics of an adnexal mass indicate ovarian malignancy; they usually are solid, irregular, multilocular, and/or large; and they typically have papillary features, central vessels, and/or irregular internal septations.[16] However, SCST has no definitive characteristics on radiographic study.[20]

To definitively diagnose ovarian cancer, a surgical procedure to inspect the abdomen is required. This can be an open procedure (laparotomy, incision through the abdominal wall) or keyhole surgery (laparoscopy). During this procedure, suspicious tissue is removed and sent for microscopic analysis. Usually, this includes a unilateral salpingo-oophorectomy, removal of a single affected ovary and Fallopian tube. Fluid from the abdominal cavity can also be analyzed for cancerous cells. If cancer is found, this procedure can also be used to determine the extent of its spread (which is a form of tumor staging).[14]

## Risk scoring [edit]

A widely recognized method of estimating the risk of malignant ovarian cancer is the risk of malignancy index (RMI), calculated based on an initial workup.[13][41] An RMI score of over 200 or 250 is generally felt to indicate high risk for ovarian cancer.[13][16]

The RMI is calculated as:

RMI = ultrasound score x menopausal score x CA-125 level in U/ml.[13]

Two methods can be used to determine the ultrasound score and menopausal score, with the resultant scores being referred to as RMI 1 and RMI 2, respectively, depending on what method is used.

| Feature | RMI 1[13] | RMI 2[16][42] |
|---|---|---|
| Ultrasound abnormalities:<br>▪ multilocular cyst<br>▪ solid areas<br>▪ ascites<br>▪ intra-abdominal metastases | 0 = no abnormality<br>1 = one abnormality<br>3 = two or more abnormalities | 0 = none<br>1 = one abnormality<br>4 = two or more abnormalities |

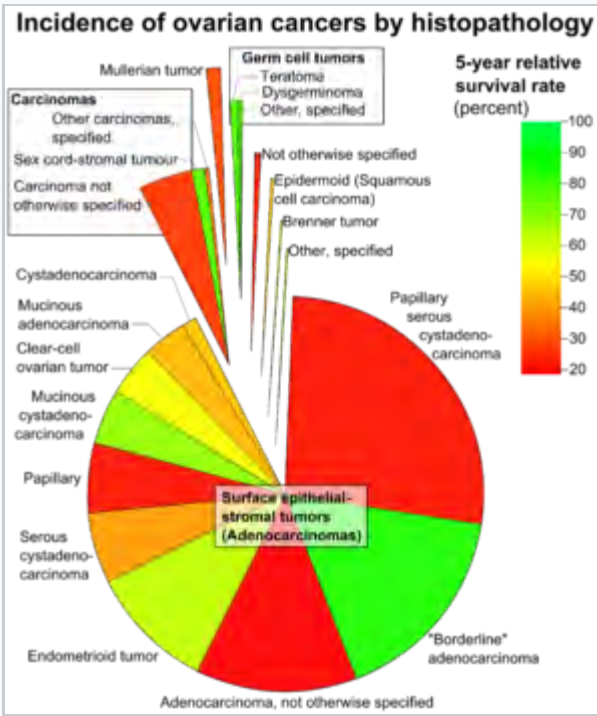
| | | |
|---|---|---|
| Menopausal score | 1 = premenopausal<br>3 = postmenopausal | 1 = premenopausal<br>4 = postmenopausal |
| CA-125 | Quantity in U/ml | Quantity in U/ml |

Another method for quantifying risk of ovarian cancer is the Risk of Ovarian Cancer Algorithm (ROCA), observes levels over time and determines if they are increasing rapidly enough to warrant transvaginal ultrasound.[18] The Risk of Ovarian Malignancy algorithm uses CA-125 levels and HE4 levels to calculate the risk of ovarian cancer; it may be more effective than RMI. The Assessment of Different Neoplasias in the Adnexa (ADNEX) model can be used to assess risk of malignancy in an adnexal mass, based on its characteristics and risk factors. The QCancer (Ovary) algorithm is used to predict likelihood of ovarian cancer from risk factors.[16]

## Pathology [edit]

Ovarian cancers are classified according to the microscopic appearance of their structures (histology or histopathology). Histology dictates many aspects of clinical treatment, management, and prognosis. The gross pathology of ovarian cancers is very similar regardless of histologic type: tumors have solid and cystic masses.[18] According to SEER, the types of ovarian cancers in women age 20 and over are:[43]

| Percent of ovarian cancers in women age 20+ | Percent of ovarian cancers in women age 20+ by subdivision | Histology | Five-year RSR |
|---|---|---|---|
| 89.7 | | Surface epithelial-stromal tumor (adenocarcinoma) | 54.4 |
| | 26.4 | Papillary serous cystadenocarcinoma | 21.0 |
| | 15.9 | "Borderline" adenocarcinoma (underestimated - short data collection interval) | 98.2 |
| | 12.6 | Adenocarcinoma, not otherwise specified | 18.3 |
| | 9.8 | Endometrioid tumor | 70.9 |
| | 5.8 | Serous cystadenocarcinoma | 44.2 |
| | 5.5 | Papillary | 21.0 |
| | 4.2 | Mucinous cystadenocarcinoma | 77.7 |
| | 4.0 | Clear-cell ovarian tumor | 61.5 |
| | 3.4 | Mucinous adenocarcinoma | 49.1 |
| | 1.3 | Cystadenocarcinoma | 50.7 |
| 5.5 | | Carcinoma | |



Ovarian cancers in women aged 20+, with area representing relative incidence and color representing five-year relative survival rate[43]

| | | | |
|---|---|---|---|
| | 4.1 | Carcinoma not otherwise specified | 26.8 |
| | 1.1 | Sex cord-stromal tumour | 87.8 |
| | 0.3 | Other carcinomas, specified | 37.3 |
| 1.7 | | Mullerian tumor | 29.8 |
| 1.5 | | Germ cell tumor | 91.0 |
| | 0.8 | Teratoma | 89.1 |
| | 0.5 | Dysgerminoma | 96.8 |
| | 0.3 | Other, specified | 85.1 |
| 0.6 | | Not otherwise specified | 23.0 |
| 0.5 | | Epidermoid (squamous cell carcinoma) | 51.3 |
| 0.2 | | Brenner tumor | 67.9 |
| 0.2 | | Other, specified | 71.7 |

Ovarian cancers are histologically and genetically divided into type I or type II. Type I cancers are of low histological grade, and include endometrioid, mucinous, and clear-cell carcinomas. Type II cancers are of higher histological grade and include serous carcinoma and carcinosarcoma.[13]

## Epithelial carcinoma [edit]

Surface epithelial-stromal tumour, also known as ovarian epithelial carcinoma, is the most common type of ovarian cancer, representing approximately 90% of ovarian cancers. It includes serous tumour, endometrioid tumor, and mucinous cystadenocarcinoma. Less common tumors are malignant Brenner tumor and transitional cell carcinoma of the ovary. Epithelial ovarian cancers develop from the epithelium, a layer of cells that covers the ovary.[44]

A pathological specimen of ovarian carcinoma

### Serous carcinoma [edit]

Most people with epithelial ovarian carcinoma, about two-thirds, have a serous carcinoma,[13] though this proportion is estimated as high as 80%.[16][45] Low-grade serous carcinoma is less aggressive than high-grade serous carcinomas, though it does not typically respond well to chemotherapy or hormonal treatments.[13] Serous carcinomas are thought to begin in the Fallopian tube.[44] Histologically, serous adenocarcinomas have psammoma bodies. Low-grade serous adenocarcinomas resemble Fallopian tube epithelium, whereas high-grade serous adenocarcinomas show anaplasia and nuclear atypia.[18]

50% of the time, serous carcinomas are bilateral, and in 85% of cases, they have spread beyond the ovary at the time of diagnosis. Most have a diameter over 15 cm.[45]

### Small-cell carcinoma [edit]

Small-cell ovarian carcinoma is rare and aggressive, with two main subtypes: hypercalcemic and pulmonary. It is typically fatal within 2 years of diagnosis. Hypercalcemic small cell ovarian carcinoma overwhelmingly affects those in their 20s, causes high blood calcium levels, and affects one ovary. Pulmonary small cell ovarian cancer usually affects both ovaries of older women and looks like oat-cell carcinoma of the lung.[18]

### Primary peritoneal carcinoma [edit]

*Main article: Primary peritoneal carcinoma*

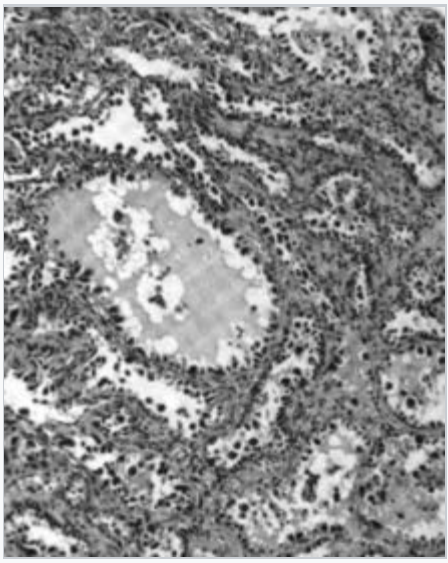
Primary peritoneal carcinomas develop from the peritoneum, a membrane that covers the abdominal cavity that has the same embryonic origin as the ovary. They are often discussed and classified with ovarian cancers when they affect the ovary.[44][46] They can develop even after the ovaries have been removed and may appear similar to mesothelioma.[18]

### Clear-cell carcinoma [edit]

Clear-cell ovarian carcinomas do not typically respond well to chemotherapy and may be related to endometriosis.[13] They represent approximately 5% of all endometrial cancers. Japanese women develop clear-cell ovarian cancer more frequently than other groups of women.[16]

### Clear-cell adenocarcinoma [edit]

Clear-cell adenocarcinomas are histopathologically similar to other clear cell carcinomas, with clear cells and hobnail cells. They represent approximately 5–10% of epithelial ovarian cancers and are associated with endometriosis in the pelvic cavity. They are typically early-stage and therefore curable by surgery, but advanced clear-cell adenocarcinomas (approximately 20%) have a poor prognosis and are often resistant to platinum chemotherapy.[18]



Hobnail cells seen in a clear cell carcinoma sample

### Endometrioid [edit]

Endometrioid adenocarcinomas make up approximately 15–20% of epithelial ovarian cancers. Because they are typically low-grade, endometrioid adenocarcinomas have a good prognosis. These tumors frequently co-occur with endometriosis or endometrial cancer.[18]

### Malignant mixed müllerian tumor (carcinosarcoma) [edit]

Mixed müllerian tumors make up less than 1% of ovarian cancer. They have epithelial and mesenchymal cells visible and tend to have a poor prognosis.[18]

### Mucinous [edit]

Mucinous tumors include mucinous adenocarcinoma and mucinous cystadenocarcinoma.[18]

### Mucinous adenocarcinoma [edit]

*Main article: Mucinous adenocarcinoma*

Mucinous adenocarcinomas make up 5–10% of epithelial ovarian cancers. Histologically, they are similar to intestinal or cervical adenocarcinomas, and are often actually metastases of appendiceal or colon cancers. Advanced mucinous adenocarcinomas have a poor prognosis, generally worse than serous tumors, and are often resistant to platinum chemotherapy, though they are rare.[18]

### Pseudomyxoma peritonei [edit]

*Main article: Pseudomyxoma peritonei*

*Pseudomyxoma peritonei* refers to a collection of encapsulated mucous or gelatinous material in the abdominopelvic cavity, which is very rarely caused by a primary mucinous ovarian tumor. More commonly, it is associated with ovarian metastases of intestinal cancer.[18]

### Undifferentiated epithelial [edit]

Undifferentiated cancers - those where the cell type cannot be determined - make up about 10% of epithelial ovarian cancers and have a comparatively poor prognosis.[18][44] When examined under the microscope, these tumors have very abnormal cells that are arranged in clumps or sheets. Usually there are [18]

recognizable clumps of serous cells inside the tumor.

### Malignant Brenner tumor [edit]

*Main article: Brenner tumor*

Malignant Brenner tumors are rare. Histologically, they have dense fibrous stroma with areas of transitional epithelium, and some squamous differentiation. To be classified as a malignant Brenner tumor, it must have Brenner tumor foci and transitional cell carcinoma. The transitional cell carcinoma component is typically poorly differentiated and resembles urinary tract cancer.[18]

### Transitional cell carcinoma [edit]

*Main article: Transitional cell carcinoma*

Transitional cell carcinomas represent less than 5% of ovarian cancers. Histologically, they appear similar to bladder carcinoma. The prognosis is intermediate - better than most epithelial cancers but worse than malignant Brenner tumors.[18]

## Sex cord-stromal tumor [edit]

*Main article: Sex cord-stromal tumor*

Sex cord-stromal tumor, including estrogen-producing granulosa cell tumor, the benign thecoma, and virilizing Sertoli-Leydig cell tumor or arrhenoblastoma, accounts for 7% of ovarian cancers. They occur most frequently in women between 50 and 69 years of age, but can occur in women of any age, including young girls. They are not typically aggressive and are usually unilateral;[14] they are therefore usually treated with surgery alone. Sex cord-stromal tumors are the main hormone-producing ovarian tumors.[20]

Several different cells from the mesenchyme can give rise to sex-cord or stromal tumors. These include fibroblasts and endocrine cells. The symptoms of a sex-cord or stromal ovarian tumor can differ from other types of ovarian cancer. Common signs and symptoms include ovarian torsion, hemorrhage from or rupture of the tumor, an abdominal mass, and hormonal disruption. In children, isosexual precocious pseudopuberty may occur with granulosa cell tumors since they produce estrogen. These tumors cause abnormalities in menstruation (excessive bleeding, infrequent menstruation, or no menstruation) or postmenopausal bleeding. Because these tumors produce estrogen, they can cause or occur at the same time as endometrial cancer or breast cancer. Other sex-cord/stromal tumors present with distinct symptoms. Sertoli-Leydig cell tumors cause virilization and excessive hair growth due to the production of testosterone and androstenedione, which can also cause Cushing's syndrome in rare cases. Also, sex-cord stromal tumors occur that do not cause a hormonal imbalance, including benign fibromas, which cause ascites and hydrothorax.[14] With germ cell tumors, sex cord-stromal tumors are the most common ovarian cancer diagnosed in women under 20.[20]

### Granulosa cell tumor [edit]

Granulosa cell tumors are the most common sex-cord stromal tumors, making up 70% of cases, and are divided into two histologic subtypes: adult granulosa cell tumors, which develop in women over 50, and juvenile granulosa tumors, which develop before puberty or before the age of 30. Both develop in the ovarian follicle from a population of cells that surrounds germinal cells.[20]

### Adult granulosa cell tumor [edit]

Adult granuosa cell tumors are characterized by later onset (30+ years, 50 on average). These tumors produce high levels of estrogen, which causes its characteristic symptoms: menometrorrhagia; endometrial hyperplasia; tender, enlarged breasts; postmenopausal bleeding; and secondary amenorrhea. The mass of the tumor can cause other symptoms, including abdominal pain and distension, or symptoms similar to an ectopic pregnancy if the tumor bleeds and ruptures.[20]

### Juvenile granulosa cell tumor [edit]

### Sertoli-Leydig cell tumor [edit]

Sertoli-Leydig tumors are most common in women before the age of 30, and particularly common before puberty.[20]

### Sclerosing stromal tumors [edit]

Sclerosing stromal tumors typically occur in girls before puberty or women before the age of 30.[20]

## Germ cell tumor [edit]

*Main article: Germ cell tumor*

Germ cell tumors of the ovary develop from the ovarian germ cells.[44] Germ cell tumor accounts for about 30% of ovarian tumors, but only 5% of ovarian cancers, because most germ-cell tumors are teratomas and most teratomas are benign. Malignant teratomas tend to occur in older women, when one of the germ layers in the tumor develops into a squamous cell carcinoma.[14] Germ-cell tumors tend to occur in young women (20s–30s) and girls, making up 70% of the ovarian cancer seen in that age group.[19] Germ-cell tumors can include dysgerminomas, teratomas, yolk sac tumors/endodermal sinus tumors, and choriocarcinomas, when they arise in the ovary. Some germ-cell tumors have an isochromosome 12, where one arm of chromosome 12 is deleted and replaced with a duplicate of the other.[14] Most germ-cell cancers have a better prognosis than other subtypes and are more sensitive to chemotherapy. They are more likely to be stage I at diagnosis.[20] Overall, they metastasize more frequently than epithelial ovarian cancers. In addition, the cancer markers used vary with tumor type: choriocarcinomas are monitored with beta-HCG and endodermal sinus tumors with alpha-fetoprotein.[14]

Germ-cell tumors are typically discovered when they become large, palpable masses. However, like sex cord tumors, they can cause ovarian torsion or hemorrhage and, in children, isosexual precocious puberty. They frequently metastasize to nearby lymph nodes, especially para-aortic and pelvic lymph nodes.[14] The most common symptom of germ cell tumors is subacute abdominal pain caused by the tumor bleeding, necrotizing, or stretching the ovarian capsule. If the tumor ruptures, causes significant bleeding, or torses the ovary, it can cause acute abdominal pain, which occurs in less than 10% of those with germ-cell tumors. They can also secrete hormones which change the menstrual cycle. In 25% of germ-cell tumors, the cancer is discovered during a routine examination and does not cause symptoms.[20]

Diagnosing germ cell tumors may be difficult because the normal menstrual cycle and puberty can cause pain and pelvic symptoms, and a young woman may even believe these symptoms to be those of pregnancy, and not seek treatment due to the stigma of teen pregnancy. Blood tests for alpha-fetoprotein, karyotype, human chorionic gonadotropin, and liver function are used to diagnose germ cell tumor and potential co-occurring gonadal dysgenesis. A germ cell tumor may be initially mistaken for a benign ovarian cyst.[20]

### Dysgerminoma [edit]

*Main article: Dysgerminoma*

Dysgerminoma accounts for 35% of ovarian cancer in young women and is the most likely germ cell tumor to metastasize to the lymph nodes; nodal metastases occur in 25–30% of cases.[19][20] These tumors may have mutations in the *KIT* gene, a mutation known for its role in gastrointestinal stromal tumor. People with an XY karyotype and ovaries (gonadal dysgenesis) or an X,0 karyotype and ovaries (Turner syndrome) who develop a unilateral dysgerminoma are at risk for a gonadoblastoma in the other ovary, and in this case, both ovaries are usually removed when a unilateral dysgerminoma is discovered to avoid the risk of another malignant tumor. Gonadoblastomas in people with Swyer or Turner syndrome become malignant in approximately 40% of cases. However, in general, dysgerminomas are bilateral 10–20% of the time.[14][20]

They are composed of cells that cannot differentiate further and develop directly from germ cells or from gonadoblastomas. Dysgerminomas contain syncytiotrophoblasts in approximately 5% of cases, and can therefore cause elevated hCG levels. On gross appearance, dysgerminomas are typically pink to tan-colored, have multiple lobes, and are solid. Microscopically, they appear identical to seminomas and very close to embryonic primordial germ cells, having large, polyhedral, rounded clear cells. The nuclei are

uniform and round or square with prominent nucleoli and the cytoplasm has high levels of glycogen. Inflammation is another prominent histologic feature of dysgerminomas.[20]

### Choriocarcinoma [edit]

*Main article: Choriocarcinoma*

Choriocarcinoma can occur as a primary ovarian tumor developing from a germ cell, though it is usually a gestational disease that metastasizes to the ovary. Primary ovarian choriocarcinoma has a poor prognosis and can occur without a pregnancy. They produce high levels of hCG and can cause early puberty in children or menometrorrhagia (irregular, heavy menstruation) after menarche.[20]

### Immature (solid) teratoma [edit]

*Main article: Immature teratoma*

Immature, or solid, teratomas are the most common type of ovarian germ cell tumor, making up 40–50% of cases. Teratomas are characterized by the presence of disorganized tissues arising from all three embryonic germ layers: ectoderm, mesoderm, and endoderm; immature teratomas also have undifferentiated stem cells that make them more malignant than mature teratomas (dermoid cysts). The different tissues are visible on gross pathology and often include bone, cartilage, hair, mucus, or sebum, but these tissues are not visible from the outside, which appears to be a solid mass with lobes and cysts. Histologically, they have large amounts of neuroectoderm organized into sheets and tubules along with glia; the amount of neural tissue determines the histologic grade. Immature teratomas usually only affect one ovary (10% co-occur with dermoid cysts) and usually metastasize throughout the peritoneum. They can also cause mature teratoma implants to grow throughout the abdomen in a disease called growing teratoma syndrome; these are usually benign but will continue to grow during chemotherapy, and often necessitate further surgery. Unlike mature teratomas, immature teratomas form many adhesions, making them less likely to cause ovarian torsion. There is no specific marker for immature teratomas, but carcinoembryonic antigen (CEA), CA-125, CA19-9, or AFP can sometimes indicate an immature teratoma.[20]

Stage I teratomas make up the majority (75%) of cases and have the best prognosis, with 98% of patients surviving 5 years; if a Stage I tumor is also grade 1, it can be treated with unilateral surgery only. Stage II though IV tumors make up the remaining quarter of cases and have a worse prognosis, with 73–88% of patients surviving 5 years.[20]

### Mature teratoma (dermoid cyst) [edit]

*Main article: Dermoid cyst*

Mature teratomas, or dermoid cysts, are rare tumors consisting of mostly benign tissue that develop after menopause. The tumors consist of disorganized tissue with nodules of malignant tissue, which can be of various types. The most common malignancy is squamous cell carcinoma, but adenocarcinoma, basal-cell carcinoma, carcinoid tumor, neuroectodermal tumor, malignant melanoma, sarcoma, sebaceous tumor, and struma ovarii can also be part of the dermoid cyst. They are treated with surgery and adjuvant platinum chemotherapy or radiation.[20]

### Yolk sac tumor/endodermal sinus tumor [edit]

*Main article: Yolk sac tumor*

Yolk sac tumors, formerly called endodermal sinus tumors, make up approximately 10–20% of ovarian germ cell malignancies, and have the worst prognosis of all ovarian germ cell tumors. They occur both before menarche (in one-third of cases) and after menarche (the remaining two-thirds of cases). Half of people with yolk sac tumors are diagnosed in stage I. Typically, they are unilateral until metastasis, which occurs within the peritoneal cavity and via the bloodstream to the lungs. Yolk sac tumors grow quickly and recur easily, and are not easily treatable once they have recurred. Stage I yolk sac tumors are highly treatable, with a 5-year disease free survival rate of 93%, but stage II-IV tumors are less treatable, with survival rates of 64–91%.[20]

Their gross appearance is solid, friable, and yellow, with necrotic and hemorrhagic areas. They also often contain cysts that can degenerate or rupture. Histologically, yolk sac tumors are characterized by the presence of Schiller-Duval bodies (which are pathognomonic for yolk sac tumors) and a reticular pattern. Yolk sac tumors commonly secrete alpha-fetoprotein and can be immunohistochemically stained for its presence; the level of alpha-fetoprotein in the blood is a useful marker of recurrence.[20]

### Embryonal carcinoma [edit]

*Main article: Embryonal carcinoma*

Embryonal carcinomas, a rare tumor type usually found in mixed tumors, develop directly from germ cells but are not terminally differentiated; in rare cases they may develop in dysgenetic gonads. They can develop further into a variety of other neoplasms, including choriocarcinoma, yolk sac tumor, and teratoma. They occur in younger people, with an average age at diagnosis of 14, and secrete both alpha-fetoprotein (in 75% of cases) and hCG.[20]

Histologically, embryonal carcinoma appears similar to the embryonic disc, made up of epithelial, anaplastic cells in disorganized sheets, with gland-like spaces and papillary structures.[20]

### Polyembryoma [edit]

*Main article: Polyembryoma*

Polyembryomas, the most immature form of teratoma and very rare ovarian tumors, are histologically characterized by having several embryo-like bodies with structures resembling a germ disk, yolk sac, and amniotic sac. Syncytiotrophoblast giant cells also occur in polyembryomas.[20]

## Squamous cell carcinoma [edit]

Primary ovarian squamous cell carcinomas are rare and have a poor prognosis when advanced. More typically, ovarian squamous cell carcinomas are cervical metastases, areas of differentiation in an endometrioid tumor, or derived from a mature teratoma.[18]

## Mixed tumors [edit]

Mixed tumors contain elements of more than one of the above classes of tumor histology. To be classed as a mixed tumor, the minor type must make up more than 10% of the tumor.[16] Though mixed carcinomas can have any combination of cell types, mixed ovarian cancers are typically serous/endometrioid or clear cell/endometrioid.[18] Mixed germ cell tumors make up approximately 25–30% of all germ cell ovarian cancers, with combinations of dysgerminoma, yolk sac tumor, and/or immature teratoma. The prognosis and treatment vary based on the component cell types.[20]

## Secondary ovarian cancer [edit]

Ovarian cancer can also be a secondary cancer, the result of metastasis from a primary cancer elsewhere in the body.[14] About 7% of ovarian cancers are due to metastases, while the rest are primary cancers.[*citation needed*] Common primary cancers are breast cancer, colon cancer, appendiceal cancer, and stomach cancer (primary gastric cancers that metastasize to the ovary are called Krukenberg tumors).[14] Krukenberg tumors have signet ring cells and mucinous cells.[18] Endometrial cancer and lymphomas can also metastasize to the ovary.[45]

## Low malignant potential tumors [edit]

Low malignant potential ovarian tumors, also called borderline tumors, have some benign and some malignant features.[18] LMP tumors make up approximately 10%-15% of all ovarian tumors.[16][44] They develop earlier than epithelial ovarian cancer, around the age of 40–49. They typically do not have extensive invasion; 10% of LMP tumors have areas of stromal microinvasion (<3mm, <5% of tumor). LMP

tumors have other abnormal features, including increased mitosis, changes in cell size or nucleus size, abnormal nuclei, cell stratification, and small projections on cells (papillary projections). Serous and/or mucinous characteristics can be seen on histological examination, and serous histology makes up the overwhelming majority of advanced LMP tumors. More than 80% of LMP tumors are Stage I; 15% are stage II and III and less than 5% are stage IV.[18] Implants of LMP tumors are often non-invasive.[44]

## Staging [edit]

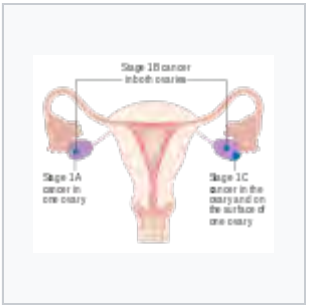
Ovarian cancer is staged using the FIGO staging system and uses information obtained after surgery, which can include a total abdominal hysterectomy via midline laparotomy, removal of (usually) both ovaries and Fallopian tubes, (usually) the omentum, pelvic (peritoneal) washings, assessment of retroperitoneal lymph nodes (including the pelvic and para-aortic lymph nodes), appendectomy in suspected mucinous tumors, and pelvic/peritoneal biopsies for cytopathology.[13][14][16][47] Around 30% of ovarian cancers that appear confined to the ovary have metastasized microscopically, which is why even stage-I cancers must be staged completely.[14] 22% of cancers presumed to be stage I are observed to have lymphatic metastases.[16] The AJCC stage is the same as the FIGO stage. The AJCC staging system describes the extent of the primary tumor (T), the absence or presence of metastasis to nearby lymph nodes (N), and the absence or presence of distant metastasis (M).[48] The most common stage at diagnosis is stage IIIc, with over 70% of diagnoses.[14]

**FIGO stages of ovarian cancer**[13][47]

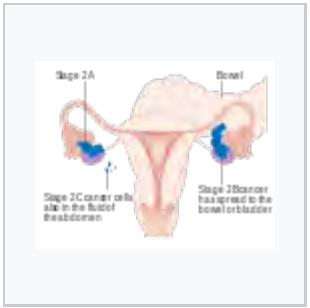
| Stage | | | | Description |
|---|---|---|---|---|
| I | | | | Cancer is completely limited to the ovary |
| | IA | | | involves one ovary, capsule intact, no tumor on ovarian surface, negative washings |
| | IB | | | involves both ovaries; capsule intact; no tumor on ovarian surface; negative washings |
| | IC | | | tumor involves one or both ovaries |
| | IC1 | | | surgical spill |
| | IC2 | | | capsule has ruptured or tumor on ovarian surface |
| | IC3 | | | positive ascites or washings |
| II | | | | pelvic extension of the tumor (must be confined to the pelvis) or primary peritoneal tumor, involves one or both ovaries |
| | IIA | | | tumor found on uterus or fallopian tubes |
| | IIB | | | tumor elsewhere in the pelvis |
| III | | | | cancer found outside the pelvis or in the retroperitoneal lymph nodes, involves one or both ovaries |
| | IIIA | | | metastasis in retroperitoneal lymph nodes or microscopic extrapelvic metastasis |
| | | IIIA1 | | metastasis in retroperitoneal lymph nodes |

Ovarian adenocarcinoma deposit in the mesentery of the small bowel

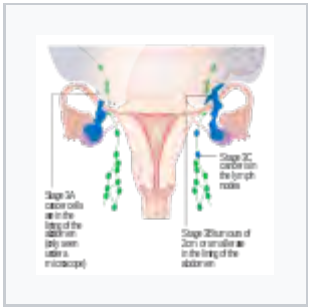
| | | | | |
|---|---|---|---|---|
| | | | IIIA1(i) | the metastasis is less than 10 mm in diameter |
| | | | IIIA1(ii) | the metastasis is greater than 10 mm in diameter |
| | | IIIA2 | | microscopic metastasis in the peritoneum, regardless of retroperitoneal lymph node status |
| | IIIB | | | metastasis in the peritoneum less than or equal to 2 cm in diameter, regardless of retroperitoneal lymph node status; or metastasis to liver or spleen capsule |
| | IIIC | | | metastasis in the peritoneum greater than 2 cm in diameter, regardless of retroperitoneal lymph node status; or metastasis to liver or spleen capsule |
| IV | | | | distant metastasis (i.e. outside of the peritoneum) |
| | IVA | | | pleural effusion containing cancer cells |
| | IVB | | | metastasis to distant organs (including the parenchyma of the spleen or liver), or metastasis to the inguinal and extra-abdominal lymph nodes |



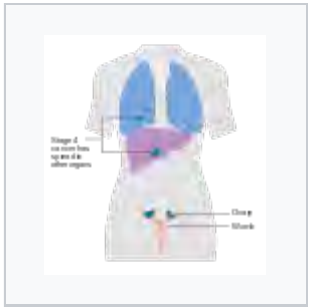
Stage 1 ovarian cancer



Stage 2 ovarian cancer



Stage 3 ovarian cancer



Stage 4 ovarian cancer

The AJCC/TNM staging system indicates where the tumor has developed, spread to lymph nodes, and metastasis.[16]

**AJCC/TNM stages of ovarian cancer**[16]

| Stage | | | Description |
|---|---|---|---|
| T | | | Primary tumor |
| | Tx | | Cannot be assessed |
| | T0 | | No evidence |
| | T1 | | Tumor limited to ovary/ovaries |
| | | T1a | One ovary with intact capsule, no surface tumor, and negative ascites/peritoneal washings |
| | | T1b | Both ovaries with intact capsules, no surface tumor, and negative ascites/peritoneal washings |
| | | T1c | One or both ovaries with ruptured capsule or capsules, surface tumor, positive ascites/peritoneal washings |

| | | | |
|---|---|---|---|
| | T2 | | Tumor is in ovaries and pelvis (extension or implantation) |
| | | T2a | Expansion to uterus or Fallopian tubes, negative ascites/peritoneal washings |
| | | T2b | Expansion in other pelvic tissues, negative ascites/peritoneal washings |
| | | T2c | Expansion to any pelvic tissue, positive ascites/peritoneal washings |
| | T3 | | Tumor is in ovaries and has metastasized outside the pelvis to the peritoneum (including the liver capsule) |
| | | T3a | Microscopic metastasis |
| | | T3b | Macroscopic metastasis less than 2 cm diameter |
| | | T3c | Macroscopic metastasis greater than 2 cm diameter |
| N | | | Regional lymph node metastasis |
| | Nx | | Cannot be assessed |
| | N0 | | No metastasis |
| | N1 | | Metastasis present |
| M | | | Distant metastasis |
| | M0 | | No metastasis |
| | M1 | | Metastasis present (excluding liver capsule, including liver parenchyma and cytologically confirmed pleural effusion) |

The AJCC/TNM stages can be correlated with the FIGO stages:[16]

| FIGO | T | N | M |
|---|---|---|---|
| I | T1 | N0 | M0 |
| IA | T1a | N0 | M0 |
| IB | T1b | N0 | M0 |
| IC | T1c | N0 | M0 |
| II | T2 | N0 | M0 |
| IIA | T2a | N0 | M0 |
| IIB | T2b | N0 | M0 |
| IIC | T2c | N0 | M0 |
| III | T3 | N0 | M0 |
| IIIA | T3a | N0 | M0 |
| IIIB | T3b | N0 | M0 |
| IIIC | T3c | N0/N1 | M0 |
| IV | Any | Any | M1 |

In addition to being staged, like all cancers, ovarian cancer is also graded. The histologic grade of a tumor measures how abnormal or malignant its cells look under the microscope. The four grades indicate the likelihood of the cancer to spread and the higher the grade, the more likely for this to occur. Grade 0 is used to describe noninvasive tumors. Grade 0 cancers are also referred to as borderline tumors.[49] Grade 1 tumors have well differentiated cells (look very similar to the normal tissue) and are the ones with the best prognosis. Grade 2 tumors are also called moderately well-differentiated and they are made up of cells that resemble the normal tissue. Grade 3 tumors have the worst prognosis and their cells are abnormal, referred to as poorly differentiated.[50]

Metastasis in ovarian cancer is very common in the abdomen, and occurs via exfoliation, where cancer cells

burst through the ovarian capsule and are able to move freely throughout the peritoneal cavity. Ovarian cancer metastases usually grow on the surface of organs rather than the inside; they are also common on the omentum and the peritoneal lining. Cancer cells can also travel through the lymphatic system and metastasize to lymph nodes connected to the ovaries via blood vessels; i.e. the lymph nodes along the infundibulopelvic ligament, the broad ligament, and the round ligament. The most commonly affected groups include the paraaortic, hypogastric, external iliac, obturator, and inguinal lymph nodes. Usually, ovarian cancer does not metastasize to the liver, lung, brain, or kidneys unless it is recurrent disease; this differentiates ovarian cancer from many other forms of cancer.[18]

## Screening [edit]

The only screening recommended for all women is an annual pelvic examination. This is not very effective in detecting early ovarian cancer because it is usually only palpable in advanced stages.[18] Ovarian cancer screening is of high clinical interest because the disease is not typically detectable at its early stages, when it is the most curable. Screening is not recommended using CA-125 measurements, HE4 levels, ultrasound, or adnexal palpation in women who are at average risk. Screening for any type of cancer must be accurate and reliable—it needs to accurately detect the disease and it must not give false positive results in people who do not have cancer.[14][51]

Ovarian cancer has low prevalence, even in the high-risk group of women from the ages of 50 to 60 (about one in 2000), and screening of women with average risk is more likely to give ambiguous results than detect a problem which requires treatment. Because ambiguous results are more likely than detection of a treatable problem, and because the usual response to ambiguous results is invasive interventions, in women of average risk, the potential harms of having screening without an indication outweigh the potential benefits. The purpose of screening is to diagnose ovarian cancer at an early stage, when it is more likely to be treated successfully.[14][51]

Screening with transvaginal ultrasound, pelvic examination, and CA-125 levels can be used instead of preventative surgery in women who have BRCA1 or BRCA2 mutations. This strategy has shown some success.[18]

## Prevention [edit]

People with strong genetic risk for ovarian cancer may consider the surgical removal of their ovaries as a preventative measure. This is often done after completion of childbearing years. This reduces the chances of developing both breast cancer (by around 50%) and ovarian cancer (by about 96%) in people at high risk. Women with *BRCA* gene mutations usually also have their Fallopian tubes removed at the same time (salpingo-oophorectomy), since they also have an increased risk of Fallopian tube cancer. However, these statistics may overestimate the risk reduction because of how they have been studied.[14][51]

People with a significant family history for ovarian cancer are often referred to a genetic counselor to see if they should be tested for BRCA mutations.[18]

## Management [edit]

Treatment usually involves chemotherapy and surgery, and sometimes radiotherapy, regardless of the subtype of ovarian cancer.[44] Surgical treatment may be sufficient for well-differentiated malignant tumors and confined to the ovary. Addition of chemotherapy may be required for more aggressive tumors confined to the ovary. For patients with advanced disease, a combination of surgical reduction with a combination chemotherapy regimen is standard. Borderline tumors, even following spread outside of the ovary, are managed well with surgery, and chemotherapy is not seen as useful.[52] Second-look surgery and maintenance chemotherapy have not been shown to provide benefit.[18]

### Surgery [edit]

Surgery is the preferred treatment and is frequently necessary to obtain a tissue specimen for differential diagnosis via its histology. The type of surgery depends upon how widespread the cancer is when diagnosed (the cancer stage), as well as the presumed type and grade of cancer. The surgeon, who is usually a specialized gynecologic oncology surgeon, may remove one (unilateral oophorectomy) or both ovaries (bilateral oophorectomy), the Fallopian tubes (salpingectomy), the uterus (hysterectomy), and the omentum (omentectomy). Typically, all of these are removed. For low-grade, unilateral stage-IA cancers, only the involved ovary (which must be unruptured) and Fallopian tube will be removed. This can be done especially in young people who wish to preserve their fertility. However, a risk of microscopic metastases exists and staging must be completed.[13] If any metastases are found, a second surgery to remove the remaining ovary and uterus is needed.[52] Tranexamic acid can be administered prior to surgery to reduce the need for blood transfusions due to blood loss during the surgery.[16]

If a tumor in a premenopausal woman is determined to be a low malignant potential tumor during surgery, and it is clearly stage I cancer, only the affected ovary is removed. For postmenopausal women with low malignant potential tumors, hysterectomy with bilateral salpingo-oophorectomy is still the preferred option. During staging, the appendix should be examined or removed. This is particularly important with mucinous tumors.[18] In children or adolescents with ovarian cancer, surgeons typically attempt to preserve one ovary to allow for the completion of puberty, but if the cancer has spread, this is not always possible. Dysgerminomas in particular tend to affect both ovaries: 8–15% of dysgerminomas are present in both ovaries.[19] People with low-grade (well-differentiated) tumors are typically treated only with surgery,[14] which is often curative.[44] In general, germ cell tumors can be treated with unilateral surgery unless the cancer is widespread or fertility is not a factor.[20]

In advanced cancers, where complete removal is not an option, as much tumor as possible is removed in a procedure called debulking surgery. This surgery is not always successful, and is less likely to be successful in women with extensive metastases in the peritoneum, stage- IV disease, cancer in the transverse fissure of the liver, mesentery, or diaphragm, and large areas of ascites. Debulking surgery is usually only done once.[13] More complete debulking is associated with better outcomes: women with no macroscopic evidence of disease after debulking have a median survival of 39 months, as opposed to 17 months with less complete surgery.[14] By removing metastases, many cells that are resistant to chemotherapy are removed, and any clumps of cells that have died are also removed. This allows chemotherapy to better reach the remaining cancer cells, which are more likely to be fast-growing and therefore chemosensitive.[18]

Interval debulking surgery is another protocol used, where neoadjuvant chemotherapy is given, debulking surgery is performed, and chemotherapy is finished after debulking.[52] Though no definitive studies have been completed, it is shown to be approximately equivalent to primary debulking surgery in terms of survival, and shows slightly lower morbidity.[18]

There are several different surgical procedures that can be employed to treat ovarian cancer. For stage I and II cancer, laparascopic (keyhole) surgery can be used, but metastases may not be found. For advanced cancer, laparoscopy is not used, since debulking metastases requires access to the entire peritoneal cavity. Depending on the extent of the cancer, procedures may include a bilateral salpingo-oophorectomy, biopsies throughout the peritoneum and abdominal lymphatic system, omentectomy, splenectomy, bowel resection, diaphragm stripping or resection, appendectomy, or even a posterior pelvic exenteration.[18]

To fully stage ovarian cancer, lymphadenectomy should be included in the surgery, but a significant survival benefit to this practice may not happen.[13] This is particularly important in germ cell tumors because they frequently metastasize to nearby lymph nodes.[14]

If ovarian cancer recurs, secondary surgery is sometimes a treatment option. This depends on how easily the tumor can be removed, how much fluid has accumulated in the abdomen, and overall health.[13] It can be helpful in people who had their first surgery done by a generalist and in epithelial ovarian cancer.[16] Secondary surgery can be effective in dysgerminomas and immature teratomas.[20]

The major side effect of an oophorectomy in younger women is early menopause, which can cause osteoporosis. After surgery, hormone replacement therapy can be considered, especially in younger women.

This therapy can consist of a combination of estrogen and progesterone, or estrogen alone. Estrogen alone is safe after hysterectomy; when the uterus is still present, unopposed estrogen dramatically raises the risk of endometrial cancer.[13] Estrogen therapy after surgery does not change survival rates.[16] People having ovarian cancer surgery are typically hospitalized afterwards for 3–4 days and spend around a month recovering at home.[53] Surgery outcomes are best at hospitals that do a large number of ovarian cancer surgeries.[18]

It is unclear if laparoscopy or laparotomy is better or worse for FIGO stage I ovarian cancer.[54][*needs update*] There is also no apparent difference between total abdominal hysterectomy and supracervical hysterectomy for advanced cancers. Approximately 2.8% of people having a first surgery for advanced ovarian cancer die within two weeks of the surgery (2.8% perioperative mortality rate).[16] More aggressive surgeries are associated with better outcomes in advanced (stage III or IV) ovarian cancer.[18]

## Chemotherapy [edit]

Chemotherapy has been a general standard of care for ovarian cancer for decades, although with highly variable protocols. Chemotherapy is used after surgery to treat any residual disease, if appropriate. In some cases, there may be reason to perform chemotherapy first, followed by surgery. This is called "neoadjuvant chemotherapy", and is common when a tumor cannot be completely removed or optimally debulked via surgery. Though it has not been shown to increase survival, it can reduce the risk of complications after surgery. If a unilateral salpingo-oophorectomy or other surgery is performed, additional chemotherapy, called "adjuvant chemotherapy", can be given.[13][16] Adjuvant chemotherapy is used in stage 1 cancer typically if the tumor is of a high histologic grade (grade 3) or the highest substage (stage 1c), provided the cancer has been optimally staged during surgery.[16][52] Bevacizumab may be used as an adjuvant chemotherapy if the tumor is not completely removed during surgery or if the cancer is stage IV; it can extend progression-free survival but has not been shown to extend overall survival.[16] Chemotherapy is curative in approximately 20% of advanced ovarian cancers;[18] it is more often curative with malignant germ cell tumors than epithelial tumors.[20]

Chemotherapy in ovarian cancer typically consists of platins, a group of platinum-based drugs, combined with non-platins. Common therapies can include paclitaxel, cisplatin, topotecan, doxorubicin, epirubicin, and gemcitabine. Carboplatin is typically given in combination with either paclitaxel or docetaxel; the typical combination is carboplatin with paclitaxel.[13][16] Carboplatin is superior to cisplatin in that it is less toxic and has fewer side effects, generally allowing for an improved quality of life in comparison, though both are similarly effective.[16] Three-drug regimens have not been found to be more effective,[13] and platins alone or nonplatins alone are less effective than platins and nonplatins in combination.[16] Chemotherapy can be given intravenously or in the peritoneal cavity.[14] Though intraperitoneal chemotherapy is associated with longer progression-free survival and overall survival, it also causes more adverse side effects than intravenous chemotherapy.[16] It is mainly used when the cancer has been optimally debulked. Intraperitoneal chemotherapy can be highly effective because ovarian cancer mainly spreads inside the peritoneal cavity, and higher doses of the drugs can reach the tumors this way.[18]

Chemotherapy can cause anemia; intravenous iron has been found to be more effective than oral iron supplements in reducing the need for blood transfusions.[16] Typical cycles of treatment involve one treatment every 3 weeks, repeated for 6 weeks or more.[55] Fewer than 6 weeks (cycles) of treatment is less effective than 6 weeks or more.[16] Germ-cell malignancies are treated differently than other ovarian cancers - a regimen of bleomycin, etoposide, and cisplatin (BEP) is used with 5 days of chemotherapy administered every 3 weeks for 3 to 4 cycles.[14][20] Chemotherapy for germ cell tumors has not been shown to cause amenorrhea, infertility, birth defects, or miscarriage.[20] Maintenance chemotherapy has not been shown to be effective.[16]

In people with *BRCA* mutations, platinum chemotherapy is more effective.[13] Germ-cell tumors and malignant sex-cord/stromal tumors are treated with chemotherapy, though dysgerminomas and sex-cord tumors are not typically very responsive.[14][19]

## Platinum-sensitive or platinum-resistant [edit]

If ovarian cancer recurs, it is considered partially platinum-sensitive or platinum-resistant, based on the time since the last recurrence treated with platins: partially platinum-sensitive cancers recurred 6–12 months after last treatment, and platinum-resistant cancers have an interval of less than 6 months. Second-line chemotherapy should be given only after the cancer becomes symptomatic, because no difference in survival is seen between treating asymptomatic (elevated CA-125) and symptomatic recurrences.

For platinum-sensitive tumors, platins are the drugs of choice for second-line chemotherapy, in combination with other cytotoxic agents. Regimens include carboplatin combined with pegylated liposomal doxorubicin, gemcitabine, or paclitaxel.[14] Carboplatin-doublet therapy can be combined with paclitaxel for increased efficacy in some cases. Another potential adjuvant therapy for platinum-sensitive recurrences is olaparib, which may improve progression-free survival but has not been shown to improve overall survival.[16] (Olaparib, a PARP inhibitor, was approved by the US FDA for use in BRCA-associated ovarian cancer that had previously been treated with chemotherapy.[56]) For recurrent germ cell tumors, an additional 4 cycles of BEP chemotherapy is the first-line treatment for those tho have been treated with surgery or platins.

If the tumor is determined to be platinum-resistant, vincristine, dactinomycin, and cyclophosphamide (VAC) or some combination of paclitaxel, gemcitabine, and oxaliplatin may be used as a second-line therapy.[20]

For platinum-resistant tumors, there are no high-efficacy chemotherapy options. Single-drug regimens (doxorubicin or topotecan) do not have high response rates,[13] but single-drug regimens of topotecan, pegylated liposomal doxorubicin, or gemcitabine are used in some cases.[14][16] Topotecan cannot be used in people with an intestinal blockage. Paclitaxel used alone is another possible regimen, or it may be combined with liposomal doxorubicin, gemcitabine, cisplatin, topotecan, etoposide, or cyclophosphamide.[55] ( See also Palliative care below.)

## Radiation therapy [edit]

Dysgerminomas are most effectively treated with radiation,[19] though this can cause infertility and is being phased out in favor of chemotherapy.[14] Radiation therapy does not improve survival in people with well-differentiated tumors.[14]

In stage 1c and 2 cancers, radiation therapy is used after surgery if there is the possibility of residual disease in the pelvis but the abdomen is cancer-free. Radiotherapy can also be used in palliative care of advanced cancers. A typical course of radiotherapy for ovarian cancer is 5 days a week for 3–4 weeks. Common side effects of radiotherapy include diarrhea, constipation, and frequent urination.[57]

## Hormonal therapy [edit]

Despite the fact that 60% of ovarian tumors have estrogen receptors, ovarian cancer is only rarely responsive to hormonal treatments. Estrogen alone does not have an effect on the cancer, and tamoxifen and letrozole are rarely effective.[13]

## Immunotherapy [edit]

Immunotherapy is a topic of current research in ovarian cancer. In some cases, the antibody drug bevacizumab, though still a topic of active research, is used to treat advanced cancer along with chemotherapy.[52] It has been approved for this use in the European Union.[58]

## Follow-up [edit]

Specific follow-up depends on, for example, the type and stage of ovarian cancer, the treatment, and the presence of any symptoms. Usually, a check-up appointment is made about every 2 to 3 months initially, followed by twice per year for up to 5 years.[59] For epithelial ovarian cancers, the most common test upon follow-up is CA-125 level. However, treatment based only on elevated CA-125 levels and not any symptoms

can increase side effects without any prolongation of life, so the implication of the outcome of a CA-125 test should be discussed before taking it.[60] The recommendation as of 2014 is recurrent cancer may be present if the CA-125 level is twice normal.[13] Treating a recurrence detected by CA-125 does not improve survival.[16]

For women with germ-cell tumors, follow-up tests generally include alpha-fetoprotein (AFP) and/or human chorionic gonadotropin. For women with stromal cancers, tests for hormones like estrogen, testosterone, and inhibin are sometimes helpful.[60] Inhibin can also be useful for monitoring the progress of sex-cord tumors, along with mullerian inhibiting substance. AFP can also be used to monitor Sertoli-Leydig tumors.[14] In dysgerminomas, lactate dehydrogenase and its two isozymes (LDH-1 and LDH-2) are used to test for recurrence.[20]

Women with ovarian cancer should not have routine surveillance imaging to monitor the cancer unless new symptoms appear or tumor markers begin rising.[61] Imaging without these indications is discouraged because it is unlikely to detect a recurrence, improve survival, and because it has its own costs and side effects.[61] However, CT imaging can be used if desired, though this is not common.[13] If a tumor is easily imaged, imaging may be used to monitor the progress of treatment.[62]

### Palliative care [edit]

Palliative care focuses on relieving symptoms and increasing or maintaining quality of life. It has been recommended as part of the treatment plan for any person with advanced ovarian cancer or patients with significant symptoms.[63] In platinum-refractory and platinum-resistant cases, palliative non-platin chemotherapy is the main treatment.[18]

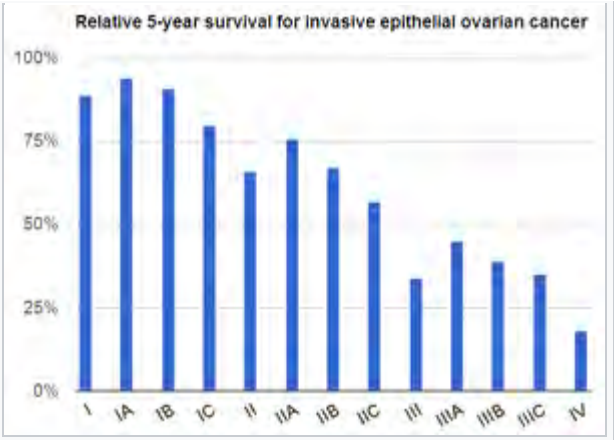
Palliative care can entail treatment of symptoms and complications of the cancer, including pain, nausea, constipation, ascites, bowel obstruction, edema, pleural effusion, and mucositis. Especially if the cancer advances and becomes incurable, treatment of symptoms becomes one of the main goals of therapy. Palliative care can also entail helping with decision-making such as if or when hospice care is appropriate, and the preferred place for the patient at end of life care.[16][64]

Bowel obstruction can be treated with palliative surgery (colostomy, ileostomy, or internal bypass) or medicine, but surgery has been shown to increase survival time.[13][16] Palliative surgery may result in short bowel syndrome, enterocutaneous fistula, or re-obstruction; or may not be possible due to the extent of obstruction.[18] Other treatments of complications can include total parenteral nutrition, a low-residue diet, palliative gastrostomy, and adequate pain control.[13] Bowel obstruction can also be treated with octreotide when palliative surgery is not an option. Cancer can also block the ureters, which can be relieved by a nephrostomy or a ureteric stent. Ascites can be relieved by repeated paracentesis or placement of a drain to increase comfort.[5] Pleural effusions can be treated in a similar manner, with repeated thoracentesis, pleurodesis, or placement of a drain.[18]

Radiation therapy can be used as part of the palliative care of advanced ovarian cancer, since it can help to shrink tumors that are causing symptoms. Palliative radiotherapy typically lasts for only a few treatments, a much shorter course of therapy than non-palliative radiotherapy.[57] It is also used for palliation of chemotherapy-resistant germ cell tumors.[20]

## Prognosis [edit]

Ovarian cancer usually has a relatively poor prognosis. It is disproportionately deadly because it lacks any clear early detection or screening test, meaning most cases are not diagnosed until they have reached advanced stages.[66] However, in some cases, ovarian cancer recurrences are chronically treatable.[13]



Relative five-year survival of invasive epithelial ovarian cancer by stage[65]

Ovarian cancer metastasizes early in its development, often before it has been diagnosed. High-grade tumors metastasize more readily than low-grade tumors. Typically, tumor cells begin to metastasize by growing in the peritoneal cavity.[14] More than 60% of women presenting with ovarian cancer have stage-III or stage-IV cancer, when it has already spread beyond the ovaries. Ovarian cancers shed cells into the naturally occurring fluid within the abdominal cavity. These cells can then implant on other abdominal (peritoneal) structures, including the uterus, urinary bladder, bowel, lining of the bowel wall, and omentum, forming new tumor growths before cancer is even suspected.

The five-year survival rate for all stages of ovarian cancer is 46%; the one-year survival rate is 72% and the ten-year survival rate is 35%.[67] For cases where a diagnosis is made early in the disease, when the cancer is still confined to the primary site, the five-year survival rate is 92.7%.[68] About 70% of women with advanced disease respond to initial treatment, most of whom attain complete remission, but half of these women experience a recurrence 1–4 years after treatment.[14] Brain metastasis is more common in stage III/IV cancer but can still occur in cancers staged at I/II. People with brain metastases survive a median of 8.2 months, though surgery, chemotherapy, and whole brain radiation therapy can improve survival.[16]

Ovarian cancer survival varies significantly with subtype. Dysgerminomas have a very favorable prognosis. In early stages, they have a five-year survival rate of 96.9%.[19] Around two-thirds of dysgerminomas are diagnosed at stage I.[20] Stage-III dysgerminomas have a five-year survival of 61%; when treated with BEP chemotherapy after incomplete surgical removal, dysgerminomas have a 95% two-year survival rate. Sex-cord-stromal malignancies also have a favorable prognosis; because they are slow-growing, even those with metastatic disease can survive a decade or more.[14] Low malignant potential tumors usually only have a bad prognosis when there are invasive tumor implants found in the peritoneal cavity.[18]

Complications of ovarian cancer can include spread of the cancer to other organs, progressive function loss of various organs, ascites, and intestinal obstructions, which can be fatal. Intestinal obstructions in multiple sites are the most common proximate cause of death.[13] Intestinal obstruction in ovarian cancer can either be a true obstruction, where tumor blocks the intestinal lumen, or a pseudo-obstruction, when tumor prevents normal peristalsis.[69] Continuous accumulation of ascites can be treated by placing a drain that can be self-drained.[13]

## Prognostic factors [edit]

There are a number of prognostic factors in ovarian cancer. Positive prognostic factors - those indicating better chances of survival - include no residual disease after surgery (stage III/IV), complete macroscopic resection (stage IV), BRCA2 mutations, young age (under 45 years), nonserous type, low histologic grade, early stage, co-occurrence with endometrial cancer, and low CA-125 levels. There is conflicting evidence for BRCA1 as a prognostic factor. Conversely, negative prognostic factors - those that indicate a worse chance of survival - include rupture of the ovarian capsule during surgery, older age (over 45 years), mucinous type, stage IV, high histologic grade, clear cell type, upper abdominal involvement, high CA-125 levels, the presence of tumor cells in the blood, and elevated cyclooxygenase-2.[16]

Expression of various mRNAs can also be prognostic for ovarian cancer. High levels of Drosha and Dicer are associated with improved survival, whereas high levels of let-7b, HIF1A, EphA1, and poly(ADP-ribose)

polymerase are associated with worse survival. Cancers that are positive for WT1 carry a worse prognosis; estrogen-receptor positive cancers have a better prognosis.[16]

## Survival rates [edit]

Overall five-year survival rates for all types of ovarian cancer are presented below by stage and histologic grade:[14]

| Stage | Survival |
|---|---|
| I | 90–95% |
| II | 70–80% |
| III | 20–50% |
| IV | 1–5% |

| Histologic grade | Survival |
|---|---|
| Low grade | 88% |
| Intermediate grade | 58% |
| High grade | 27% |

The survival rates given below are for the different types of ovarian cancer, according to American Cancer Society.[70] They come from the National Cancer Institute, SEER, and are based on patients diagnosed from 2004 to 2010.

| Invasive epithelial ovarian cancer | |
|---|---|
| **Stage** | **Relative five-year survival rate** |
| I | 90% |
| IA | 94% |
| IB | 92% |
| IC | 85% |
| II | 70% |
| IIA | 78% |
| IIB | 73% |
| III | 39% |
| IIIA | 59% |
| IIIB | 52% |
| IIIC | 39% |
| IV | 17% |

| Ovarian stromal tumors | |
|---|---|
| **Stage** | **Relative five-year survival rate** |
| I | 95% |
| II | 78% |
| III | 65% |
| IV | 35% |

| Germ cell tumors of the ovary | |
|---|---|
| **Stage** | **Relative 5-yr Survival Rate** |
| I | 98% |
| II | 94% |
| III | 87% |
| IV | 69% |

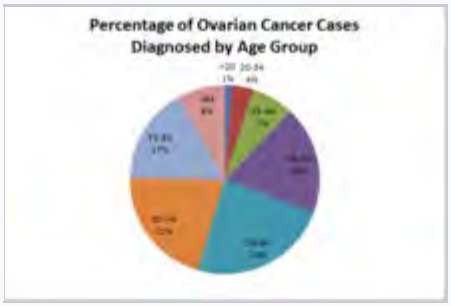
| Fallopian tube carcinoma | |
|---|---|
| **Stage** | **Relative five-year survival rate** |
| I | 87% |
| II | 86% |
| III | 52% |
| IV | 40% |

| Low malignant potential tumors[18] | |
|---|---|
| **Stage** | **Relative five-year survival rate** |
| I | 99% |
| II | 98% |
| III | 96% |
| IV | 77% |

## Recurrence rates [edit]

Ovarian cancer frequently recurs after treatment. Overall, in a 5-year period, 20% of stage I and II cancers recur. Most recurrences are in the abdomen.[18] If a recurrence occurs in advanced disease, it typically occurs within 18 months of initial treatment (18 months progression-free survival). Recurrences can be treated, but the disease-free interval tends to shorten and chemoresistance increases with each recurrence.[13] When a dysgerminoma recurs, it is most likely to recur within a year of diagnosis, and other malignant germ cell tumors recur within 2 years 90% of the time. Germ cell tumors other than dysgerminomas have a poor prognosis when they relapse, with a 10% long-term survival rate.[20] Low malignant potential tumors rarely relapse, even when fertility-sparing surgery is the treatment of choice. 15% of LMP tumors relapse after unilateral surgery in the previously unaffected ovary, and they are typically easily treated with surgery. More advanced tumors may take up to 20 years to relapse, if they relapse at all, and are only treated with surgery unless the tumor has changed its histological characteristics or grown very quickly. In these cases, and when there is significant ascites, chemotherapy may also be used. Relapse is usually indicated by rising CA-125 levels and then progresses to symptomatic relapse within 2–6 months.[18] Recurrent sex cord-stromal tumors are typically unresponsive to treatment but not aggressive.[20]

## Epidemiology [edit]



Ovarian cancer cases diagnosed by age group[68]

Globally, as of 2010, about 160,000 people died from ovarian cancer, up from 113,000 in 1990.[72] As of 2014, more than 220,000 diagnoses of epithelial ovarian cancer were made yearly.[13] In 2010, in the United States, an estimated 21,880 new cases were diagnosed and 13,850 women died of ovarian cancer. Around 1800 of the new diagnoses were sex-cord or stromal tumors.[14] In the United Kingdom as of 2014, approximately 7,000–7,100 yearly diagnoses were made and 4,200 deaths occurred.[13][21] It is the 5th most common cancer in UK women.[16][21] Ovarian cancer is most commonly diagnosed after menopause,[21] between the ages of 60 and 64. 90% of ovarian cancer occurs in women over the age of 45 and 80% in women over 50.[16] Germ cell tumors and sex cord-stromal tumors are far less common than epithelial tumors in US women, with incidence of 0.4 per 100,000 women and 0.2 per 100,000 women, respectively. When diagnosed in young people, they make up 1% of overall ovarian cancer.[20]

Age-standardized death from ovarian cancer per 100,000 inhabitants in 2004[71]

| | |
|---|---|
| no data | 3–3.6 |
| less than 0.6 | 3.6–4.2 |
| 0.6–1.2 | 4.2–4.8 |
| 1.2–1.8 | 4.8–5.4 |
| 1.8–2.4 | 5.4–6 |
| 2.4–3 | 6–7 |
| | more than 7 |

The overall lifetime risk is around 1.6%[14] (one woman in 48–70).[16] The risk in the UK is similar, at 1.7% (one woman in 60). Ashkenazi Jewish women carry mutated *BRCA* alleles at a rate five times that of the rest of the population, putting them at higher risk for ovarian cancer.[13] Black women are at double the risk for sex cord-stromal tumors compared to non-Black women.[20]

In the US, ovarian cancer affects 1.3–1.4% and is the cause of death of about 1% of women.[18][73] This made it the fifth-leading cause of cancer-related deaths with an estimated 15,000 deaths in 2008.[14][73] Ovarian cancer represents approximately 4% of cancers diagnosed in women.[16] It occurs more commonly in developed countries.[73] Ovarian cancer is the fifth-most common cancer in women in the UK (around 7,100 women were diagnosed with the disease in 2011), and it is the fifth-most common cause of cancer death in women (around 4,300 women died in 2012).[74] In the United States, it is also the fifth-most common cancer in women but the fourth-most common cause of cancer death.[16] It is the most deadly

gynecologic cancer.[18] In 2014, the incidence rate for women in developed countries was about 9.4 per 100,000, compared to 5.0 per 100,000 in developing countries.[13] In the US, the incidence rate in women over 50 is approximately 33 per 100,000.[75] In the UK, the incidence rate over the whole population is 21.6 per 100,000. In Europe, Lithuania, Latvia, Ireland, Slovakia, and the Czech Republic have the highest incidences of ovarian cancer, whereas Portugal and Cyprus have the lowest incidences. The overall incidence in Europe is approximately 5–15 per 100,000 women.[16]

The rate of ovarian cancer between 1993 and 2008 decreased in women of the 40–49 age cohort and in the 50–64 age cohort, possibly due to this group's widespread adoption of oral contraceptives.[13] This decrease made it the ninth-most common cancer in women.[18]

## In pregnancy [edit]

Malignant germ cell tumors are the type of ovarian cancer most likely to occur during pregnancy. They are typically diagnosed when an adnexal mass is found on examination (in 1–2% of all pregnancies), a tumor is seen on ultrasound, or the parent's level of alpha-fetoprotein is elevated. Dermoid cysts and dysgerminomas are the most common germ cell tumors during pregnancy. Germ cell tumors diagnosed during pregnancy are unlikely to have metastasized and can be treated by surgery and, in some cases, chemotherapy, which carries the risk of birth defects. Yolk sac tumors and immature teratomas grow particularly quickly and are usually treated with chemotherapy even during pregnancy; however, dysgerminomas that have been optimally debulked may be treated after childbirth.[20]

## Other animals [edit]

Ovarian tumors have been reported in equine mares. Reported tumor types include teratoma,[76][77] cystadenocarcinoma,[78] and particularly granulosa cell tumor.[79][80][81][82][83]

## Research [edit]

Researchers are assessing different ways to screen for ovarian cancer. Screening tests that could potentially be used alone or in combination for routine screening include the CA-125 marker and transvaginal ultrasound.[84] Doctors can measure the levels of the CA-125 protein in a woman's blood; high levels could be a sign of ovarian cancer, but this is not always the case, and not all women with ovarian cancer have high CA-125 levels. Transvaginal ultrasound involves using an ultrasound probe to scan the ovaries from inside the vagina, giving a clearer image than scanning the abdomen. The UK Collaborative Trial of Ovarian Cancer Screening is testing a screening technique that combines CA-125 blood tests with transvaginal ultrasound. Several large studies are going on, but none has identified an effective technique.[13][85] In 2009, however, early results from the UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) showed that a technique combining annual CA-125 tests with ultrasound imaging did help to detect the disease at an early stage.[58][86] However, it's not yet clear if this approach could actually help to save lives —the full results of the trial will be published in 2015.[87] One major problem with screening is no clear progression of the disease from stage I (noninvasive) to stage III (invasive) is seen, and it may not be possible to find cancers before they reach stage III. Another problem is that screening methods tend to find too many suspicious lesions, most of which are not cancer, but malignancy can only be assessed with surgery.[13] The ROCA method combined with transvaginal ultrasonography is being researched in high-risk women to determine if it is a viable screening method. It is also being investigated in normal-risk women as it has shown promise in the wider population.[18] Studies are also in progress to determine if screening helps detect cancer earlier in people with BRCA mutations.[58]

Research into various prognostic factors for ovarian cancer is also going on. Recent research shows that thrombocytosis predicts lower survival and higher stage cancer.[13] Ongoing research is also investigating the benefits of surgery for recurrent ovarian cancer.[58]

While an active area of research, no immunotherapy has been shown to be effective as of 2013.[88] However, trials of the antibody and VEGF inhibitor bevacizumab, which can slow the growth of new blood vessels in the cancer, have shown promising results, especially in combination with pazopanib, which also slows the process of blood vessel growth. Bevacizumab has been particularly effective in preliminary studies on stage-III and -IV cancer[13] and has been cited as having at least a 15% response rate.[14] It is being investigated particularly in mucinous ovarian cancers.[58] Bevacizumab can also be combined with platinum chemotherapy, a combination that has had positive preliminary results in PFS, but equivocal results regarding overall survival. One disadvantage to these treatments is the side effect profile, which includes high blood pressure and proteinuria. The drug can also exacerbate bowel disease, leading to fistulae or bowel perforation. Vintafolide, which consists of an antifolate conjugated with vinblastine, is also in clinical trials; it may prove beneficial because folate receptors are overexpressed in many ovarian cancers.[13] Another potential immunotherapy is trastuzumab (Herceptin), which is active against tumors positive for Her2/neu mutations.[14] Other angiogenesis inhibitors are also being investigated as potential ovarian cancer treatments. Combretastatin and pazopanib are being researched in combination for recurrent ovarian cancer. Trebananib and tasquinimod are other angiogenesis inhibitors being investigated. The monoclonal antibody farletuzumab is being researched as an adjuvant to traditional chemotherapy. Another type of immunotherapy involves vaccines, including TroVax.[58]

An alternative to BEP chemotherapy, a regimen of 3 cycles of carboplatin and etoposide, is a current topic of research for germ cell malignancies.[20]

Intraperitoneal chemotherapy has also been under investigation during the 2000s and 2010s for its potential to deliver higher doses of cytotoxic agent to tumors. Preliminary trials with cisplatin and paclitaxel have shown it is not well tolerated, but does improve survival, and more tolerable regimens are being researched.[13] Cisplatin and paclitaxel are both being researched as intraperitoneal chemotherapy agents. A specific chemotherapy regimen for rare clear-cell cancers is also under investigation: irinotecan combined with cisplatin.[58]

PARP inhibitors have also shown promise in early trials, particularly in people with *BRCA* gene mutations, since the BRCA protein interacts with the PARP pathway. It is also being studied in recurrent ovarian cancer in general, where preliminary studies have shown longer PFS. Specifically, olaparib has shown greater survival compared to doxorubicin, though this treatment is still being investigated. It is not clear yet which biomarkers are predictive of responsiveness to PARP inhibitors.[13] Rucaparib is another PARP inhibitor being researched in BRCA-positive and BRCA-negative recurrent advanced ovarian cancer. Niraparib is a PARP inhibitor being tested in BRCA-positive recurrent ovarian cancer.[58]

mTOR inhibitors were a highly investigated potential treatment in the 2000s and 2010s, but the side effects of these drugs (particularly hyperglycemia and hyperlipidemia) were not well tolerated and the survival benefit not confirmed. PI3 kinase inhibitors have been of interest, but they tend to be highly toxic and cause diarrhea. Another investigated drug is selumetinib, a MAPK inhibitor. It improved survival, but did not correlate with any mutations found in tumors.[13]

Tyrosine kinase inhibitors are another investigational drug class that may have applications in ovarian cancer. Angiogenesis inhibitors in the receptor tyrosine kinase inhibitor group, including pazopanib, cediranib, and nintedanib, have also been shown to increase progression free survival (PFS), but their benefit for overall survival has not been investigated as of 2015.[13] Preliminary research showed that cediranib combined with platins in recurrent ovarian cancer increased the time to second recurrence by 3–4 months and increased survival by 3 months.[58] MK-1775 is a tyrosine kinase inhibitor that is being used in combination with paclitaxel and carboplatin in platinum-sensitive cancers with p53 mutations. Nintedanib is being researched as a potential therapy in combination with cyclophosphamide for people with recurrences.[58]

Hormone therapies are a topic of current research in ovarian cancer, particularly, the value of certain medications used to treat breast cancer. These include tamoxifen, letrozole, and anastrozole. Preliminary studies have showed a benefit for tamoxifen in a small number of people with advanced ovarian cancer. Letrozole may help to slow or stop growth of estrogen receptor positive ovarian cancer. Anastrozole is being investigated in postmenopausal people with estrogen receptor-positive cancer.[58]

Research into mitigating side effects of ovarian cancer treatment is also ongoing. Radiation fibrosis, the formation of scar tissue in an area treated with radiation, may be relieved with hyperbaric oxygen therapy, but research has not been completed in this area. Treatment of ovarian cancer may also cause people to experience psychiatric difficulties, including depression. Research is ongoing to determine how counseling and psychotherapy can help people who have ovarian cancer during treatment.[58]

# Pancreatic cancer

From Wikipedia, the free encyclopedia

**Pancreatic cancer** arises when cells in the pancreas, a glandular organ behind the stomach, begin to multiply out of control and form a mass. These cancerous cells have the ability to invade other parts of the body.[1] There are a number of types of pancreatic cancer. The most common, **pancreatic adenocarcinoma**, accounts for about 85% of cases, and the term "pancreatic cancer" is sometimes used to refer only to that type. These adenocarcinomas start within the part of the pancreas which makes digestive enzymes. Several other types of cancer, which collectively represent the majority of the non-adenocarcinomas, can also arise from these cells. One to two percent of cases of pancreatic cancer are neuroendocrine tumors, which arise from the hormone-producing cells of the pancreas. These are generally less aggressive than pancreatic adenocarcinoma.[2]

Signs and symptoms of the most common form of pancreatic cancer may include yellow skin, abdominal or back pain, unexplained weight loss, light-colored stools, dark urine and loss of appetite.[3] There are usually no symptoms in the disease's early stages, and symptoms that are specific enough to suggest pancreatic cancer typically do not develop until the disease has reached an advanced stage.[3][4] By the time of diagnosis, pancreatic cancer has often spread to other parts of the body.[2][5]

Pancreatic cancer rarely occurs before the age of 40, and more than half of cases of pancreatic adenocarcinoma occur in those over 70.[4] Risk factors for pancreatic cancer include tobacco smoking, obesity, diabetes, and certain rare genetic conditions.[4] About 25% of cases are linked to smoking,[6] and 5–10% are linked to inherited genes.[4] Pancreatic cancer is usually diagnosed by a combination of medical imaging techniques such as ultrasound or computed tomography, blood tests, and examination of tissue samples (biopsy).[6][7] The disease is divided into stages, from early (stage I) to late (stage IV).[5] Screening the general population has not been found to be effective.[8]

The risk of developing pancreatic cancer is lower among non-smokers, and people who maintain a healthy weight and limit their consumption of red or processed meat.[9] A smoker's chance of developing the disease decreases if they stop smoking, and almost returns to that of the rest of the population after 20 years.[2] Pancreatic cancer can be treated with surgery, radiotherapy, chemotherapy, palliative care, or

a combination of these. Treatment options are partly based on the cancer stage. Surgery is the only treatment that can cure pancreatic adenocarcinoma,[5] and may also be done to improve quality of life without the potential for cure.[3][5] Pain management and medications to improve digestion are sometimes needed.[5] Early palliative care is recommended even for those receiving treatment that aims for a cure.[10][11]

In 2012, pancreatic cancers of all types were the seventh most common cause of cancer deaths, resulting in 330,000 deaths globally.[2] Pancreatic cancer is the fifth most common cause of death from cancer in the United Kingdom,[12] and the fourth most common in the United States.[13][14] The disease occurs most often in the developed world, where about 70% of the new cases in 2012 originated.[2] Pancreatic adenocarcinoma typically has a very poor prognosis: after diagnosis, 25% of people survive one year and 5% live for five years.[2][15] For cancers diagnosed early, the five-year survival rate rises to about 20%.[16] Neuroendocrine cancers have better outcomes; at five years from diagnosis, 65% of those diagnosed are living, though survival varies considerably depending on the type of tumor.[2]

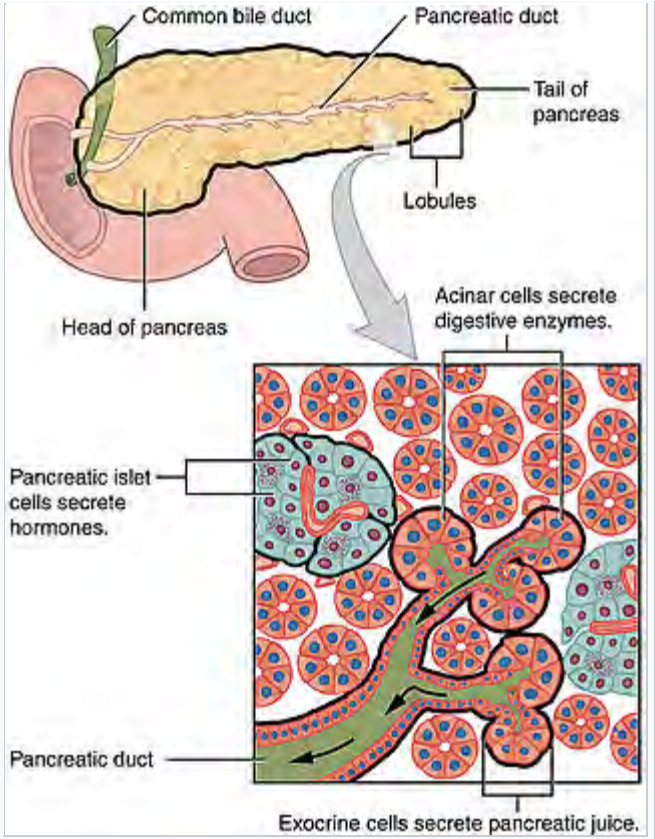
## Types [edit]

The many types of pancreatic cancer can be divided into two general groups. The vast majority of cases (about 99%) occur in the part of the pancreas which produces digestive enzymes, known as the exocrine component. There are several sub-types of exocrine pancreatic cancers, but their diagnosis and treatment have much in common. The small minority of cancers that arise in the hormone-producing (endocrine) tissue of the pancreas



The pancreas has multiple functions, served by the endocrine cells in the islets of Langerhans and the exocrine acinar cells. Pancreatic cancer may arise from any of these and disrupt any of their functions.

have different clinical characteristics. Both groups occur mainly (but not exclusively) in people over 40, and are slightly more common in men, but some rare sub-types mainly occur in women or children.[17][18]

## Exocrine cancers [edit]

The exocrine group is dominated by pancreatic adenocarcinoma (variations of this name may add "invasive" and "ductal"), which is by far the most common type, representing about 85% of all pancreatic cancers.[4] Nearly all these start in the ducts of the pancreas, and pancreatic ductal adenocarcinoma is often abbreviated as PDAC.[19] This is despite the fact that the tissue from which it arises – the pancreatic ductal epithelium – represents less than 10% of the pancreas by cell volume.[20] This cancer originates in the ducts that carry secretions (such as enzymes and bicarbonate) away from the pancreas. About 60–70% of adenocarcinomas occur in the 'head' of the pancreas.[4]

The next most common type, acinar cell carcinoma of the pancreas, arises in the clusters of cells that produce these enzymes, and represents 5% of exocrine pancreas cancers.[21] Like the 'functioning' endocrine cancers described below, acinar cell carcinomas may cause over-production of certain molecules, in this case digestive enzymes, which may cause symptoms such as skin rashes and joint pain.

Cystadenocarcinomas account for 1% of pancreatic cancers, and they have a better prognosis than the other exocrine types.[21]

Pancreatoblastoma is a rare form, mostly occurring in childhood, and with a relatively good prognosis. Other exocrine cancers include adenosquamous carcinomas, signet ring cell carcinomas, hepatoid carcinomas, colloid carcinomas, undifferentiated carcinomas, and undifferentiated carcinomas with osteoclast-like giant cells. Solid pseudopapillary tumor is a rare low-grade neoplasm that mainly affects younger women, and generally has a very good prognosis.[4][22]

Pancreatic mucinous cystic neoplasms are a broad group of pancreas tumors that have varying malignant potential. They are being detected at a greatly increased rate as CT scans become more powerful and common, and discussion continues as how best to assess and treat them, given that many are benign.[23]

## Neuroendocrine [edit]

*Main article: Pancreatic neuroendocrine tumor*

The small minority of tumors that arise elsewhere in the pancreas are mainly pancreatic neuroendocrine tumors (PanNETs).[24] Neuroendocrine tumors (NETs) are a diverse group of benign or malignant tumors that arise from the body's neuroendocrine cells, which are responsible for integrating the nervous and endocrine systems. NETs can start in most organs of the body, including the pancreas, where the various malignant types are all considered to be rare. PanNETs are grouped into 'functioning' and 'non-functioning'

types, depending on the degree to which they produce hormones. The functioning types secrete hormones such as insulin, gastrin, and glucagon into the bloodstream, often in large quantities, giving rise to serious symptoms such as low blood sugar, but also favoring relatively early detection. The most common functioning PanNETs are insulinomas and gastrinomas, named after the hormones they secrete. The non-functioning types do not secrete hormones in a sufficient quantity to give rise to overt clinical symptoms. For this reason, non-functioning PanNETs are often diagnosed only after the cancer has spread to other parts of the body.[25]

As with other neuroendocrine tumors, the history of the terminology and classification of PanNETs is complex.[24] PanNETs are sometimes called "islet cell cancers",[26] even though it is now known that they do not actually arise from islet cells as previously thought.[25]

## Signs and symptoms [edit]

Since pancreatic cancer usually does not cause recognizable symptoms in its early stages, the disease is typically not diagnosed until it has spread beyond the pancreas itself.[7] This is one of the main reasons for the generally poor survival rates. Exceptions to this are the functioning PanNETs, where over-production of various active hormones can give rise to symptoms (which depend on the type of hormone).[27]

Jaundice can be a symptom, due to biliary obstruction from a pancreatic tumor

Bearing in mind that the disease is rarely diagnosed before the age of 40, common symptoms of pancreatic adenocarcinoma occurring before diagnosis include:

- Pain in the upper abdomen or back, often spreading from around the stomach to the back. The location of the pain can indicate the part of the pancreas where a tumor is located. The pain may be worse at night and may increase over time to become severe and unremitting.[21] It may be slightly relieved by bending forward. In the UK, about half of new cases of pancreatic cancer are diagnosed following a visit to a hospital emergency department for pain or jaundice. In up to two-thirds of people abdominal pain is the main symptom, for 46% of the total accompanied by jaundice, with 13% having jaundice without pain.[5]
- Jaundice, a yellow tint to the whites of the eyes or skin, with or without pain, and possibly in combination with darkened urine. This results when a cancer in the head of the pancreas obstructs the common bile duct as it runs through the pancreas.[28]
- Unexplained weight loss, either from loss of appetite, or loss of exocrine function resulting in poor digestion.[5]
- The tumor may compress neighboring organs, disrupting digestive processes and making it difficult for the stomach to empty, which may cause nausea and a feeling of fullness. The undigested fat leads to foul-smelling, fatty feces that are difficult to flush away.[5] Constipation is common.[29]
- At least 50% of people with pancreatic adenocarcinoma have diabetes at the time of diagnosis.[4] While long-standing diabetes is a known risk factor for pancreatic cancer (see Risk factors), the cancer can itself cause diabetes, in which case recent onset of diabetes could be considered an early sign of the disease.[30] People over 50 who develop diabetes have eight times the usual risk of developing pancreatic adenocarcinoma within three years, after which the relative risk declines.[5]

### Other findings [edit]

- Trousseau's syndrome, in which blood clots form spontaneously in the portal blood vessels, the deep veins of the extremities, or the superficial veins anywhere on the body, may be associated with pancreatic cancer, and is found in about 10% of cases.[6]

- Clinical depression has been reported in association with pancreatic cancer in some 10–20% of cases, and can be a hindrance to optimal management. The depression sometimes appears before the diagnosis of cancer, suggesting that it may be brought on by the biology of the disease.[6]

Other common manifestations of the disease include: weakness and tiring easily; dry mouth; sleep problems; and a palpable abdominal mass."[29]

## Symptoms of spread (metastasis) [edit]
