The spread of pancreatic cancer to other organs (metastasis) may also cause symptoms. Typically, pancreatic adenocarcinoma first spreads to nearby lymph nodes, and later to the liver or to the peritoneal cavity, large intestine or lungs.[6] It is uncommon for it to spread to the bones or brain.[31]

Cancers in the pancreas may also be secondary cancers that have spread from other parts of the body. This is uncommon, found in only about 2% of cases of pancreatic cancer. Kidney cancer is by far the most common cancer to spread to the pancreas, followed by colorectal cancer, and then cancers of the skin, breast, and lung. Surgery may be performed on the pancreas in such cases, whether in hope of a cure or to alleviate symptoms.[32]

## Risk factors [edit]

Risk factors for pancreatic adenocarcinoma include:[2][4][5][33]

- Age, gender, and ethnicity; the risk of developing pancreatic cancer increases with age. Most cases occur after age 65,[2] while cases before age 40 are uncommon. The disease is slightly more common in men than women, and in the United States is over 1.5 times more common in African Americans, though incidence in Africa is low.[2]
- Cigarette smoking is the best-established avoidable risk factor for pancreatic cancer, approximately doubling risk among long-term smokers, the risk increasing with the number of cigarettes smoked and the years of smoking. The risk declines slowly after smoking cessation, taking some 20 years to return to almost that of non-smokers.[34]
- Obesity; a BMI greater than 35 increases relative risk by about half.[5]
- Family history; 5–10% of pancreatic cancer cases have an inherited component, where people have a family history of pancreatic cancer.[4][35] The risk escalates greatly if more than one first-degree relative had the disease, and more modestly if they developed it before the age of 50.[7] Most of the genes involved have not been identified.[4][36] Hereditary pancreatitis gives a greatly increased lifetime risk of pancreatic cancer of 30–40% to the age of 70.[6] Screening for early pancreatic cancer may be offered to individuals with hereditary pancreatitis on a research basis.[37] Some people may choose to have their pancreas surgically removed to prevent cancer developing in the future.[6]
  Pancreatic cancer has been associated with the following other rare hereditary syndromes: Peutz–Jeghers syndrome due to mutations in the *STK11* tumor suppressor gene (very rare, but a very strong risk factor); dysplastic nevus syndrome (or familial atypical multiple mole and melanoma syndrome, FAMMM-PC) due to mutations in the *CDKN2A* tumor suppressor gene; autosomal recessive ataxia-telangiectasia and autosomal dominantly inherited mutations in the *BRCA2* gene and *PALB2* gene; hereditary non-polyposis colon cancer (Lynch syndrome); and familial adenomatous polyposis. PanNETs have been associated with multiple endocrine neoplasia type 1 (MEN1) and von Hippel Lindau syndromes.[4][6][7]
- Chronic pancreatitis appears to almost triple risk, and as with diabetes, new-onset pancreatitis may be a symptom of a tumor.[6] The risk of pancreatic cancer in individuals with familial pancreatitis is [6][36]

particularly high.
- Diabetes mellitus is a risk factor for pancreatic cancer and (as noted in the Signs and symptoms section) new-onset diabetes may also be an early sign of the disease. People who have been diagnosed with Type 2 diabetes for longer than ten years may have a 50% increased risk, as compared with non-diabetics.[6]
- Specific types of food (as distinct from obesity) have not been clearly shown to increase the risk of pancreatic cancer.[4] Dietary factors for which there is some evidence of slightly increased risk include processed meat, red meat, and meat cooked at very high temperatures (e.g. by frying, broiling or barbecuing).[38][39]

### Alcohol [edit]

Drinking alcohol excessively is a major cause of chronic pancreatitis, which in turn predisposes to pancreatic cancer. However, considerable research has failed to firmly establish alcohol consumption as a direct risk factor for pancreatic cancer. Overall, the association is consistently weak and the majority of studies have found no association, with smoking a strong confounding factor. The evidence is stronger for a link with heavy drinking, of at least six drinks per day.[6][40]

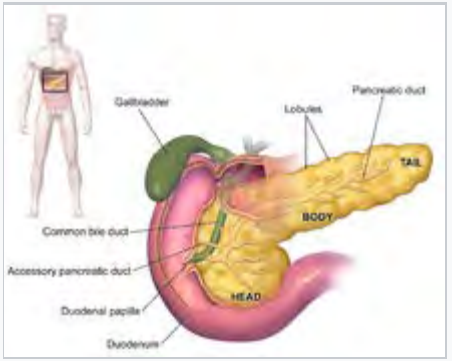
## Diagnosis [edit]

The symptoms of pancreatic adenocarcinoma do not usually appear in the disease's early stages, and are individually not distinctive to the disease.[5][6][28] The symptoms at diagnosis vary according to the location of the cancer in the pancreas, which anatomists divide (from left to right on most diagrams) into the thick head, the neck, and the tapering body, ending in the tail.

Regardless of a tumor's location, the most common symptom is unexplained weight loss, which may be considerable. A large minority (between 35% and 47%) of people diagnosed with the disease will have had nausea, vomiting or a feeling of weakness. Tumors in the head of the pancreas typically also cause jaundice, pain, loss of appetite, dark urine, and light-colored stools. Tumors in the body and tail typically also cause pain.[28]

People sometimes have recent onset of atypical type 2 diabetes that is difficult to control, a history of recent but unexplained blood vessel inflammation caused by blood clots (thrombophlebitis) known as Trousseau sign, or a previous attack of pancreatitis.[28] A doctor may suspect pancreatic cancer when the onset of diabetes in someone over 50 years old is accompanied by typical symptoms such as unexplained weight loss, persistent abdominal or back pain, indigestion, vomiting, or fatty feces.[5] Jaundice accompanied by a painlessly swollen gallbladder (known as Courvoisier's sign) may also raise suspicion, and can help differentiate pancreatic cancer from gallstones.[41]

Medical imaging techniques, such as computed tomography (CT scan) and endoscopic ultrasound (EUS) are used both to confirm the diagnosis and to help decide whether the tumor can be surgically removed (its "resectability").[5] Magnetic resonance imaging and positron emission tomography may also be used,[4] and magnetic resonance cholangiopancreatography may be useful in some cases.[28] Abdominal ultrasound is less sensitive and will miss small tumors, but can identify cancers that have spread to the liver and build-up of fluid in the peritoneal cavity (ascites).[5] It may be used for a quick and cheap first [42]



The head, body and tail of the pancreas. The stomach is faded out in this image to show the entire pancreas, of which the body and tail lie behind the stomach, and the neck partially behind.

examination before other techniques.

the pancreatic head.

A biopsy by fine needle aspiration, often guided by endoscopic ultrasound, may be used where there is uncertainty over the diagnosis, but a histologic diagnosis is not usually required for removal of the tumor by surgery to go ahead.[5]

Liver function tests can show a combination of results indicative of bile duct obstruction (raised conjugated bilirubin, γ-glutamyl transpeptidase and alkaline phosphatase levels). CA19-9 (carbohydrate antigen 19.9) is a tumor marker that is frequently elevated in pancreatic cancer. However, it lacks sensitivity and specificity, not least because 5% of people lack the Lewis (a) antigen and cannot produce CA19-9. It has a sensitivity of 80% and specificity of 73% in detecting pancreatic adenocarcinoma, and is used for following known cases rather than diagnosis.[4][5]

The most common form of pancreatic cancer (adenocarcinoma) is typically characterized by moderately to poorly differentiated glandular structures on microscopic examination. There is typically considerable desmoplasia or formation of a dense fibrous stroma or structural tissue consisting of a range of cell types (including myofibroblasts, macrophages, lymphocytes and mast cells) and deposited material (such as type I collagen and hyaluronic acid). This creates a tumor microenvironment that is short of blood vessels (hypovascular) and so of oxygen (tumor hypoxia).[4] It is thought that this prevents many chemotherapy drugs from reaching the tumor, as one factor making the cancer especially hard to treat.[4][6]

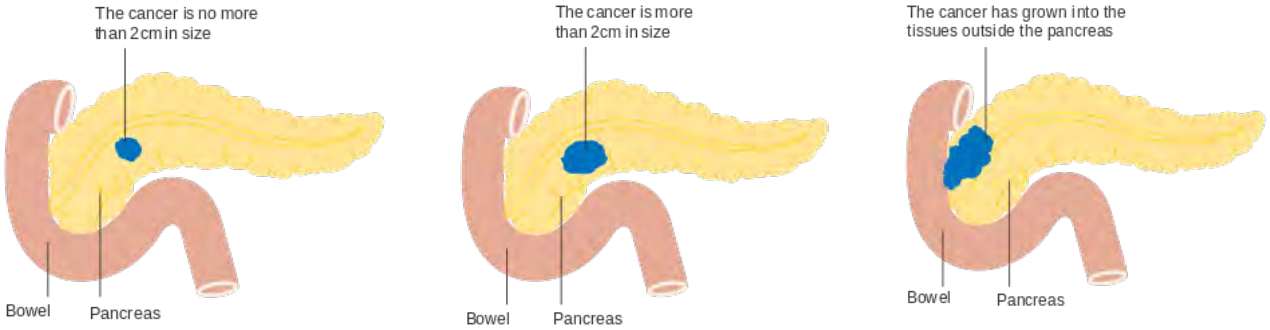
## Staging [edit]

### Exocrine cancers [edit]

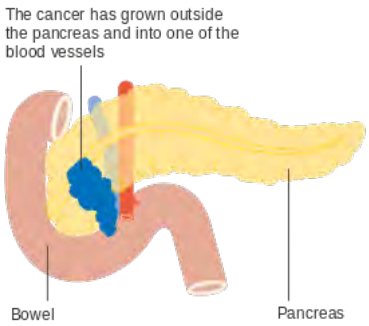
Pancreatic cancer is usually staged following a CT scan.[28] The most widely used cancer staging system for pancreatic cancer is the one formulated by the American Joint Committee on Cancer (AJCC) together with the Union for International Cancer Control (UICC). The AJCC-UICC staging system designates four main overall stages, ranging from early to advanced disease, based on TNM classification of **T**umor size, spread to lymph **N**odes, and **M**etastasis.[43]

To help decide treatment, the tumors are also divided into three broader categories based on whether surgical removal seems possible: in this way, tumors are judged to be "resectable", "borderline resectable", or "unresectable".[44] When the disease is still in an early stage (AJCC-UICC stages I and II), without spread to large blood vessels or distant organs such as the liver or lungs, surgical resection of the tumor can normally be performed, if the patient is willing to undergo this major operation and is thought to be sufficiently fit.[5] The AJCC-UICC staging system allows distinction between stage III tumors that are judged to be "borderline resectable" (where surgery is technically feasible because the celiac axis and superior mesenteric artery are still free) and those that are "unresectable" (due to more locally advanced disease); in terms of the more detailed TNM classification, these two groups correspond to T3 and T4 respectively.[6]

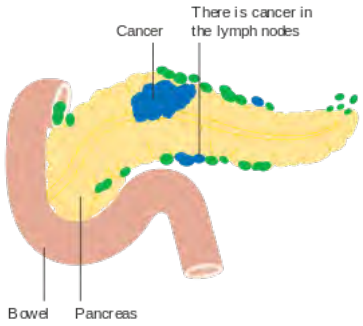
**Pancreatic cancer staging (TNM classification)**



Stage T1 pancreatic cancer  Stage T2 pancreatic cancer  Stage T3 pancreatic cancer

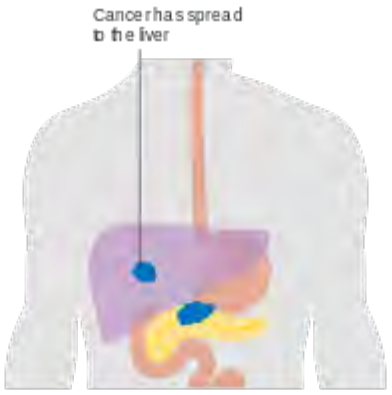


Stage T4 pancreatic cancer



Pancreatic cancer in nearby lymph nodes – Stage N1

Locally advanced adenocarcinomas have spread into neighboring organs, which may be any of the following (in roughly decreasing order of frequency): the duodenum, stomach, transverse colon, spleen, adrenal gland, or kidney. Very often they also spread to the important blood or lymphatic vessels and nerves that run close to the pancreas, making surgery far more difficult. Typical sites for metastatic spread (stage IV disease) are the liver, peritoneal cavity and lungs, all of which occur in 50% or more of fully advanced cases.[45]



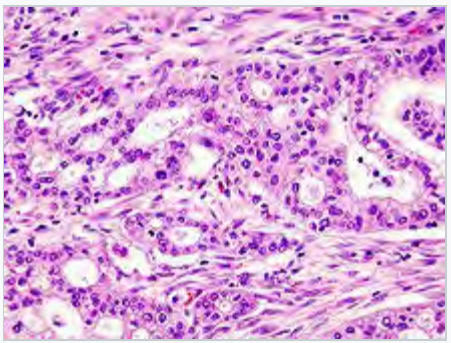
Pancreatic cancer metastasized – stage M1

## PanNETs [edit]

The 2010 WHO classification of tumors of the digestive system grades all the pancreatic neuroendocrine tumors (PanNETs) into three categories, based on their degree of cellular differentiation (from "NET G1" through to the poorly differentiated "NET G3").[18] The U.S. National Comprehensive Cancer Network recommends use of the same AJCC-UICC staging system as pancreatic adenocarcinoma.[46]:52 Using this scheme, the stage-by-stage outcomes for PanNETs are dissimilar to those of the exocrine cancers.[47] A different TNM system for PanNETs has been proposed by the European Neuroendocrine Tumor Society.[18]

# Precursors [edit]

## Exocrine cancers [edit]

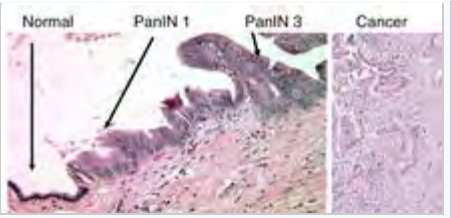


Micrograph of pancreatic ductal adenocarcinoma (the most common type of pancreatic cancer). H&E stain.

These cancers are thought to arise from several types of precancerous lesions within the pancreas. But these lesions do not always progress to cancer, and the increased numbers detected as a by-product of the increasing use of CT scans for other reasons are not all treated.[6] Apart from pancreatic serous cystadenomas (SCNs), which are almost always benign, three types of precancerous lesion are recognized.

The first is pancreatic intraepithelial neoplasia. These are microscopic abnormalities in the pancreas, which are often found in autopsies of people with no diagnosed cancer. These may progress from low to high grade and then to a tumor. More than 90% of cases at all grades carry a faulty *KRAS* gene, while in grades 2 and 3 damage to three further genes – *CDKN2A* (*p16*), *p53* and *SMAD4* – are increasingly often found.[4]

Secondly, intraductal papillary mucinous neoplasms (IPMNs) are macroscopic lesions, which occur in about 2% of all adults, rising to



Micrographs of normal pancreas, pancreatic intraepithelial neoplasia (precursors to pancreatic carcinoma) and pancreatic carcinoma. H&E stain.

about 10% by age 70, and have about a 25% risk of developing into invasive cancer. They also very often have *KRAS* gene mutations, in about 40–65% of cases, and in the GNAS Gs alpha subunit and RNF43, affecting the Wnt signaling pathway.[4] Even if removed surgically, there remains a considerably increased risk of pancreatic cancer developing subsequently.[6]

The last type, pancreatic mucinous cystic neoplasms (MCNs) mainly occur in women, and may remain benign or progress to cancer.[48] If they become large, cause symptoms, or have suspicious features, they can usually be successfully removed by surgery.[6]

The genetic events found in ductal adenocarcinoma have been well characterized, and complete exome sequencing has been done for the common types of tumor. Four genes have each been found to be mutated in the majority of adenocarcinomas: *KRAS* (in 95% of cases), *CDKN2A* (also in 95%), *TP53* (75%), and *SMAD4* (55%). The last of these are especially associated with a poor prognosis.[6] *SWI/SNF* mutations/deletions occur in about 10–15% of the adenocarcinomas.[4] The genetic alterations in several other types of pancreatic cancer and precancerous lesions have also been researched.[6]

### PanNETs [edit]

The genes often found mutated in PanNETs are different from those in pancreatic adenocarcinoma.[49] For example, *KRAS* mutation is normally absent. Instead, hereditary *MEN1* gene mutations give rise to MEN1 syndrome, in which primary tumors occur in two or more endocrine glands. About 40–70% of people born with a *MEN1* mutation eventually develop a PanNet.[50] Other genes that are frequently mutated include *DAXX*, *mTOR* and *ATRX*.[25]

## Prevention and screening [edit]

Apart from not smoking, the American Cancer Society recommends keeping a healthy weight, and increasing consumption of fruits, vegetables, and whole grains, while decreasing consumption of red and processed meat, although there is no consistent evidence this will prevent or reduce pancreatic cancer specifically.[51] A 2014 review of research concluded that there was evidence that consumption of citrus fruits and curcumin reduced risk of pancreatic cancer, while there was possibly a beneficial effect from whole grains, folate, selenium, and non-fried fish.[40]

In the general population, screening of large groups is not currently considered effective, although newer techniques, and the screening of tightly targeted groups, are being evaluated.[52][53] Nevertheless, regular screening with endoscopic ultrasound and MRI/CT imaging is recommended for those at high risk from inherited genetics.[7][42][53][54]

## Management [edit]

### Exocrine cancer [edit]

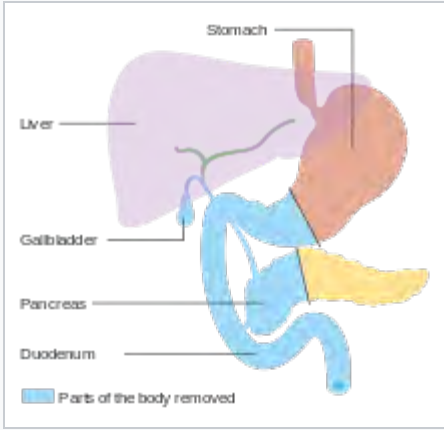
A key assessment that is made after diagnosis is whether surgical removal of the tumor is possible (see Staging), as this is the only cure for this cancer. Whether or not surgical resection can be offered depends on how much the cancer has spread. The exact location of the tumor is also a significant factor, and CT can show how it relates to the major blood vessels passing close to the pancreas. The general health of the person must also be assessed, though age in itself is not an obstacle to surgery.[6]

Chemotherapy and, to a lesser extent, radiotherapy are likely to be offered to most people, whether or not

surgery is possible. Specialists advise that the management of pancreatic cancer should be in the hands of a multidisciplinary team including specialists in several aspects of oncology, and is, therefore, best conducted in larger centers.[4][6]

## Surgery [edit]

Surgery with the intention of a cure is only possible in around one-fifth (20%) of new cases.[5] Although CT scans help, in practice it can be difficult to determine whether the tumor can be fully removed (its "resectability"), and it may only become apparent during surgery that it is not possible to successfully remove the tumor without damaging other vital tissues. Whether or not surgical resection can be offered depends on various factors, including the precise extent of local anatomical adjacency to, or involvement of, the venous or arterial blood vessels,[4] as well as surgical expertise and a careful consideration of projected post-operative recovery.[55][56] The age of the person is not in itself a reason not to operate, but their general performance status needs to be adequate for a major operation.[5]

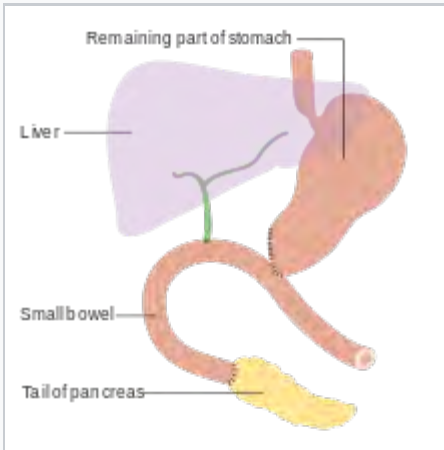


Parts of the body removed in Whipple's operation

One particular feature that is evaluated is the encouraging presence, or discouraging absence, of a clear layer or plane of fat creating a barrier between the tumor and the vessels.[6] Traditionally, an assessment is made of the tumor's proximity to major venous or arterial vessels, in terms of "abutment" (defined as the tumor touching no more than half a blood vessel's circumference without any fat to separate it), "encasement" (when the tumor encloses most of the vessel's circumference), or full vessel involvement.[57]:22 A resection that includes encased sections of blood vessels may be possible in some cases,[58][59] particularly if preliminary neoadjuvant therapy is feasible,[60][61][62] using chemotherapy[56][57]:36[63] and/or radiotherapy.[57]:29–30

Even when the operation appears to have been successful, cancerous cells are often found around the edges ("margins") of the removed tissue, when a pathologist examines them microscopically (this will always be done), indicating the cancer has not been entirely removed.[4] Furthermore, cancer stem cells are usually not evident microscopically, and if they are present they may continue to develop and spread.[64][65] An exploratory laparoscopy (a small, camera-guided surgical procedure) may therefore be performed to gain a clearer idea of the outcome of a full operation.[66][*needs update*]

For cancers involving the head of the pancreas, the Whipple procedure is the most commonly attempted curative surgical treatment. This is a major operation which involves removing the pancreatic head and the curve of the duodenum together ("pancreato-duodenectomy"), making a bypass for food from the stomach to the jejunum ("gastro-jejunostomy") and attaching a loop of jejunum to the cystic duct to drain bile ("cholecysto-jejunostomy"). It can be performed only if the person is likely to survive major surgery and if the cancer is localized without invading local structures or metastasizing. It can, therefore, be performed only in a minority of cases. Cancers of the tail of the pancreas can be resected using a procedure known as a distal pancreatectomy, which often also entails removal of the spleen.[4][6] Nowadays, this can often be done using minimally invasive surgery.[4][6]



How the pancreas and bowel are joined back together after a Whipple's operation

Although curative surgery no longer entails the very high death rates that occurred until the 1980s, a high proportion of people (about 30–45%) still have to be treated for a post-operative sickness that is not caused by the cancer itself. The most common complication of surgery is difficulty in emptying the stomach.[6] Certain more limited surgical procedures may also be used to ease symptoms (see Palliative care).

For instance, if the cancer is invading or compressing the duodenum or colon. In such cases, bypass surgery might overcome the obstruction and improve quality of life but is not intended as a cure.[5]

## Chemotherapy [edit]

After surgery, adjuvant chemotherapy with gemcitabine or 5-FU can be offered if the person is sufficiently fit, after a recovery period of one to two months.[7][42] In people not suitable for curative surgery, chemotherapy may be used to extend life or improve its quality.[6] Before surgery, neoadjuvant chemotherapy or chemoradiotherapy may be used in cases that are considered to be "borderline resectable" (see Staging) in order to reduce the cancer to a level where surgery could be beneficial. In other cases neoadjuvant therapy remains controversial, because it delays surgery.[6][7][67]

Gemcitabine was approved by the United States Food and Drug Administration (FDA) in 1997, after a clinical trial reported improvements in quality of life and a 5-week improvement in median survival duration in people with advanced pancreatic cancer.[68] This was the first chemotherapy drug approved by the FDA primarily for a nonsurvival clinical trial endpoint.[69] Chemotherapy using gemcitabine alone was the standard for about a decade, as a number of trials testing it in combination with other drugs failed to demonstrate significantly better outcomes. However, the combination of gemcitabine with erlotinib was found to increase survival modestly, and erlotinib was licensed by the FDA for use in pancreatic cancer in 2005.[70]

The FOLFIRINOX chemotherapy regimen using four drugs was found more effective than gemcitabine, but with substantial side effects, and is thus only suitable for people with good performance status. This is also true of protein-bound paclitaxel (nab-paclitaxel), which was licensed by the FDA in 2013 for use with gemcitabine in pancreas cancer.[71] By the end of 2013, both FOLFIRINOX and nab-paclitaxel with gemcitabine were regarded as good choices for those able to tolerate the side-effects, and gemcitabine remained an effective option for those who were not. A head-to-head trial between the two new options is awaited, and trials investigating other variations continue. However, the changes of the last few years have only increased survival times by a few months.[68] Clinical trials are often conducted for novel adjuvant therapies.[7]

## Radiotherapy [edit]

The role of radiotherapy as an auxiliary (adjuvant) treatment after potentially curative surgery has been controversial since the 1980s.[6] The European Society for Medical Oncology recommends that adjuvant radiotherapy should only be used for people enrolled in clinical trials.[42] However, there is a continuing tendency for clinicians in the US to be more ready to use adjuvant radiotherapy than those in Europe. Many clinical trials have tested a variety of treatment combinations since the 1980s, but have failed to settle the matter conclusively.[6][7]

Radiotherapy may form part of treatment to attempt to shrink a tumor to a resectable state, but its use on unresectable tumors remains controversial as there are conflicting results from clinical trials. The preliminary results of one trial, presented in 2013, "markedly reduced enthusiasm" for its use on locally advanced tumors.[4]

## PanNETs [edit]

*Main articles: Neuroendocrine tumor and Pancreatic neuroendocrine tumor*

Treatment of PanNETs, including the less common malignant types, may include a number of approaches.[46][72][73][74] Some small tumors of less than 1 cm. that are identified incidentally, for example on a CT scan performed for other purposes, may be followed by watchful waiting.[46] This depends on the assessed risk of surgery which is influenced by the site of the tumor and the presence of other medical problems.[46] Tumors within the pancreas only (localized tumors), or with limited metastases, for example to the liver, may be removed by surgery. The type of surgery depends on the tumor location, and the degree of spread to lymph nodes.[18]

For localized tumors, the surgical procedure may be much less extensive than the types of surgery used to treat pancreatic adenocarcinoma described above, but otherwise surgical procedures are similar to those for exocrine tumors. The range of possible outcomes varies greatly; some types have a very high survival rate after surgery while others have a poor outlook. As all this group are rare, guidelines emphasize that treatment should be undertaken in a specialized center.[18][25] Use of liver transplantation may be considered in certain cases of liver metastasis.[75]

For functioning tumors, the somatostatin analog class of medications, such as octreotide, can reduce the excessive production of hormones.[18] Lanreotide can slow tumor growth.[76] If the tumor is not amenable to surgical removal and is causing symptoms, targeted therapy with everolimus or sunitinib can reduce symptoms and slow progression of the disease.[25][77][78] Standard cytotoxic chemotherapy is generally not very effective for PanNETs, but may be used when other drug treatments fail to prevent the disease from progressing,[25][79] or in poorly differentiated PanNET cancers.[80]

Radiation therapy is occasionally used if there is pain due to anatomic extension, such as metastasis to bone. Some PanNETs absorb specific peptides or hormones, and these PanNETs may respond to nuclear medicine therapy with radiolabeled peptides or hormones such as iobenguane (iodine-131-MIBG).[81][82][83][84] Radiofrequency ablation (RFA), cryoablation, and hepatic artery embolization may also be used.[85][86]

### Palliative care [edit]

Palliative care is medical care which focuses on treatment of symptoms from serious illness, such as cancer, and improving quality of life.[87] Because pancreatic adenocarcinoma is usually diagnosed after it has progressed to an advanced stage, palliative care as a treatment of symptoms is often the only treatment possible.[88]

Palliative care focuses not on treating the underlying cancer, but on treating symptoms such as pain or nausea, and can assist in decision-making, including when or if hospice care will be beneficial.[89] Pain can be managed with medications such as opioids or through procedural intervention, by a nerve block on the celiac plexus (CPB). This alters or, depending on the technique used, destroys the nerves that transmit pain from the abdomen. CPB is a safe and effective way to reduce the pain, which generally reduces the need to use opioid painkillers, which have significant negative side effects.[6][90]

Other symptoms or complications that can be treated with palliative surgery are obstruction by the tumor of the intestines or bile ducts. For the latter, which occurs in well over half of cases, a small metal tube called a stent may be inserted by endoscope to keep the ducts draining.[28] Palliative care can also help treat depression that often comes with the diagnosis of pancreatic cancer.[6]

Both surgery and advanced inoperable tumors often lead to digestive system disorders from a lack of the exocrine products of the pancreas (exocrine insufficiency). These can be treated by taking pancreatin which contains manufactured pancreatic enzymes, and is best taken with food.[5] Difficulty in emptying the stomach (delayed gastric emptying) is common and can be a serious problem, involving hospitalization. Treatment may involve a variety of approaches, including draining the stomach by nasogastric aspiration and drugs called proton-pump inhibitors or H2 antagonists, which both reduce production of gastric acid.[5]

## Outcomes [edit]

Pancreatic adenocarcinoma and the other less common exocrine cancers have a very poor prognosis, as they are normally diagnosed at a late stage when the cancer is already locally advanced or has spread to other parts of the body.[4] Outcomes are much better for PanNETs: many are benign and completely without clinical symptoms, and even those cases not treatable with surgery have an average five-year survival rate of

**Outcomes in pancreatic cancers according to clinical stage**[44]

| Clinical stage | Five-year survival (%) – U.S., diagnoses 1992–98 | |
|---|---|---|
| | Exocrine pancreatic cancer | Neuroendocrine treated with surgery |
| **IA / I** | 14 | 61 |

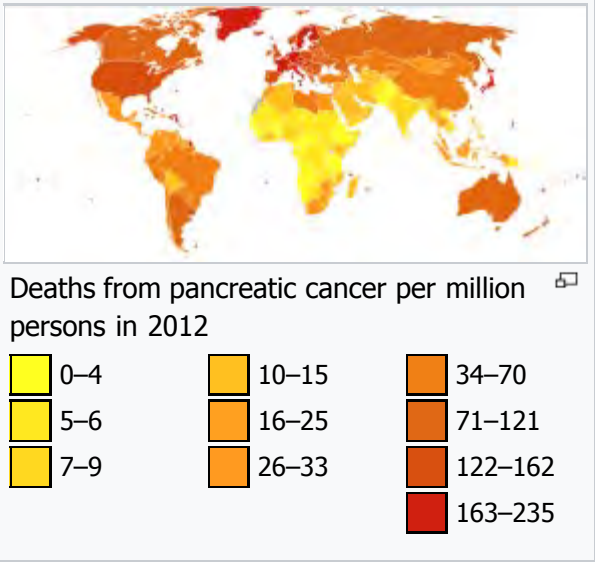
16%,[44] although the outlook varies considerably according to the type.[27]

| | | |
|---|---|---|
| **IB** | 12 | |
| **IIA / II** | 7 | 52 |
| **IIB** | 5 | |
| **III** | 3 | 41 |
| **IV** | 1 | 16 |

For locally advanced and metastatic pancreatic adenocarcinomas, which together represent over 80% of cases, numerous recent trials comparing chemotherapy regimes have shown increased survival times, but not to more than one year.[4][68] Overall five-year survival for pancreatic cancer in the US has improved from 2% in cases diagnosed in 1975–77, and 4% in 1987–89 diagnoses, to 6% in 2003–09.[91] In the less than 20% of cases of pancreatic adenocarcinoma with a diagnosis of a localized and small cancerous growth (less than 2 cm in Stage T1), about 20% of Americans survive to five years.[16]

## Distribution [edit]

As of 2012, pancreatic cancer resulted in 330,000 deaths globally,[2] up from 310,000 in 2010 and 200,000 in 1990.[92] In 2014, an estimated 46,000 people in the US are expected to be diagnosed with pancreatic cancer and 40,000 to die of it.[4] Although it accounts for only 2.5% of new cases, pancreatic cancer is responsible for 6% of cancer deaths each year.[93] It is the seventh highest cause of death from cancer worldwide.[2]



Globally pancreatic cancer is the 11th most common cancer in women and the 12th most common in men.[2] The majority of recorded cases occur in developed countries.[2] People from the United States have an average lifetime risk of about 1 in 67 (or 1.5%) of developing the disease,[94] slightly higher than the figure for the UK.[95] The disease is more common in men than women,[2][4] though the difference in rates has narrowed over recent decades, probably reflecting earlier increases in female smoking. In the United States the risk for African Americans is over 50% greater than for whites, but the rates in Africa and East Asia are much lower than those in North America or Europe. The United States, Central and eastern Europe, and Argentina and Uruguay all have high rates.[2]

Pancreatic cancer is the 10th most common cancer in the UK (around 8,800 people were diagnosed with the disease in 2011), and it is the 5th most common cause of cancer death (around 8,700 people died in 2012).[96]

### PanNETs [edit]

The annual incidence of clinically recognized PanNETs is low (about 5 per one million person-years) and is dominated by the non-functioning types.[22] Somewhere between 45% and 90% of PanNETs are thought to be of the non-functioning types.[18][25] Studies of autopsies have uncovered small PanNETs rather frequently, suggesting that the prevalence of tumors that remain inert and asymptomatic may be relatively high.[25] Overall PanNETs are thought to account for about 1 to 2% of all pancreatic tumors.[22] The definition and classification of PanNETs has changed over time, affecting what is known about their epidemiology and clinical relevance.[49]

## History [edit]

*See also: Timeline of pancreatic cancer*

The earliest recognition of pancreatic cancer has been attributed to the 18th-century Italian scientist Giovanni Battista Morgagni, the historical father of modern-day anatomic pathology, who claimed to have traced several cases of cancer in the pancreas. Many 18th and 19th-century physicians were skeptical about the existence of the disease, given the similar appearance of pancreatitis. Some case reports were published in the 1820s and 1830s, and a genuine histopathologic diagnosis was eventually recorded by the American clinician Jacob Mendes Da Costa, who also doubted the reliability of Morgagni's interpretations. By the start of the 20th century, cancer of the head of the pancreas had become a well-established diagnosis.[97]

Regarding the recognition of PanNETs, the possibility of cancer of the islet cells was initially suggested in 1888. The first case of hyperinsulinism due to a tumor of this type was reported in 1927. Recognition of a non-insulin-secreting type of PanNET is generally ascribed to the American surgeons, R. M. Zollinger and E. H. Ellison, who gave their names to Zollinger–Ellison syndrome, after postulating the existence of a gastrin-secreting pancreatic tumor in a report of two cases of unusually severe peptic ulcers published in 1955.[97] In 2010, the WHO recommended that PanNETs be referred to as "neuroendocrine" rather than "endocrine" tumors.[24]

The first reported partial pancreaticoduodenectomy was performed by the Italian surgeon Alessandro Codivilla in 1898, but the patient only survived 18 days before succumbing to complications. Early operations were compromised partly because of mistaken beliefs that people would die if their duodenum were removed, and also, at first, if the flow of pancreatic juices stopped. Later it was thought, also mistakenly, that the pancreatic duct could simply be tied up without serious adverse effects; in fact, it will very often leak later on. In 1907–08, after some more unsuccessful operations by other surgeons, experimental procedures were tried on corpses by French surgeons.[98]

In 1912 the German surgeon Walther Kausch was the first to remove large parts of the duodenum and pancreas together (*en bloc*). This was in Breslau, now Wrocław in Poland. In 1918 it was demonstrated in operations on dogs that total removal of the duodenum is compatible with life, but this was not reported in human surgery until 1935, when the American surgeon Allen Oldfather Whipple published the results of a series of three operations at Columbia Presbyterian Hospital in New York. Only one of the patients had the duodenum totally removed, but he survived for two years before dying of metastasis to the liver. The first operation was unplanned, as cancer was only discovered in the operating theater. Whipple's success showed the way for the future, but the operation remained a difficult and dangerous one until recent decades. He published several refinements to his procedure, including the first total removal of the duodenum in 1940, but he only performed a total of 37 operations.[98]

The discovery in the late 1930s that vitamin K prevented bleeding with jaundice, and the development of blood transfusion as an everyday process, both improved post-operative survival,[98] but about 25% of people never left hospital alive as late as the 1970s.[99] In the 1970s a group of American surgeons wrote urging that the procedure was too dangerous and should be abandoned. Since then outcomes in larger centers have improved considerably, and mortality from the operation is often less than 4%.[20] In 2006 a report was published of a series of 1,000 consecutive pancreaticoduodenectomies performed by a single surgeon from Johns Hopkins Hospital between 1969 and 2003. The rate of these operations had increased steadily over this period, with only three of them before 1980, and the median operating time reduced from 8.8 hours in the 1970s to 5.5 hours in the 2000s, and mortality within 30 days or in hospital was only 1%.[98][99] Another series of 2,050 operations at the Massachusetts General Hospital between 1941 and 2011 showed a similar picture of improvement.[100]

Small precancerous neoplasms for many pancreatic cancers are being detected at greatly increased rates by modern medical imaging. One type, the intraductal papillary mucinous neoplasm (IPMN) was first described by Japanese researchers in 1982. It was noted in 2010 that: "For the next decade, little attention was paid to this report; however, over the subsequent 15 years, there has been a virtual explosion in the recognition of this tumor."[45]

## Research directions [edit]

Worldwide efforts on many levels are underway to understand pancreatic cancer, but progress has been slow, particularly into understanding the disease's causes.[101] There are several fundamental unanswered questions.[102][103] The nature of the changes that lead to the disease are being intensely investigated, such as the roles played by genes such as *KRAS* and *p53*.[36][104][105] A key question is the timing of events as the disease develops and progresses – particularly the role of diabetes,[106] and how and when the disease spreads.[107]

Research on early detection is ongoing.[52][53] For instance, the European Registry of Hereditary Pancreatitis and Familial Pancreatic Cancer (EUROPAC) trial is aiming to determine whether regular screening is appropriate for people with a family history of the disease, or who have hereditary pancreatitis.[108] The knowledge that new onset of diabetes can be an early sign of the disease could facilitate timely diagnosis and prevention if a workable screening strategy can be developed.[106][109][110]

Another area of interest is in assessing whether keyhole surgery (laparoscopy) would be better than Whipple's procedure in treating the disease surgically, particularly in terms of recovery time.[111] Irreversible electroporation is a relatively novel ablation technique that has shown promise in downstaging and prolonging survival in persons with locally advanced disease. It is especially suitable for treatment of tumors that are in proximity to peri-pancreatic vessels without risk of vascular trauma.[112][113] The limited success of outcomes after surgery has led to a number of trials that were running in 2014 to test outcomes using chemotherapy or radiochemotherapy before surgery. This had previously not been found to be helpful, but is being trialed again, using drug combinations which have emerged from the many trials of post-operative therapies, such as FOLFIRINOX.[4]

Efforts are underway to develop new drugs.[36][114] Some of these involve targeted therapies against the cancer cells' molecular mechanisms.[115][116][117] Others aim to target the highly resistant cancer stem cells.[65][118] Still others aim to affect the non-neoplastic stroma and microenvironment of the tumor, which is known to influence cell proliferation and metastasis.[117][118][119][120][121] A further approach involves the use of immunotherapy, such as oncolytic viruses.[122][123]

# Prostate cancer

From Wikipedia, the free encyclopedia

**Prostate cancer**, also known as **carcinoma of the prostate**, is the development of cancer in the prostate, a gland in the male reproductive system.[1] Most prostate cancers are slow growing; however, some grow relatively quickly.[2][3] The cancer cells may spread from the prostate to other parts of the body, particularly the bones and lymph nodes.[4] It may initially cause no symptoms.[3] In later stages it can lead to difficulty urinating, blood in the urine, or pain in the pelvis, back or when urinating.[5] A disease known as benign prostatic hyperplasia may produce similar symptoms. Other late symptoms may include feeling tired due to low levels of red blood cells.[3]

Factors that increase the risk of prostate cancer include: older age, a family history of the disease, and race. About 99% of cases occur in those over the age of 50. Having a first-degree relative with the disease increases the risk two to threefold. In the United States it is more common in the African American population than the white American population. Other factors that may be involved include a diet high in processed meat, red meat, or milk products or low in certain vegetables.[2] An association with gonorrhea has been found, but a reason for this relationship has not been identified.[6] Prostate cancer is diagnosed by biopsy. Medical imaging may then be done to determine if the cancer has spread to other parts of the body.[5]

Prostate cancer screening is controversial.[2][3] Prostate-specific antigen (PSA) testing increases cancer detection but does not decrease mortality.[7] The United States Preventive Services Task Force recommends against screening using the PSA test, due to the risk of overdiagnosis and overtreatment, as most cancer diagnosed would remain asymptomatic. The USPSTF concludes that the potential benefits of testing do not outweigh the expected harms.[8] While 5α-reductase inhibitors appear to decrease low-grade cancer risk they do not affect high-grade cancer risk and thus are not recommended for prevention.[2] Supplementation with vitamins or minerals does not appear to affect the risk.[2][9]

Many cases can be safely followed with active surveillance or watchful waiting. Other treatments may include a combination of surgery, radiation therapy, hormone therapy or chemotherapy.[5] When it only occurs inside the prostate it may be curable.[3] In those in whom the disease has spread to the bones, pain medications, bisphosphonates and targeted therapy, among others, may be useful. Outcomes depend on a

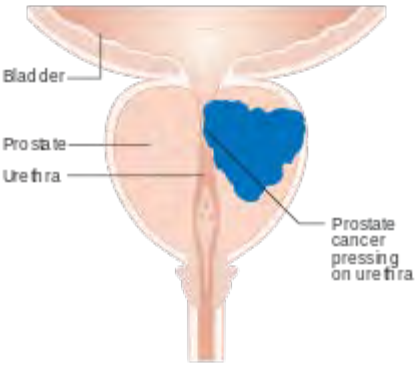
person's age and other health problems as well as how aggressive and extensive the cancer is. Most people with prostate cancer do not end up dying from the disease.[5] The 5-year survival rate in the United States is 99%.[10] Globally it is the second most common type of cancer and the fifth leading cause of cancer-related death in men.[11] In 2012 it occurred in 1.1 million men and caused 307,000 deaths.[11] It was the most common cancer in males in 84 countries,[2] occurring more commonly in the developed world. Rates have been increasing in the developing world.[12] Detection increased significantly in the 1980s and 1990s in many areas due to increased PSA testing.[2] Studies of males who died from unrelated causes have found prostate cancer in 30% to 70% of those over age 60.[3]

**Contents**

## Signs and symptoms [edit]

Early prostate cancer usually has no clear symptoms. Sometimes, however, prostate cancer does cause symptoms, often similar to those of diseases such as benign prostatic hyperplasia. These include frequent urination, nocturia (increased urination at night), difficulty starting and maintaining a steady stream of urine, hematuria (blood in the urine),



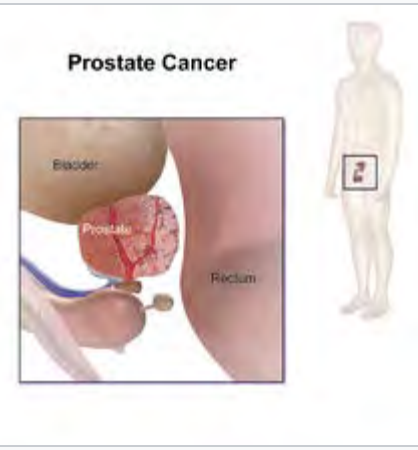
A diagram of prostate cancer pressing on the urethra, which can cause symptoms.

and dysuria (painful urination). A study based on the 1998 Patient Care Evaluation in the US found that about a third of patients diagnosed with prostate cancer had one or more such symptoms, while two-thirds had no symptoms.[13]

Edit links

Prostate cancer is associated with urinary dysfunction as the prostate gland surrounds the prostatic urethra. Changes within the gland, therefore, directly affect urinary function. Because the *vas deferens* deposits seminal fluid into the prostatic urethra, and secretions from the prostate gland itself are included in semen content, prostate cancer may also cause problems with sexual function and performance, such as difficulty achieving erection or painful ejaculation.[13]

Metastatic prostate cancer that has spread to other parts of the body can cause additional symptoms. The most common symptom is bone pain, often in the vertebrae (bones of the spine), pelvis, or ribs. Spread of cancer into other bones such as the femur is usually to the proximal or nearby part of the bone. Prostate cancer in the spine can also compress the spinal cord, causing tingling, leg weakness and urinary and fecal incontinence.[14]



Prostate cancer

## Risk factors [edit]

A complete understanding of the causes of prostate cancer remains elusive.[15] The primary risk factors are obesity, age and family history. Prostate cancer is very uncommon in men younger than 45, but becomes more common with advancing age. The average age at the time of diagnosis is 70.[16] However, many men never know they have prostate cancer. Autopsy studies of Chinese, German, Israeli, Jamaican, Swedish, and Ugandan men who died of other causes have found prostate cancer in 30% of men in their fifties, and in 80% of men in their seventies.[17] Men who have first-degree family members with prostate cancer appear to have double the risk of getting the disease compared to men without prostate cancer in the family.[18] This risk appears to be greater for men with an affected brother than for men with an affected father. In the United States in 2005, there were an estimated 230,000 new cases of prostate cancer and 30,000 deaths due to prostate cancer.[19] Men with high blood pressure are more likely to develop prostate cancer.[20] There is a small increased risk of prostate cancer associated with lack of exercise.[21] A 2010 study found that prostate basal cells were the most common site of origin for prostate cancers.[22]

### Genetic [edit]

Genetic background may contribute to prostate cancer risk, as suggested by associations with race, family, and specific gene variants. Men who have a first-degree relative (father or brother) with prostate cancer have twice the risk of developing prostate cancer, and those with two first-degree relatives affected have a fivefold greater risk compared with men with no family history.[23] In the United States, prostate cancer more commonly affects black men than white or Hispanic men, and is also more deadly in black men.[24][25] In contrast, the incidence and mortality rates for Hispanic men are one third lower than for non-Hispanic whites. Studies of twins in Scandinavia suggest that 40% of prostate cancer risk can be explained by inherited factors.[26]

No single gene is responsible for prostate cancer; many different genes have been implicated. Mutations in

*BRCA1* and *BRCA2*, important risk factors for ovarian cancer and breast cancer in women, have also been implicated in prostate cancer.[27] Other linked genes include the Hereditary Prostate cancer gene 1 (HPC1), the androgen receptor, and the vitamin D receptor.[24] TMPRSS2-ETS gene family fusion, specifically TMPRSS2-ERG or TMPRSS2-ETV1/4 promotes cancer cell growth.[28]

Two large genome-wide association studies linking single nucleotide polymorphisms (SNPs) to prostate cancer were published in 2008.[29][30] These studies identified several SNPs which substantially affect the risk of prostate cancer. For example, individuals with TT allele pair at SNP rs10993994 were reported to be at 1.6 times higher risk of prostate cancer than those with the CC allele pair. This SNP explains part of the increased prostate cancer risk of African American men as compared to American men of European descent, since the C allele is much more prevalent in the latter; this SNP is located in the promoter region of the *MSMB* gene, thus affects the amount of MSMB protein synthesized and secreted by epithelial cells of the prostate.[31]

## Dietary [edit]

While some dietary factors have been associated with prostate cancer the evidence is still tentative.[32] Evidence supports little role for dietary fruits and vegetables in prostate cancer occurrence.[33] Red meat and processed meat also appear to have little effect in human studies.[34] Higher meat consumption has been associated with a higher risk in some studies.[35]

Lower blood levels of vitamin D may increase the risk of developing prostate cancer.[36]

Folic acid supplements have no effect on the risk of developing prostate cancer.[37]

## Medication exposure [edit]

There are also some links between prostate cancer and medications, medical procedures, and medical conditions.[38] Use of the cholesterol-lowering drugs known as the statins may also decrease prostate cancer risk.[39]

Infection or inflammation of the prostate (prostatitis) may increase the chance for prostate cancer while another study shows infection may help prevent prostate cancer by increasing blood to the area. In particular, infection with the sexually transmitted infections chlamydia, gonorrhea, or syphilis seems to increase risk.[40] Finally, obesity[41] and elevated blood levels of testosterone[42] may increase the risk for prostate cancer. There is an association between vasectomy and prostate cancer; however, more research is needed to determine if this is a causative relationship.[43]

Research released in May 2007, found that US war veterans who had been exposed to Agent Orange had a 48% increased risk of prostate cancer recurrence following surgery.[44]

## Infectious disease [edit]

An association with gonorrhea has been found, but a mechanism for this relationship has not been identified.[6]

In 2006, a previously unknown retrovirus, Xenotropic MuLV-related virus or XMRV, was associated with human prostate tumors,[45] but subsequent reports on the virus were contradictory,[46][47] and the original 2006 finding was instead due to a previously undetected contamination.[48] The journals *Science* and *PlosONE* both retracted XMRV related articles.[49][50]

## Sexual factors [edit]

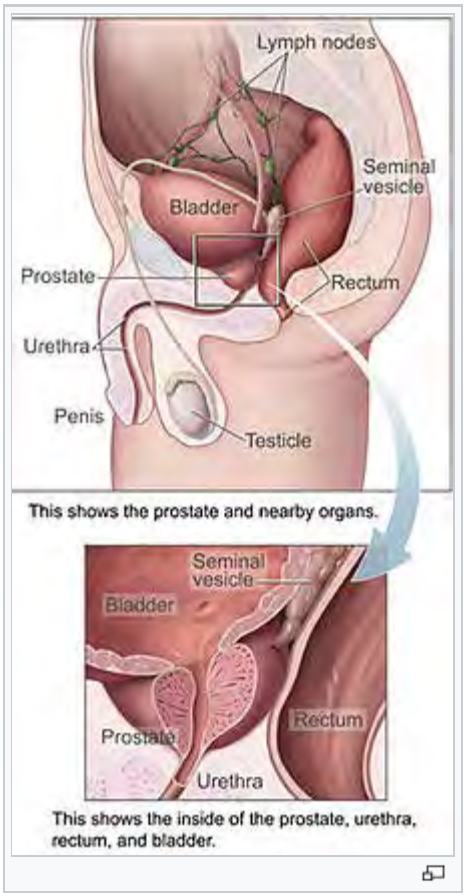
Several case-control studies have shown that having many lifetime sexual partners or starting sexual activity early in life substantially increases the risk of prostate cancer.[51][52][53]

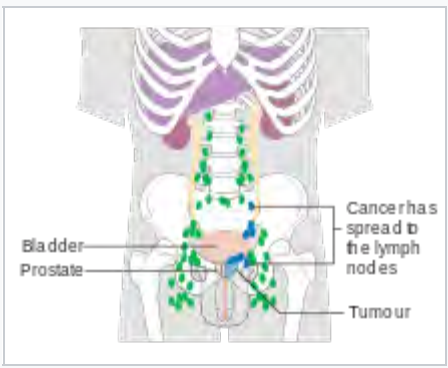
While the available evidence is weak,[54] tentative results suggest that frequent ejaculation may decrease

the risk of prostate cancer.[55] A study, over eight years, showed that those that ejaculated most frequently (over 21 times per month on average) were less likely to get prostate cancer (however, the researchers asserted "ejaculation frequency was not statistically significantly associated with risk of advanced prostate cancer" and concluded "our results suggest that ejaculation frequency is not related to increased risk of prostate cancer").[56] The results were broadly similar to the findings of a smaller Australian study.[57]

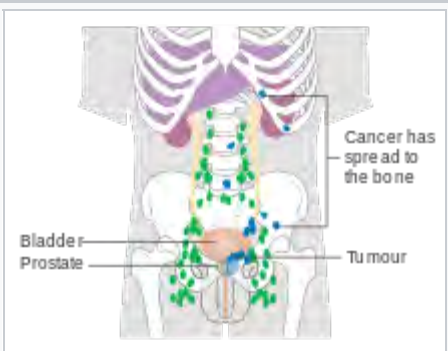
## Pathophysiology [edit]

The prostate is a part of the male reproductive system that helps make and store seminal fluid. In adult men, a typical prostate is about 3 centimeters long and weighs about 20 grams.[58] It is located in the pelvis, under the urinary bladder and in front of the rectum. The prostate surrounds part of the urethra, the tube that carries urine from the bladder during urination and semen during ejaculation.[59] Because of its location, prostate diseases often affect urination, ejaculation, and rarely defecation. The prostate contains many small glands which make about 20% of the fluid constituting semen.[60] In prostate cancer, the cells of these prostate glands mutate into cancer cells. The prostate glands require male hormones, known as androgens, to work properly. Androgens include testosterone, which is made in the testes; dehydroepiandrosterone, made in the adrenal glands; and dihydrotestosterone, which is converted from testosterone within the prostate itself. Androgens are also responsible for secondary sex characteristics such as facial hair and increased muscle mass.





Prostate cancer that has metastasized to the lymph nodes



Prostate cancer that has metastasized to the bone

Prostate cancer is classified as an adenocarcinoma, or glandular cancer, that begins when normal semen-secreting prostate gland cells mutate into cancer cells. The region of prostate gland where the adenocarcinoma is most common is the peripheral zone. Initially, small clumps of cancer cells remain confined to otherwise normal prostate glands, a condition known as carcinoma in situ or prostatic intraepithelial neoplasia (PIN). Although there is no proof that PIN is a cancer precursor, it is closely associated with cancer. Over time, these cancer cells begin to multiply and spread to the surrounding prostate tissue (the stroma) forming a tumor. Eventually, the tumor may grow large enough to invade nearby organs such as the seminal vesicles or the rectum, or the tumor cells may develop the ability to travel in the bloodstream and lymphatic system. Prostate cancer is considered a malignant tumor because it is a mass of cells that can invade other parts of the body. This invasion of other organs is called metastasis. Prostate cancer most commonly metastasizes to the bones, lymph nodes, and may invade rectum, bladder and lower ureters after local progression. The route of metastasis to bone is thought to be venous as the prostatic venous plexus draining the prostate connects with the vertebral veins.[61]

The prostate is a zinc-accumulating, citrate-producing organ. The protein ZIP1 is responsible for the active transport of zinc into prostate cells. One of the zinc's important roles is to change the metabolism of the cell in order to produce citrate, an important component of semen. The process of zinc accumulation, alteration of metabolism, and citrate

production is energy inefficient, and prostate cells sacrifice enormous amounts of energy (ATP) in order to accomplish this task. Prostate cancer cells are generally devoid of zinc. This allows prostate cancer cells to save energy not making citrate, and utilize the new abundance of energy to grow and spread. The absence of zinc is thought to occur via a silencing of the gene that produces the transporter protein ZIP1. ZIP1 is now called a tumor suppressor gene product for the gene SLC39A1. The cause of the epigenetic silencing is unknown. Strategies which transport zinc into transformed prostate cells effectively eliminate these cells in animals. Zinc inhibits NF-κB pathways, is anti-proliferative and induces apoptosis in abnormal cells. Unfortunately, oral ingestion of zinc is ineffective since high concentrations of zinc into prostate cells is not possible without the active transporter, ZIP1.[62]

Loss of cancer suppressor genes, early in the prostatic carcinogenesis, have been localized to chromosomes *8p*, *10q*, *13q*, and *16q*. P53 mutations in the primary prostate cancer are relatively low and are more frequently seen in metastatic settings, hence, p53 mutations are a late event in the pathology of prostate cancer. Other tumor suppressor genes that are thought to play a role in prostate cancer include PTEN (gene) and KAI1. "Up to 70 percent of men with prostate cancer have lost one copy of the PTEN gene at the time of diagnosis"[63] Relative frequency of loss of E-cadherin and CD44 has also been observed.

RUNX2 is a transcription factor that prevents cancer cells from undergoing apoptosis thereby contributing to the development of prostate cancer.[64]

The PI3k/Akt signaling cascade works with the transforming growth factor beta/SMAD signaling cascade to ensure prostate cancer cell survival and protection against apoptosis.[65] X-linked inhibitor of apoptosis (XIAP) is hypothesized to promote prostate cancer cell survival and growth and is a target of research because if this inhibitor can be shut down then the apoptosis cascade can carry on its function in preventing cancer cell proliferation.[66] Macrophage inhibitory cytokine-1 (MIC-1) stimulates the focal adhesion kinase (FAK) signaling pathway which leads to prostate cancer cell growth and survival.[67]

The androgen receptor helps prostate cancer cells to survive and is a target for many anti cancer research studies; so far, inhibiting the androgen receptor has only proven to be effective in mouse studies.[68] Prostate specific membrane antigen (PSMA) stimulates the development of prostate cancer by increasing folate levels for the cancer cells to use to survive and grow; PSMA increases available folates for use by hydrolyzing glutamated folates.[69]

## Diagnosis [edit]

The American Cancer Society's position regarding early detection is "Research has not yet proven that the potential benefits of testing outweigh the harms of testing and treatment. The American Cancer Society believes that men should not be tested without learning about what we know and don't know about the risks and possible benefits of testing and treatment. Starting at age 50, (45 if African American or brother or father suffered from condition before age 65) talk to your doctor about the pros and cons of testing so you can decide if testing is the right choice for you."[70]

The only test that can fully confirm the diagnosis of prostate cancer is a biopsy, the removal of small pieces of the prostate for microscopic examination. However, prior to a biopsy, less invasive testing can be conducted.

There are also several other tests that can be used to gather more information about the prostate and the urinary tract. Digital rectal examination (DRE) may allow a doctor to detect prostate abnormalities. Cystoscopy shows the urinary tract from inside the bladder, using a thin, flexible camera tube inserted down the urethra. Transrectal ultrasonography creates a picture of the prostate using sound waves from a probe in the rectum.

### Prostate imaging [edit]

Ultrasound (US) and magnetic resonance imaging (MRI) are the two main imaging methods used for prostate cancer detection. Urologists use transrectal ultrasound during prostate biopsy and can sometimes see a hypoechoic area (tissues or structures that reflect relatively less of the ultrasound waves directed at

them). However, the US has poor tissue resolution and thus, is generally not clinically used.

Prostate MRI has better soft tissue resolution than ultrasound.[71]

MRI in those who are at low risk might help people choose active surveillance, in those who are at intermediate risk it may help with determining the stage of disease, while in those who are at high risk it might help find bone disease.[72]

Currently (2011), MRI is used to identify targets for prostate biopsy using fusion MRI with ultrasound (US) or MRI-guidance alone. In men who are candidates for active surveillance, fusion MR/US guided prostate biopsy detected 33% of cancers compared to 7% with standard ultrasound guided biopsy.[73]

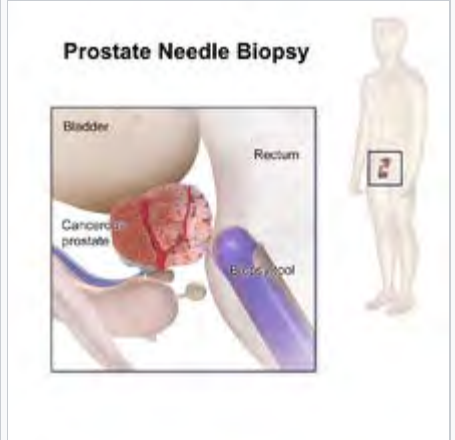
Prostate MRI is also used for surgical planning for men undergoing robotic prostatectomy. It has also shown to help surgeons decide whether to resect or spare the neurovascular bundle, determine return to urinary continence, and help assess surgical difficulty.[74]

For Prostate MRI exists the PI-RADS Reporting system. PI-RADS is an acronym for Prostate Imaging-Reporting and Data System, defining standards of high-quality clinical service for multi-parametric Magnetic Resonance Imaging (mpMRI), including image creation and reporting.

## Biopsy [edit]

*Main article: Prostate biopsy*

If cancer is suspected, a biopsy is offered expediently. During a biopsy a urologist or radiologist obtains tissue samples from the prostate via the rectum. A biopsy gun inserts and removes special hollow-core needles (usually three to six on each side of the prostate) in less than a second. Prostate biopsies are routinely done on an outpatient basis and rarely require hospitalization. Antibiotics should be used to prevent complications like fever, urinary tract infections, and sepsis.[75] Fifty-five percent of men report discomfort during prostate biopsy.[76]



Prostate needle biopsy

## Gleason score [edit]

*Main article: Gleason score*

The tissue samples are then examined under a microscope to determine whether cancer cells are present, and to evaluate the microscopic features (or Gleason score) of any cancer found. Prostate specific membrane antigen is a transmembrane carboxypeptidase and exhibits folate hydrolase activity.[77] This protein is overexpressed in prostate cancer tissues and is associated with a higher Gleason score.[77]

Micrograph showing a prostate cancer (conventional adenocarcinoma) with perineural invasion. H&E stain.

## Tumor markers [edit]

Tissue samples can be stained for the presence of PSA and other tumor markers in order to determine the origin of malignant cells that have metastasized.[78]

Small cell carcinoma is a very rare (1%[79]) type of prostate cancer that cannot be diagnosed using the PSA.[79][80] As of 2009 researchers were researching ways to screen for this type of prostate cancer, because it is relatively unknown and rare, but very serious and quick to spread to other parts of the body.[80] Possible methods include chromatographic separation methods by mass spectrometry, or protein capturing by immunoassays or immunized antibodies. The test method will involve quantifying the amount of the biomarker PCI, with reference to the Gleason Score. This test quick and sensitive. It can detect patients in the diagnostic grey zone, particularly those with a serum free to total

Prostate Specific Antigen ratio of 10-20%.[81]

The oncoprotein BCL-2 is associated with the development of androgen-independent prostate cancer, due to its high levels of expression in androgen-independent tumours in advanced stages of the pathology. The upregulation of BCL-2 after androgen ablation in prostate carcinoma cell lines and in a castrated-male rat model further established a connection between BCL-2 expression and prostate cancer progression.[82]

The expression of Ki-67 by immunohistochemistry may be a significant predictor of patient outcome for men with prostate cancer.[83]

ERK5 is a protein that may be used as a marker. It is present in abnormally high levels in cases of prostate cancer, including invasive cancer that has metastasized. It is also present in relapsed cancer following previous hormone therapy. Reducing the amount of ERK5 in cancerous cells reduces their invasiveness.[84]

## Staging [edit]

*Main article: Prostate cancer staging*

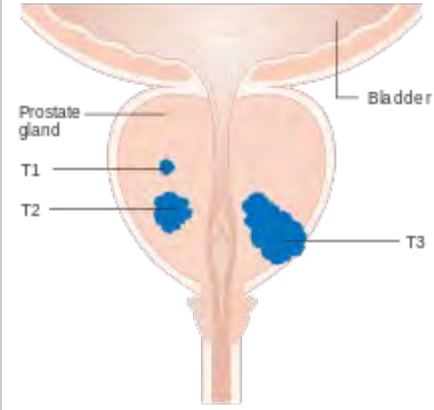


Diagram showing T1-3 stages of prostate cancer.

An important part of evaluating prostate cancer is determining the stage, or how far the cancer has spread. Knowing the stage helps define prognosis and is useful when selecting therapies. The most common system is the four-stage TNM system (abbreviated from Tumor/Nodes/Metastases). Its components include the size of the tumor, the number of involved lymph nodes, and the presence of any other metastases.[85]

The most important distinction made by any staging system is whether or not the cancer is still confined to the prostate. In the TNM system, clinical T1 and T2 cancers are found only in the prostate, while T3 and T4 cancers have spread elsewhere. Several tests can be used to look for evidence of spread. Medical specialty professional organizations recommend against the use of PET scans, CT scans, or bone scans when a physician stages early prostate cancer with low risk for metastasis.[86] Those tests would be appropriate in such cases as when a CT scan evaluates spread within the pelvis, a bone scan look for spread to the bones, and endorectal coil magnetic resonance imaging to closely evaluate the prostatic capsule and the seminal vesicles. Bone scans should reveal osteoblastic appearance due to *increased* bone density in the areas of bone metastasis—opposite to what is found in many other cancers that metastasize.

After a prostate biopsy, a pathologist looks at the samples under a microscope. If cancer is present, the pathologist reports the grade of the tumor. The grade tells how much the tumor tissue differs from normal prostate tissue and suggests how fast the tumor is likely to grow. The Gleason system is used to grade prostate tumors from 2 to 10, where a Gleason score of 10 indicates the most abnormalities. The pathologist assigns a number from 1 to 5 for the most common pattern observed under the microscope, then does the same for the second-most-common pattern. The sum of these two numbers is the Gleason score. The Whitmore-Jewett stage is another method sometimes used.

# Prevention [edit]

## Diet and lifestyle [edit]

The data on the relationship between diet and prostate cancer is poor.[87] In light of this the rate of prostate cancer is linked to the consumption of the Western diet.[87] There is little if any evidence to support an association between trans fat, saturated fat and carbohydrate intake and risk of prostate cancer.[87][88] Evidence regarding the role of omega-3 fatty acids in preventing prostate cancer does not suggest that they reduce the risk of prostate cancer, although additional research is needed.[87][89] Vitamin supplements appear to have no effect and some may increase the risk.[9][87] High calcium intake has been linked to advanced prostate cancer.[90] Consuming fish may lower prostate cancer deaths but does not appear to affect its occurrence.[91] Some evidence supports lower rates of prostate cancer with a vegetarian diet.[92] There is some tentative evidence for foods containing lycopene and selenium.[93] Diets rich in cruciferous vegetables, soy, beans and other legumes may be associated with a lower risk of prostate cancer, especially more advanced cancers.[94]

Men who get regular exercise may have a slightly lower risk, especially vigorous activity and the risk of advanced prostate cancer.[94]

## Medications [edit]

In those who are being regularly screened 5-alpha-reductase inhibitor (finasteride and dutasteride) reduce the overall risk of being diagnosed with prostate cancer however there is insufficient data to determine if they have an effect on the risk of death and may increase the chance of more serious cases.[95]

# Screening [edit]

*Main article: Prostate cancer screening*

Prostate cancer screening is an attempt to find unsuspected cancers. Initial screens may lead to more invasive follow-up tests such as a biopsy.[96] Options include the digital rectal exam (DRE) and the prostate-specific antigen (PSA) blood test. Such screening is controversial and, in some people, may lead to unnecessary disruption and possibly harmful consequences.[97] Routine screening with either a DRE or PSA is not supported by the evidence as there is no mortality benefit from screening.[7]

The United States Preventive Services Task Force (USPSTF) recommends against the PSA test for prostate cancer screening in healthy men regardless of age.[98] They concluded that the potential benefit of testing does not outweigh the expected harms.[8][99] The Centers for Disease Control and Prevention shared that conclusion.[100] The American Society of Clinical Oncology and the American College of Physicians discourages screening for those who are expected to live less than ten to fifteen years, while in those with a greater life expectancy a decision should be made by the person in question based on the potential risks and benefits.[101] In general, they concluded, "it is uncertain whether the benefits associated with PSA testing for prostate cancer screening are worth the harms associated with screening and subsequent unnecessary treatment."[102] American Urological Association (AUA 2013) guidelines call for weighing the benefits of preventing prostate cancer mortality in 1 man for every 1,000 men screened over a ten-year period against the known harms associated with diagnostic tests and treatment. The AUA recommends screening decisions in those 55 to 69 be based on shared decision making, and that if screening is performed it should occur no more often than every two years.[103]

# Management [edit]

*Main article: Management of prostate cancer*

The first decision to be made in managing prostate cancer is whether treatment is needed. Prostate cancer, especially low-grade forms found in elderly men, often grows so slowly that no treatment is required.[104] Treatment may also be inappropriate if a person has other serious health problems or is not expected to live long enough for symptoms to appear.

Which option is best depends on the stage of the disease, the Gleason score, and the PSA level. Other important factors are age, general health, and a person's views about potential treatments and their possible side effects. Because most treatments can have significant side effects, such as erectile dysfunction and urinary incontinence, treatment discussions often focus on balancing the goals of therapy with the risks of lifestyle alterations. A combination of the treatment options is often recommended for managing prostate cancer.[105][106][107]

Guidelines for treatment for specific clinical situations requires a good estimation of a person's long-term life expectancy.[108] People can also use an 18-item questionnaire to learn whether they have good knowledge and understanding about their treatment options before they choose. Most of those who are newly diagnosed and made a treatment choice can not correctly answer over half of the questions.[108]

If radiation therapy is done first, and fails, then radical prostatectomy becomes a very technically challenging surgery and may not be feasible. On the other hand, radiation therapy done after surgical failure may have many complications.[109] It is associated with a small increase in bladder and colon cancer.[110]

In localized disease, it is unknown if radical prostatectomy is better or worse than watchful waiting.[111]

A meta-analysis on the effects of voiding position during urination in males with prostate enlargement showed that sitting was superior to standing. Bladder emptying was significantly improved, while there was a trend towards a higher urinary flow and shorter voiding time.[112]

## Surveillance [edit]

Many men diagnosed with low-risk prostate cancer are eligible for *active surveillance*. This term implies careful observation of the tumor over time, with the intention of treatment for a cure if there are signs of cancer progression. Active surveillance is *not* synonymous with watchful waiting, an older term which implies no treatment or specific program of monitoring, with the assumption that *palliative*, not curative, treatment would be used if advanced, symptomatic disease develops.

Active surveillance involves monitoring the tumor for signs of growth or the appearance of symptoms. The monitoring process may involve serial PSA, physical examination of the prostate, and/or repeated biopsies. The goal of surveillance is to avoid overtreatment and the sometimes serious, permanent side effects of treatment for a slow-growing or self-limited tumor that would never cause any problems for the person. This approach is not used for aggressive cancers, but it may cause anxiety for people who wrongly believe that all cancer is deadly or themselves to have life-threatening cancer. For 50% to 75% of people with prostate cancer it will cause no harm before a person dies from other causes.[113]

## Aggressive cancer [edit]

Treatment of aggressive prostate cancers may involve surgery (i.e. radical prostatectomy), radiation therapy including brachytherapy (prostate brachytherapy) and external beam radiation therapy, high-intensity focused ultrasound (HIFU), chemotherapy, oral chemotherapeutic drugs (Temozolomide/TMZ), cryosurgery, hormonal therapy, or some combination.[114][115]

Although the widespread use of prostate-specific antigen (PSA) screening in the USA has resulted in diagnosis at earlier age and cancer stage, the vast majority of cases are still diagnosed in men older than 65 years, and approximately 25% of cases are diagnosed in men older than 75 years.[116] Though US

National Comprehensive Cancer Network guidelines recommend using life expectancy greater than or less than 10 years to help make treatment decisions, in practice, many elderly patients are not offered curative treatment options such as radical prostatectomy or radiation therapy and are instead treated with hormonal therapy or watchful waiting.[117] This pattern can be attributed to factors such as medical co-morbidity and patient preferences is regard to quality of life in addition to prostate cancer specific risk factors such as pretreatment PSA, Gleason score and clinical stage. As the average life expectancy increases due to advances in the treatment of cardiovascular, pulmonary and other chronic diseases, it is likely that more elderly patients will be living long enough to suffer the consequences of their prostate cancer. Therefore, there is currently much interest in the role of aggressive prostate cancer treatment modalities such as with surgery or radiation in the elderly population who have localized disease.

If the cancer has spread beyond the prostate, treatment options significantly change, so most doctors that treat prostate cancer use a variety of nomograms to predict the probability of spread. Treatment by watchful waiting/active surveillance, external beam radiation therapy, brachytherapy, cryosurgery, HIFU, and surgery are, in general, offered to men whose cancer remains within the prostate. Hormonal therapy and chemotherapy are often reserved for disease that has spread beyond the prostate. However, there are exceptions: radiation therapy may be used for some advanced tumors, and hormonal therapy is used for some early stage tumors. Cryotherapy (the process of freezing the tumor), hormonal therapy, and chemotherapy may also be offered if initial treatment fails and the cancer progresses.

Sipuleucel-T, a cancer vaccine has been found to result in a benefit (a four-month increase in survival) for men with metastatic prostate cancer.[118]

## Castration-resistant [edit]

*Main article: Castration-resistant prostate cancer*

Most hormone dependent cancers become resistant to treatment after one to three years and resume growth despite hormone therapy. Previously considered "hormone-refractory prostate cancer" or "androgen-independent prostate cancer", the term castration-resistant has replaced "hormone refractory" because while they are no longer responsive to castration treatment (reduction of available androgen/testosterone/DHT by chemical or surgical means), these cancers still show reliance upon hormones for androgen receptor activation.[119]

The cancer chemotherapic docetaxel has been used as treatment for CRPC with a median survival benefit of 2 to 3 months.[120][121] A second-line chemotherapy treatment is cabazitaxel.[122] A combination of bevacizumab, docetaxel, thalidomide and prednisone appears effective in the treatment of CRPC.[123]

The immunotherapy treatment with sipuleucel-T in CRPC increases survival by 4 months.[124] The second line hormonal therapy abiraterone increases survival by 4.6 months when compared to placebo.[125] Enzalutamide is another second line hormonal agent with a 5-month survival advantage over placebo. Both abiraterone and enzalutamide are currently being tested in clinical trials in those with CRPC who have not previously received chemotherapy.[126][127]

Only a subset of people respond to androgen signaling blocking drugs and certain cells with characteristics resembling stem cells remain unaffected.[128][129] Therefore, the desire to improve outcome of people with CRPC has resulted in the claims of increasing doses further or combination therapy with synergistic androgen signaling blocking agents.[130] But even these combination will not affect stem-like cells that do not exhibit androgen signaling. It is possible that for further advances, a combination of androgen signaling blocking agent with stem-like cell directed differentiation therapy drug would prove ideal.[131]

## Palliative care [edit]

Palliative care is medical care which focuses on treatment of symptoms of serious illness, like cancer, and improving quality of life.[132] One of the goals of treatment in palliative care is symptom control rather than a cure of the underlying cancer. Pain is common in metastatic prostate cancer, and cancer pain related to bone metastases can be treated with bisphosphonates, medications such as opioids, and palliative radiation therapy to known metastases. Spinal cord compression can occur with metastases to the spine and can be

treated with steroids, surgery, or radiation therapy. Other symptoms that can be addressed through palliative care include fatigue, delirium, lymphedema in the scrotum or penis, nausea, vomiting, and weight loss.[133]

## Prognosis [edit]

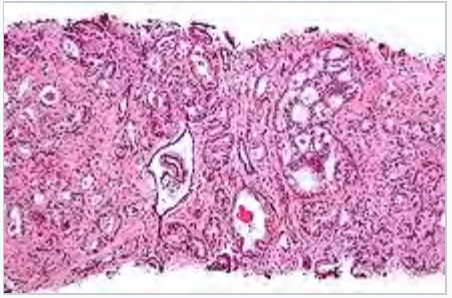
Prostate cancer rates are higher and prognoses are poorer in developed countries than in the rest of the world. Many of the risk factors for prostate cancer are more prevalent in the developed world, including longer life expectancy and diets high in red meat. Also, where there is more access to screening programs, there is a higher detection rate. Prostate cancer affected 18% of American men and caused death in 3% in 2005.[19] In the United States, prostate cancers that are local or regional at the time of diagnosis have a 5-year survival rate of nearly 100%, while those with distant metastases have a 5-year survival rate of 28%.[134] In Japan, death from prostate cancer was one-fifth to one-half the rates in the United States and Europe in the 1990s.[135] In India in the 1990s, half of the people with prostate cancer confined to the prostate died within 19 years.[136] African-American men have 50–60 times more prostate cancer and prostate cancer deaths than men in Shanghai, China.[137] In Nigeria, 2% of men develop prostate cancer, and 64% of them are dead after 2 years.[138]

In patients who undergo treatment, the most important clinical prognostic indicators of disease outcome are the stage, pretherapy PSA level, and Gleason score. In general, the higher the grade and the stage, the poorer the prognosis. Nomograms can be used to calculate the estimated risk of the individual patient. The predictions are based on the experience of large groups of patients suffering from cancers at various stages.[139]

In 1941, Charles Huggins reported that androgen ablation therapy causes regression of primary and metastatic androgen-dependent prostate cancer.[140] He was awarded the 1966 Nobel Prize for Physiology or Medicine for this discovery. Androgen ablation therapy causes remission in 80-90% of patients undergoing therapy, resulting in a median progression-free survival of 12 to 33 months. After remission, an androgen-independent phenotype typically emerges, wherein the median overall survival is 23–37 months from the time of initiation of androgen ablation therapy.[141] It is not clear how the prostate cancer becomes androgen-independent or how it reestablishes progression, although a few possibilities (on how) have been proposed.[142] And the way the cancer changes, to overcome the lack of androgen, may vary between individual patients.

### Classification systems [edit]

Many prostate cancers are not destined to be lethal, and most men will ultimately not die as a result of the disease. Decisions about treatment type and timing may, therefore, be informed by an estimation of the risk that the tumor will ultimately recur after treatment and/or progress to metastases and mortality. Several tools are available to help predict outcomes, such as pathologic stage and recurrence after surgery or radiation therapy. Most combine stage, grade, and PSA level, and some also add the number or percentage of biopsy cores positive, age, and/or other information.



Micrograph of prostate adenocarcinoma, acinar type, the most common type of prostate cancer. Needle biopsy, H&E stain

- The *D'Amico classification* stratifies men by low, intermediate, or high risk based on stage, grade, and PSA. It is used widely in clinical practice and research settings. The major downside to the 3-level system is that it does not account for multiple adverse parameters (e.g., high Gleason score *and* high PSA) in stratifying patients.
- The Partin tables[143] predict pathologic outcomes (margin status, extraprostatic extension, and seminal vesicle invasion) based on the same three variables and are published as lookup tables.
- The *Kattan nomograms* predict recurrence after surgery and/or radiation therapy, based on data

available either at the time of diagnosis or after surgery. The nomograms can be calculated using paper graphs or software available on a website or for handheld computers. The Kattan score represents the likelihood of remaining free of disease at a given time interval following treatment.
- The UCSF *Cancer of the Prostate Risk Assessment (CAPRA) score* predicts both pathologic status and recurrence after surgery. It offers comparable accuracy as the Kattan preoperative nomogram and can be calculated without paper tables or a calculator. Points are assigned based on PSA, Grade, stage, age, and percentage of cores positive; the sum yields a 0–10 score, with every 2 points representing roughly a doubling of risk of recurrence. The CAPRA score was derived from community-based data in the CaPSURE database. It has been validated among over 10,000 prostatectomy patients, including patients from CaPSURE;[144] the SEARCH registry, representing data from several Veterans Administration and active military medical centers;[145] a multi-institutional cohort in Germany;[146] and the prostatectomy cohort at Johns Hopkins University.[147] More recently, it has been shown to predict metastasis and mortality following prostatectomy, radiation therapy, watchful waiting, or androgen deprivation therapy.[148]

## Life expectancy [edit]

Life expectancy projections are averages for an entire male population, and many medical and lifestyle factors modify these numbers. For example, studies have shown that a 40-year-old man will lose 3.1 years of life if he is overweight (BMI 25-29) and 5.8 years of life if he is obese (BMI 30 or more), compared to men of normal weight. If he is both overweight and a smoker, he will lose 6.7 years, and if obese and a smoker, he will lose 13.7 years.[149]

At this time, there is no evidence that either surgery or beam radiation has an advantage over the other in this regard, the lower death rates reported with surgery appear to occur because surgery is more likely to be offered to younger men with less serious forms of cancer. Insufficient information is available to determine whether seed radiation extends life more readily than the other treatments, but data so far do not suggest that it does.[150]

People with low-grade disease (Gleason 2-4) were unlikely to die of prostate cancer within 15 years of diagnosis. Older men (age 70-75) with low-grade disease had an approximately 20% overall survival at 15 years due to deaths from competing causes. Men with high-grade disease (Gleason 8-10) experienced high prostate cancer mortality within 15 years of diagnosis, regardless of their age at diagnosis, underscoring the very aggressive nature of poorly differentiated prostate cancer.[151]

# Epidemiology [edit]

As of 2012, prostate cancer is the second most frequently diagnosed cancer (at 15% of all male cancers)[153] and the sixth leading cause of cancer death in males worldwide.[154] In 2010 it resulted in 256,000 deaths up from 156,000 deaths in 1990.[155] Rates of prostate cancer vary widely across the world. Although the rates vary widely between countries, it is least common in South and East Asia, and more common in Europe, North America, Australia and New Zealand.[156] Prostate cancer is least common among Asian men and most common among black men, with figures for white men in between.[157][158] The average annual incidence rate of prostate cancer between 1988 and 1992 among Chinese men in the United States was 15 times higher than that of their counterparts living in Shanghai and Tianjin.[157][158][159] However, these high rates may be affected by increasing rates of detection.[160] Many suggest that prostate cancer may be under reported, yet BPH incidence in China and Japan is similar to rates in Western countries.[161][162] In Europe in 2012 it was the 3rd most diagnosed cancer after breast and colorectal at 417,000

Age-standardized death from prostate cancer per 100,000 inhabitants in 2004.[152]

| 4-8 | 20-24 | 36-40 |
| 8-12 | 24-28 | 40-44 |
| | | >44 |

cases.[163]

Prostate cancer develops primarily in men over fifty. It is the most common type of cancer in men in the United States, with 186,000 new cases in 2008 and 28,600 deaths.[164] It is the second leading cause of cancer death in U.S. men after lung cancer. In the United Kingdom it is also the second most common cause of cancer death after lung cancer, where around 35,000 cases are diagnosed every year and of which around 10,000 die of it.[165]

More than 80% of men will develop prostate cancer by the age of 80.[166] However, in the majority of cases, it will be slow-growing and harmless. In such men, diagnosing prostate cancer is overdiagnosis—the needless identification of a technically aberrant condition that will never harm the patient—and treatment in such men exposes them to all of the adverse effects, with no possibility of extending their lives.[167]

## History [edit]

Although the prostate was first described by Venetian anatomist Niccolò Massa in 1536, and illustrated by Flemish anatomist Andreas Vesalius in 1538, prostate cancer was not identified until 1853.[168] Prostate cancer was initially considered a rare disease, probably because of shorter life expectancies and poorer detection methods in the 19th century. The first treatments of prostate cancer were surgeries to relieve urinary obstruction.[169] Removal of the entire gland (radical perineal prostatectomy) was first performed in 1904 by Hugh H. Young at Johns Hopkins Hospital.[170] Surgical removal of the testes (orchiectomy) to treat prostate cancer was first performed in the 1890s, but with limited success. Transurethral resection of the prostate (TURP) replaced radical prostatectomy for symptomatic relief of obstruction in the middle of the 20th century because it could better preserve penile erectile function. Radical retropubic prostatectomy was developed in 1983 by Patrick Walsh.[171] This surgical approach allowed for removal of the prostate and lymph nodes with maintenance of penile function.

In 1941, Charles B. Huggins published studies in which he used estrogen to oppose testosterone production in men with metastatic prostate cancer. This discovery of "chemical castration" won Huggins the 1966 Nobel Prize in Physiology or Medicine.[172] The role of the gonadotropin-releasing hormone (GnRH) in reproduction was determined by Andrzej W. Schally and Roger Guillemin, who both won the 1977 Nobel Prize in Physiology or Medicine for this work. GnRH receptor agonists, such as leuprolide and goserelin, were subsequently developed and used to treat prostate cancer.[173][174]

Radiation therapy for prostate cancer was first developed in the early 20th century and initially consisted of intraprostatic radium implants. External beam radiotherapy became more popular as stronger [X-ray] radiation sources became available in the middle of the 20th century. Brachytherapy with implanted seeds (for prostate cancer) was first described in 1983.[175]

Systemic chemotherapy for prostate cancer was first studied in the 1970s. The initial regimen of cyclophosphamide and 5-fluorouracil was quickly joined by multiple regimens using a host of other systemic chemotherapy drugs.[176]

### Cell-of-origin [edit]

A series of studies published in *Science* involved introduced viruses known to cause cancerous mutation in prostate cells: AKT, ERG, and AR into isolated samples of basal and luminal cells and grafted the treated tissue into mice. After 16 weeks, none of the luminal samples had undergone malignant mutation, while the basal samples had mutated into prostate-like tubules which had then developed malignancy and formed cancerous tumors, which appeared identical to human samples under magnification. This led to the conclusion that the prostate basal cell may be the most likely "site of origin" of prostate cancer.[22]

## Society and culture [edit]

People with prostate cancer generally encounter significant disparities in awareness, funding, media

coverage, and research—and therefore, inferior treatment and poorer outcomes—compared to other cancers of equal prevalence.[177] In 2001, *The Guardian* noted that Britain had 3,000 nurses specializing in breast cancer, compared to only one for prostate cancer. It also discovered that the waiting time between referral and diagnosis was two weeks for breast cancer but three months for prostate cancer.[178] A 2007 report by the U.S.-based National Prostate Cancer Coalition stated that for every prostate cancer drug on the market, there were seven used to treat breast cancer. *The Times* also noted an "anti-male bias in cancer funding" with a four-to-one discrepancy in the United Kingdom by both the government and by cancer charities such as Cancer Research UK.[177][179] Equality campaigners such as author Warren Farrell cite such stark spending inequalities as a clear example of governments unfairly favouring women's health over men's health.[180]

Disparities also extend into areas such as detection, with governments failing to fund or mandate prostate cancer screening while fully supporting breast cancer programs. For example, a 2007 report found 49 U.S. states mandate insurance coverage for routine breast cancer screening, compared to 28 for prostate cancer.[177][181] Prostate cancer also experiences significantly less media coverage than other, equally prevalent cancers, with a study by Prostate Coalition showing 2.6 breast cancer stories for each one covering cancer of the prostate.[177]

Prostate Cancer Awareness Month takes place in September in a number of countries. A light blue ribbon is used to promote the cause.[182][183]

## Research [edit]

### CRPC [edit]

MDV3100 was in phase III trials for CRPC (chemo-naive and post-chemo patient populations)[184] and gained FDA approval in 2012 as enzalutamide for the treatment of castration-resistant prostate cancer.[126][127]

Alpharadin completed a phase 3 trial for CRPC patients with bone metastasis. A pre-planned interim analysis showed improved survival and quality of life. The study was stopped for ethical reasons to give the placebo group the same treatment. Alpharadin uses bone targeted Radium-223 isotopes to kill cancer cells by alpha radiation.[185] It was approved by the U.S. Food and Drug Administration (FDA) on May, 15th 2013 ahead of schedule under the priority review program.[186] Alpharadin still waits for approval by the European Medicines Agency (EMA).

As of 2016 PARP inhibitor olaparib has shown promise in clinical trials for CRPC.[187] Also in trials for CRPC are : checkpoint inhibitor ipilimumab, CYP17 inhibitor galeterone (TOK-001), and immunotherapy PROSTVAC.[187]

### Pre-clinical [edit]

Arachidonate 5-lipoxygenase has been identified as playing a significant role in the survival of prostate cancer cells.[188][189][190] Medications which target this enzyme may be an effective therapy for limiting tumor growth and cancer metastasis as well as inducing programmed cell death in cancer cells.[188][189][190] In particular, arachidonate 5-lipoxygenase inhibitors produce massive, rapid programmed cell death in prostate cancer cells.[188][189][190]

### Cancer models [edit]

Scientists have established a few prostate cancer cell lines to investigate the mechanism involved in the progression of prostate cancer. LNCaP, PC-3 (PC3), and DU-145 (DU145) are commonly used prostate cancer cell lines. The LNCaP cancer cell line was established from a human lymph node metastatic lesion of prostatic adenocarcinoma. PC-3 and DU-145 cells were established from human prostatic adenocarcinoma metastatic to bone and to brain, respectively. LNCaP cells express androgen receptor (AR); however, PC-3

and DU-145 cells express very little or no AR. AR, an androgen-activated transcription factor, belongs to the steroid nuclear receptor family. Development of the prostate is dependent on androgen signaling mediated through AR, and AR is also important during the development of prostate cancer. The proliferation of LNCaP cells is androgen-dependent but the proliferation of PC-3 and DU-145 cells is androgen-insensitive. Elevation of AR expression is often observed in advanced prostate tumors in patients.[191][192] Some androgen-independent LNCaP sublines have been developed from the ATCC androgen-dependent LNCaP cells after androgen deprivation for study of prostate cancer progression. These androgen-independent LNCaP cells have elevated AR expression and express prostate specific antigen upon androgen treatment. The paradox is that androgens inhibit the proliferation of these androgen-independent prostate cancer cells.[193][194][195]

## Diagnosis [edit]

At present, an active area of research and non-clinically applied investigations involve non-invasive methods of prostate tumor detection.

A molecular test that detects the presence of cell-associated PCA3 mRNA in fluid massaged from the prostate by the doctor and first-void urinated out has also been under investigation. PCA3 mRNA is expressed almost exclusively by prostate cells and has been shown to be highly over-expressed in prostate cancer cells. The test result is currently reported as a specimen ratio of PCA3 mRNA to PSA mRNA. Although not a replacement for serum PSA level, the PCA3 test is an additional tool to help decide whether, in men suspected of having prostate cancer (especially if an initial biopsy fails to explain the elevated serum PSA), a biopsy/rebiopsy is really needed. The higher the expression of PCA3 in the sample, the greater the likelihood of a positive biopsy; i.e., the presence of cancer cells in the prostate.[196]

"The 5-lipoxygenase (5-LOX) pathway is implicated in the development and progression of human cancers. 5-LOX, whose crystal structure was recently identified (118), is a key enzyme in metabolizing arachidonic acid to leukotrienes. 5-LOX can be induced by pro-inflammatory stimuli and is expressed in epithelial cancers including lung, prostate, breast, and colon (113). Hence, 5-LOX inhibitors have been targeted for their chemopreventive effects. Inhibition of 5-LOX activity is shown to block prostate cancer cell proliferation as well as carcinogen-induced lung tumorigenesis (119, 120). ... Both 5-HETE and 12-HETE are also products of lipoxygenase and are involved in tumor progression (12). Exogenous 5-HETE can stimulate the proliferation of prostate cancer cells and act as a survival factor (137, 138). These results require relatively high concentrations (at a concentration of 10 μM). Blocking the formation of 5-HETE, by inhibiting 5-lipoxygenase, results in massive apoptosis of human prostate cancer cells (139)."
190. ^ *a b c* Bishayee K, Khuda-Bukhsh AR (September 2013). "5-lipoxygenase antagonist therapy: a new approach

towards targeted cancer chemotherapy". *Acta Biochim. Biophys. Sin. (Shanghai)*. **45** (9): 709–719. doi:10.1093/abbs/gmt064. PMID 23752617. "Recent studies demonstrated the involvement of growth factors, such as epidermal growth factor (EGF) and neurotensin in the 5-LOX-mediated tumor progression in prostate cancer [22,23]. Recent studies with 5-LOX siRNA [10] and specific blocker of 5-LOX [24] revealed the relation of this gene with the tumor cell proliferation. ... Meclofenamate sodium (MS) is known for its anti-inflammatory activity, and apart from this, Boctor et al. [37] reported that it caused reduction in the formation of 5-HETE in human leucocytes when used. MS can thus be considered a dual inhibitor of 5-LOX and COX pathways of arachidonic acid cascade. Further investigation with this substance revealed that it could interfere with the LT receptors in the lung carcinoma [38]. In a recent study, a group of scientists have shown the effect of MS on prostate cancer cells both in vitro and in vivo [39], and their result suggests a profound reduction in the tumor growth and cancer metastasis. ... While the commonly used inhibitors produced strong cytotoxicity, notably, zileuton, the only commercialized 5-LOX inhibitor, failed to induce an anti-proliferative or cytotoxic response in all other types of tumor cells where 5-LOX was in inactive state (e.g. HeLa cells); however, where 5-LOX was in active state, zileuton could effectively inhibit progression, as in case of prostate cancer."

# Skin cancer

From Wikipedia, the free encyclopedia

**Skin cancers** are cancers that arise from the skin. They are due to the development of abnormal cells that have the ability to invade or spread to other parts of the body.[1] There are three main types of skin cancers: basal-cell skin cancer (BCC), squamous-cell skin cancer (SCC) and melanoma.[2] The first two together along with a number of less common skin cancers are known as nonmelanoma skin cancer (NMSC).[3][4] Basal-cell cancer grows slowly and can damage the tissue around it but is unlikely to spread to distant areas or result in death.[3] It often appears as a painless raised area of skin, that may be shiny with small blood vessels running over it or may present as a raised area with an ulcer.[2] Squamous-cell cancer is more likely to spread.[3] It usually presents as a hard lump with a scaly top but may also form an ulcer.[5] Melanomas are the most aggressive. Signs include a mole that has changed in size, shape, color, has irregular edges, has more than one color, is itchy or bleeds.[6]

Greater than 90% of cases are caused by exposure to ultraviolet radiation from the Sun.[7] This exposure increases the risk of all three main types of skin cancer.[7] Exposure has increased partly due to a thinner ozone layer.[3][8] Tanning beds are becoming another common source of ultraviolet radiation.[7] For melanomas and basal-cell cancers exposure during childhood is particularly harmful.[9] For squamous-cell cancers total exposure, irrespective of when it occurs, is more important.[7] Between 20% and 30% of melanomas develop from moles.[9] People with light skin are at higher risk[2] as are those with poor immune function such as from medications or HIV/AIDS.[3][10] Diagnosis is by biopsy.[6]

Decreasing exposure to ultraviolet radiation and the use of sunscreen appear to be effective methods of preventing melanoma and squamous-cell cancer.[9][11] It is not clear if sunscreen affects the risk of basal-cell cancer.[11] Nonmelanoma skin cancer is usually curable.[3] Treatment is generally by surgical removal but may less commonly involve radiation therapy or topical medications such as fluorouracil.[2] Treatment of melanoma may involve some combination of surgery, chemotherapy, radiation therapy, and targeted therapy.[6] In those people whose disease has spread to other areas of their bodies, palliative care may be used to improve quality of life.[6] Melanoma has one of the higher survival rates among cancers, with over 86% of people in the UK and more than 90% in the United States surviving more than 5 years.[12][13]

Skin cancer is the most common form of cancer, globally accounting for at least 40% of cases.[3][14] It is

**Skin cancer**

A basal-cell skin cancer. Note the pearly appearance and telangiectasia.

especially common among people with light skin.[15] The most common type is nonmelanoma skin cancer, which occurs in at least 2-3 million people per year.[9][16] This is a rough estimate, however, as good statistics are not kept.[2] Of nonmelanoma skin cancers, about 80% are basal-cell cancers and 20% squamous-cell cancers.[4] Basal-cell and squamous-cell cancers rarely result in death.[9] In the United States they were the cause of less than 0.1% of all cancer deaths.[2] Globally in 2012 melanoma occurred in 232,000 people, and resulted in 55,000 deaths.[9] Australia and New Zealand have the highest rates of melanoma in the world.[9] The three main types of skin cancer have become more common in the last 20 to 40 years, especially in those areas which are mostly Caucasian.[3][9]

**Contents**

## Classification [edit]

There are three main types of skin cancer: basal-cell skin cancer (basal-cell carcinoma) (BCC), squamous-cell skin cancer (squamous-cell carcinoma) (SCC) and malignant melanoma.

| Cancer | Description | Illustration |
|---|---|---|
| Basal-cell carcinoma | Note the pearly translucency to fleshy color, tiny blood vessels on the surface, and sometime ulceration which can be characteristics. The key term is translucency. |  |
| Squamous-cell carcinoma | Commonly presents as a red, crusted, or scaly patch or bump. Often a very rapid growing tumor. |  |
| Malignant melanoma | The common appearance is an asymmetrical area, with an irregular border, color variation, and often greater than 6 mm diameter.[17] | |

Basal-cell carcinomas are present on sun-exposed areas of the skin, especially the face. They rarely metastasize and rarely cause death. They are easily treated with surgery or radiation. Squamous-cell skin cancer are common, but much less common than basal-cell cancers. They metastasize more frequently than BCCs. Even then, the metastasis rate is quite low, with the exception of SCC of the lip, ear, and in people who are immunosuppressed. Melanoma are the least frequent of the 3 common skin cancers. They frequently metastasize, and could potentially cause death once they spread.

Less common skin cancers include: dermatofibrosarcoma protuberans, Merkel cell carcinoma, Kaposi's sarcoma, keratoacanthoma, spindle cell tumors, sebaceous carcinomas, microcystic adnexal carcinoma, Paget's disease of the breast, atypical fibroxanthoma, leiomyosarcoma, and angiosarcoma.

BCC and SCC often carry a UV-signature mutation indicating that these cancers are caused by UVB radiation via direct DNA damage. However malignant melanoma is predominantly caused by UVA radiation via indirect DNA damage. The indirect DNA damage is caused by free radicals and reactive oxygen species. Research indicates that the absorption of three sunscreen ingredients into the skin, combined with a 60-minute exposure to UV, leads to an increase of free radicals in the skin, if applied in too little quantities and too infrequently.[18] However, the researchers add that newer creams often do not contain these specific compounds, and that the combination of other ingredients tends to retain the compounds on the surface of the skin. They also add the frequent re-application reduces the risk of radical formation.

## Signs and symptoms [edit]

There are a variety of different skin cancer symptoms. These include changes in the skin that do not heal, ulcering in the skin, discolored skin, and changes in existing moles, such as jagged edges to the mole and enlargement of the mole.

### Basal-cell skin cancer [edit]

Basal-cell skin cancer (BCC) usually presents as a raised, smooth, pearly bump on the sun-exposed skin of the head, neck or shoulders. Sometimes small blood vessels (called telangiectasia) can be seen within the tumor. Crusting and bleeding in the center of the tumor frequently develops. It is often mistaken for a sore that does not heal. This form of skin cancer is the least deadly and with proper treatment can be completely eliminated, often without scarring.

### Squamous-cell skin cancer [edit]

Squamous-cell skin cancer (SCC) is commonly a red, scaling, thickened patch on sun-exposed skin. Some are firm hard nodules and dome shaped like keratoacanthomas. Ulceration and bleeding may occur. When SCC is not treated, it may develop into a large mass. Squamous-cell is the second most common skin cancer. It is dangerous, but not nearly as dangerous as a melanoma.

### Melanoma [edit]

Most melanoma consist of various colours from shades of brown to black. A small number of melanoma are pink, red or fleshy in colour; these are called amelanotic melanoma and tend to be more aggressive. Warning signs of malignant melanoma include change in the size, shape, color or elevation of a mole. Other signs are the appearance of a new mole during adulthood or pain, itching, ulceration, redness around the site, or bleeding at the site. An often-used mnemonic is "ABCDE", where A is for "asymmetrical", B for "borders" (irregular: "Coast of Maine sign"), C for "color" (variegated), D for "diameter" (larger than 6 mm—[19][20]

the size of a pencil eraser) and E for "evolving."

### Other [edit]

Merkel cell carcinomas are most often rapidly growing, non-tender red, purple or skin colored bumps that are not painful or itchy. They may be mistaken for a cyst or another type of cancer.[21]

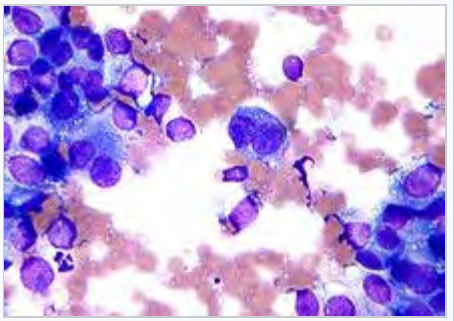
## Causes [edit]

Ultraviolet radiation from sun exposure is the primary environmental cause of skin cancer.[22][23][24] Other risk factors that play a role include:

- Smoking tobacco[23]
- HPV infections increase the risk of squamous-cell carcinoma.[23]
- Some genetic syndromes[23] including congenital melanocytic nevi syndrome which is characterized by the presence of nevi (birthmarks or moles) of varying size which are either present at birth, or appear within 6 months of birth. Nevi larger than 20 mm (3/4") in size are at higher risk for becoming cancerous.
- Chronic non-healing wounds.[23] These are called Marjolin's ulcers based on their appearance, and can develop into squamous-cell carcinoma.
- Ionizing radiation, environmental carcinogens, artificial UV radiation (e.g. tanning beds), aging, and light skin color.[23] It is believed that tanning beds are the cause of hundreds of thousands of basal and squamous-cell carcinomas.[25] The World Health Organization now places people who use artificial tanning beds in its highest risk category for skin cancer.[26] Alcohol consumption, specifically excessive drinking increase the risk of sunburns.[27]
- The use of many immunosuppressive medications increases the risk of skin cancer. Cyclosporin A, a calcineurin inhibitor for example increases the risk approximately 200 times, and azathioprine about 60 times.[28]

## Pathophysiology [edit]

A malignant epithelial tumor that primarily originates in the epidermis, in squamous mucosa or in areas of squamous metaplasia is referred to as a squamous-cell carcinoma.[29]



Micrograph of melanoma. FNA specimen. Field stain

Macroscopically, the tumor is often elevated, fungating, or may be ulcerated with irregular borders. Microscopically, tumor cells destroy the basement membrane and form sheets or compact masses which invade the subjacent connective tissue (dermis). In well differentiated carcinomas, tumor cells are pleomorphic/atypical, but resembling normal keratinocytes from prickle layer (large, polygonal, with abundant eosinophilic (pink) cytoplasm and central nucleus).[29]

Their disposal tends to be similar to that of normal epidermis: immature/basal cells at the periphery, becoming more mature to the centre of the tumor masses. Tumor cells transform into keratinized squamous cells and form round nodules with concentric, laminated layers, called "cell nests" or "epithelial/keratinous pearls". The surrounding stroma is reduced and contains inflammatory infiltrate (lymphocytes). Poorly differentiated squamous carcinomas contain more pleomorphic cells and no keratinization.[29]

## Prevention [edit]

[30] [31]

Sunscreen is effective and thus recommended to prevent melanoma and squamous-cell carcinoma. There is little evidence that it is effective in preventing basal-cell carcinoma.[32] Other advice to reduce rates of skin cancer includes avoiding sunburning, wearing protective clothing, sunglasses and hats, and attempting to avoid sun exposure or periods of peak exposure.[33] The U.S. Preventive Services Task Force recommends that people between 9 and 25 years of age be advised to avoid ultraviolet light.[34]

The risk of developing skin cancer can be reduced through a number of measures including decreasing indoor tanning and mid day sun exposure, increasing the use of sunscreen,[35] and avoiding the use of tobacco products.

There is insufficient evidence either for or against screening for skin cancers.[36] Vitamin supplements and antioxidant supplements have not been found to have an effect in prevention.[37] Evidence for a benefit from dietary measures is tentative.[38]

Zinc oxide and titanium oxide are often used in sun screen to provide broad protection from UVA and UVB ranges.[39]

Eating certain foods may decrease the risk of sunburns but this is much less than the protection provided by sunscreen.[40]

## Treatment [edit]

Treatment is dependent on type of cancer, location of the cancer, age of the person, and whether the cancer is primary or a recurrence. Treatment is also determined by the specific type of cancer. For a small basal-cell cancer in a young person, the treatment with the best cure rate (Mohs surgery or CCPDMA) might be indicated. In the case of an elderly frail man with multiple complicating medical problems, a difficult to excise basal-cell cancer of the nose might warrant radiation therapy (slightly lower cure rate) or no treatment at all. Topical chemotherapy might be indicated for large superficial basal-cell carcinoma for good cosmetic outcome, whereas it might be inadequate for invasive nodular basal-cell carcinoma or invasive squamous-cell carcinoma.[*citation needed*]. In general, melanoma is poorly responsive to radiation or chemotherapy.

For low-risk disease, radiation therapy (external beam radiotherapy[41] or brachytherapy), topical chemotherapy (imiquimod or 5-fluorouracil) and cryotherapy (freezing the cancer off) can provide adequate control of the disease; all of them, however, may have lower overall cure rates than certain type of surgery. Other modalities of treatment such as photodynamic therapy, topical chemotherapy, electrodesiccation and curettage can be found in the discussions of basal-cell carcinoma and squamous-cell carcinoma.

Mohs' micrographic surgery (Mohs surgery) is a technique used to remove the cancer with the least amount of surrounding tissue and the edges are checked immediately to see if tumor is found. This provides the opportunity to remove the least amount of tissue and provide the best cosmetically favorable results. This is especially important for areas where excess skin is limited, such as the face. Cure rates are equivalent to wide excision. Special training is required to perform this technique. An alternative method is CCPDMA and can be performed by a pathologist not familiar with Mohs surgery.

In the case of disease that has spread (metastasized), further surgical procedures or chemotherapy may be required.[42]

Treatments for metastatic melanoma include biologic immunotherapy agents ipilimumab, pembrolizumab, and nivolumab; BRAF inhibitors, such as vemurafenib and dabrafenib; and a MEK inhibitor trametinib.[43]

### Reconstruction [edit]

Currently, surgical excision is the most common form of treatment for skin cancers. The goal of reconstructive surgery is restoration of normal appearance and function. The choice of technique in reconstruction is dictated by the size and location of the defect. Excision and reconstruction of facial skin cancers is generally more challenging due to presence of highly visible and functional anatomic structures in the face.

When skin defects are small in size, most can be repaired with simple repair where skin edges are approximated and closed with sutures. This will result in a linear scar. If the repair is made along a natural skin fold or wrinkle line, the scar will be hardly visible. Larger defects may require repair with a skin graft, local skin flap, pedicled skin flap, or a microvascular free flap. Skin grafts and local skin flaps are by far more common than the other listed choices.

Skin grafting is patching of a defect with skin that is removed from another site in the body. The skin graft is sutured to the edges of the defect, and a bolster dressing is placed atop the graft for seven to ten days, to immobilize the graft as it heals in place. There are two forms of skin grafting: split thickness and full thickness. In a split thickness skin graft, a shaver is used to shave a layer of skin from the abdomen or thigh. The donor site regenerates skin and heals over a period of two weeks. In a full thickness skin graft, a segment of skin is totally removed and the donor site needs to be sutured closed.[44]

Split thickness grafts can be used to repair larger defects, but the grafts are inferior in their cosmetic appearance. Full thickness skin grafts are more acceptable cosmetically. However, full thickness grafts can only be used for small or moderate sized defects.

Local skin flaps are a method of closing defects with tissue that closely matches the defect in color and quality. Skin from the periphery of the defect site is mobilized and repositioned to fill the deficit. Various forms of local flaps can be designed to minimize disruption to surrounding tissues and maximize cosmetic outcome of the reconstruction. Pedicled skin flaps are a method of transferring skin with an intact blood supply from a nearby region of the body. An example of such reconstruction is a pedicled forehead flap for repair of a large nasal skin defect. Once the flap develops a source of blood supply form its new bed, the vascular pedicle can be detached.[45]

## Prognosis [edit]

The mortality rate of basal-cell and squamous-cell carcinoma are around 0.3%, causing 2000 deaths per year in the US. In comparison, the mortality rate of melanoma is 15–20% and it causes 6500 deaths per year.[46]:29,31 Even though it is much less common, malignant melanoma is responsible for 75% of all skin cancer-related deaths.[47]

The survival rate for people with melanoma depends upon when they start treatment. The cure rate is very high when melanoma is detected in early stages, when it can easily be removed surgically. The prognosis is less favorable if the melanoma has spread to other parts of the body.[48] As of 2003 the overall five year cure rate with Mohs' micrographic surgery was around 95 percent for recurrent basal cell carcinoma.[49]

Australia and New Zealand exhibit one of the highest rates of skin cancer incidence in the world, almost four times the rates registered in the United States, the UK and Canada. Around 434,000 people receive treatment for non-melanoma skin cancers and 10,300 are treated for melanoma. Melanoma is the most common type of cancer in people between 15–44 years in both countries. The incidence of skin cancer has been increasing.[50] The incidence of melanoma among Auckland residents of European descent in 1995 was 77.7 cases per 100,000 people per year, and was predicted to increase in the 21st century because of "the effect of local stratospheric ozone depletion and the time lag from sun exposure to melanoma development."[51]

## Epidemiology [edit]

Skin cancers result in 80,000 deaths a year as of 2010, 49,000 of which are due to melanoma and 31,000 of which are due to non-melanoma skin cancers.[53] This is up from 51,000 in 1990.[53]

In the US in 2008, 59,695 people were diagnosed with melanoma, and 8,623 people died from it.[54] In Australia more than 12,500 new cases of melanoma are reported each year, out of which more than 1,500 die from the disease. Australia has the highest per capita incidence of

Age-standardized death from

melanoma in the world.[55]

More than 3.5 million cases of skin cancer are diagnosed annually in the United States, which makes it the most common form of cancer in that country. According to the Skin Cancer Foundation, one in five Americans will develop skin cancer at some point of their lives. The most common form of skin cancer is basal-cell carcinoma, followed by squamous cell carcinoma. Although the incidence of many cancers in the United States is falling, the incidence of melanoma keeps growing, with approximately 68,729 melanomas diagnosed in 2004 according to reports of the National Cancer Institute.[56]

Skin cancer (malignant melanoma) is the fifth most common cancer in the UK (around 13,300 people were diagnosed with malignant melanoma in 2011), and the disease accounts for 1% all cancer deaths (around 2,100 people died in 2012).[57]

melanoma and other skin cancers per 100,000 inhabitants in 2004[52]

# Stomach cancer

From Wikipedia, the free encyclopedia

**Stomach cancer**, also known as **gastric cancer**, is cancer developing from the lining of the stomach.[1] Early symptoms may include heartburn, upper abdominal pain, nausea and loss of appetite. Later signs and symptoms may include weight loss, yellowing of the skin and whites of the eyes, vomiting, difficulty swallowing, and blood in the stool among others.[2] The cancer may spread from the stomach to other parts of the body, particularly the liver, lungs, bones, lining of the abdomen and lymph nodes.[3]

The most common cause is infection by the bacterium *Helicobacter pylori*, which accounts for more than 60% of cases.[4][5][6] Certain types of *H. pylori* have greater risks than others. Other common causes include eating pickled vegetables and smoking. About 10% of cases run in families and between 1% and 3% of cases are due to genetic syndromes inherited from a person's parents such as hereditary diffuse gastric cancer. Most cases of stomach cancers are gastric carcinomas. This type can be divided into a number of subtypes. Lymphomas and mesenchymal tumors may also develop in the stomach. Most of the time, stomach cancer develops in stages over years.[5] Diagnosis is usually by biopsy done during endoscopy. This is followed by medical imaging to determine if the disease has spread to other parts of the body.[2] Japan and South Korea, two countries that have high rates of the disease, screen for stomach cancer.[5]

A Mediterranean diet lowers the risk of cancer as does the stopping of smoking. There is tentative evidence that treating *H. pylori* decreases the future risk.[5][7] If cancer is treated early, many cases can be cured.[5] Treatments may include some combination of surgery, chemotherapy, radiation therapy, and targeted therapy.[2] If treated late, palliative care may be advised.[5] Outcomes are often poor with a less than 10% 5-year survival rate globally. This is largely because most people with the condition present with advanced disease.[8] In the United States 5-year survival is 28% while in South Korea it is over 65% partly due to screening efforts.[5]

Globally stomach cancer is the fifth leading cause of cancer and the third leading cause of death from cancer making up 7% of cases and 9% of deaths.[10] In 2012 it occurred in 950,000 people and caused 723,000 deaths.[10] Before the 1930s in much of the world, including most Western developed countries, it was the most common cause of death from cancer.[11][12][13] Rates of death have been decreasing in many areas of the world since then.[5] This is believed to be due to the eating of less salted and pickled foods as [14]

**Stomach cancer**

a result of the development of refrigeration as a method of keeping food fresh. Stomach cancer occurs most commonly in East Asia and Eastern Europe. It occurs twice as often in males as in females.[5]

Contents

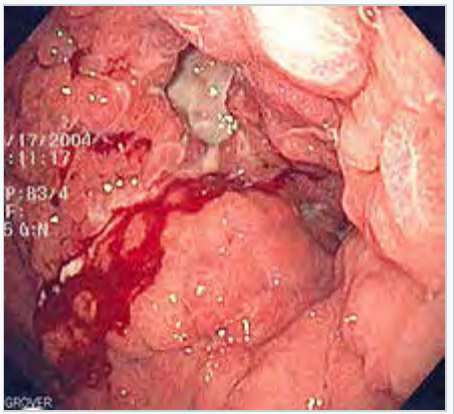
## Signs and symptoms [edit]

Stomach cancer is often either asymptomatic (producing no noticeable symptoms) or it may cause only nonspecific symptoms (symptoms that are not specific to stomach cancer and to other related or unrelated disorders) in its early stages. By the time symptoms occur, the cancer has often reached an advanced stage (see below) and may have metastasized (spread to other, perhaps distant, parts of the body), which is one of the main reasons for its relatively poor prognosis.[15] Stomach cancer can cause the following signs and symptoms:

Early cancers may be associated with indigestion or a burning sensation (heartburn). However, less than 1 in every 50 people referred for endoscopy due to indigestion has cancer.[16] Abdominal discomfort and loss of appetite, especially for meat, can occur.

Gastric cancers that have enlarged and invaded normal tissue can cause weakness, fatigue, bloating of the stomach after meals, abdominal pain in the upper abdomen, nausea and occasional vomiting, diarrhea or constipation. Further enlargement may cause weight loss or bleeding with vomiting blood or having blood in the stool, the latter apparent as black discolouration (melena) and sometimes leading to anemia. Dysphagia suggests a tumour in the cardia or extension of the gastric tumour into the esophagus.

These can be symptoms of other problems such as a stomach virus, gastric ulcer, or tropical sprue.



Endoscopic image of linitis plastica, a type of stomach cancer where the entire stomach is invaded, leading to a leather bottle-like appearance with blood coming out of it.

## Causes [edit]

Endoscopic images of the stomach cancer in early stage. Its histology was poorly differentiated adenocarcinoma with signet ring cells. Left above: normal, right above: FICE, left low: acetate stained, right low: AIM stained

Gastric cancer occurs as a result of many factors.[17] It occurs twice as common in males as females. Estrogen may protect women against the development of this cancer form.[18][19]

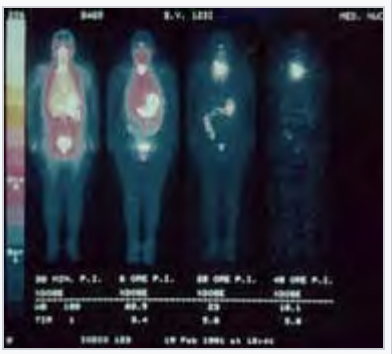
## Infections [edit]

*Helicobacter pylori* infection is an essential risk factor in 65–80% of gastric cancers, but only 2% of people with Helicobacter infections develop stomach cancer.[20][21] The mechanism by which *H. pylori* induces stomach cancer potentially involves chronic inflammation, or the action of *H. pylori* virulence factors such as CagA.[22] It was estimated that Epstein–Barr virus is responsible for 84,000 cases per year.[23] Other factors associated with increased risk are AIDS.[21]

## Smoking [edit]

Smoking increases the risk of developing gastric cancer significantly, from 40% increased risk for current smokers to 82% increase for heavy smokers. Gastric cancers due to smoking mostly occur in the upper part of the stomach near the esophagus.[24][25][26] Some studies show increased risk with alcohol consumption as well.[21][27]

## Diet [edit]



Sequence of 123-iodine human scintiscans after an intravenous injection: (from left) after 30 minutes, 20 hours and 48 hours. A high and rapid concentration of radio-iodine is evident in gastric mucosa of the stomach, in salivary glands, oral mucosa and in the periencephalic and cerebrospinal fluid (left). In the thyroid gland, I- concentration is more

Dietary factors are not proven causes,[29] but some foods including smoked foods,[30] salt and salt-rich foods, red meat, processed meat, pickled vegetables,[21] and bracken[31] are associated with a higher risk of stomach cancer. Nitrates and nitrites in cured meats can be converted by certain bacteria, including *H. pylori*, into compounds that have been found to cause stomach cancer in animals.

Fresh fruit and vegetable intake, citrus fruit intake, and antioxidant intake are associated with a lower risk of stomach cancer.[21][24] A Mediterranean diet is associated with lower rates of stomach cancer,[32] as is regular aspirin use.[21]

Obesity is a physical risk factor that has been found to increase the risk of gastric adenocarcinoma by contributing to the development of gastroesophageal reflux disease (GERD).[33] The exact mechanism by which obesity causes GERD is not completely known. Studies hypothesize that increased dietary fat leading to increased pressure on the stomach and the lower esophageal sphincter, due to excess adipose tissue, could play a role, yet no statistically significant data has been collected.[34] However, the risk of gastric cardia adenocarcinoma, with GERD present, has been found to increase more than 2 times for an obese person.[33] There is a correlation between iodine deficiency and gastric cancer.[35][36][37]

## Genetics [edit]

About 10% of cases run in families and between 1% and 3% of cases are

due to genetic syndromes inherited from a person's parents such as hereditary diffuse gastric cancer.[5]

A genetic risk factor for gastric cancer is a genetic defect of the CDH1 gene known as hereditary diffuse gastric cancer (HDGC). The CDH1 gene, which codes for E-cadherin, lies on the 16th chromosome.[38] When the gene experiences a particular mutation, gastric cancer develops through a mechanism that is not fully understood.[38] This mutation is considered autosomal dominant meaning that half of a carrier's children will likely experience the same mutation.[38] Diagnosis of hereditary diffuse gastric cancer usually takes place when at least two cases involving a family member, such as a parent or grandparent, are diagnosed, with at least one diagnosed before the age of 50.[38] The diagnosis can also be made if there are at least three cases in the family, in which case age is not considered.[38]

progressive, also in the reservoir (from 1% after 30 minutes to 5.8 % after 48 hours, of the total injected dose).[28]

The International Cancer Genome Consortium is leading efforts to identify genomic changes involved in stomach cancer.[39][40] A very small percentage of diffuse-type gastric cancers (see Histopathology below) arise from an inherited abnormal *CDH1* gene. Genetic testing and treatment options are available for families at risk.[41]

### Other [edit]

Other risks include diabetes,[42] pernicious anemia,[27] chronic atrophic gastritis,[43] Menetrier's disease (hyperplastic, hypersecretory gastropathy),[44] and intestinal metaplasia.[45]

## Diagnosis [edit]

To find the cause of symptoms, the doctor asks about the patient's medical history, does a physical exam, and may order laboratory studies. The patient may also have one or all of the following exams:

- Gastroscopic exam is the diagnostic method of choice. This involves insertion of a fibre optic camera into the stomach to visualise it.[27]
- Upper GI series (may be called barium roentgenogram).
- Computed tomography or CT scanning of the abdomen may reveal gastric cancer. It is more useful to determine invasion into adjacent tissues or the presence of spread to local lymph nodes. Wall thickening of more than 1 cm that is focal, eccentric and enhancing favours malignancy.[46]

In 2013, Chinese and Israeli scientists reported a successful pilot study of a breathalyzer-style breath test intended to diagnose stomach cancer by analyzing exhaled chemicals without the need for an intrusive endoscopy.[47] A larger-scale clinical trial of this technology was completed in 2014.[48]

Abnormal tissue seen in a gastroscope examination will be biopsied by the surgeon or gastroenterologist. This tissue is then sent to a pathologist for histological examination under a microscope to check for the presence of cancerous cells. A biopsy, with subsequent histological analysis, is the only sure way to confirm the presence of cancer cells.[27]

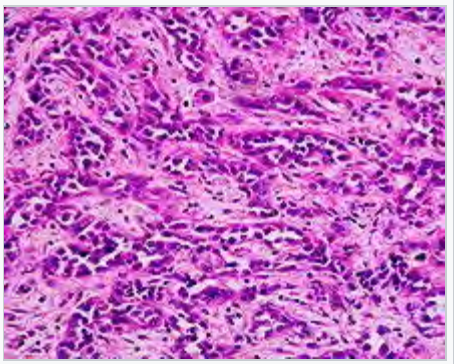
Various gastroscopic modalities have been developed to increase yield of detected mucosa with a dye that accentuates the cell structure and can identify areas of dysplasia. *Endocytoscopy* involves ultra-high magnification to visualise cellular structure to better determine areas of dysplasia. Other gastroscopic modalities such as optical coherence tomography are being tested investigationally for similar applications.[49]

A number of cutaneous conditions are associated with gastric cancer. A condition of darkened hyperplasia of the skin, frequently of the axilla and groin, known as acanthosis nigricans, is associated with intra-abdominal cancers such as gastric cancer. Other cutaneous manifestations of gastric cancer include *tripe palms* (a similar darkening hyperplasia of the skin of the palms) and the Leser-Trelat sign, which is the rapid development of skin lesions known as seborrheic keratoses.[50]

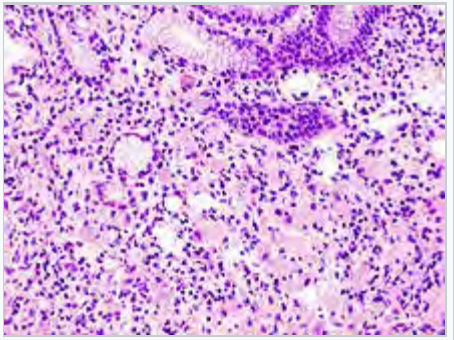
Various blood tests may be done including a complete blood count (CBC) to check for anaemia, and a fecal occult blood test to check for blood in the stool.

## Histopathology [edit]

- *Gastric adenocarcinoma* is a malignant epithelial tumour, originating from glandular epithelium of the gastric mucosa. Stomach cancers are overwhelmingly adenocarcinomas (90%).[51] Histologically, there are two major types of gastric adenocarcinoma (Lauren classification): intestinal type or diffuse type. Adenocarcinomas tend to aggressively invade the gastric wall, infiltrating the muscularis mucosae, the submucosa and thence the muscularis propria. Intestinal type adenocarcinoma tumour cells describe irregular tubular structures, harbouring pluristratification, multiple lumens, reduced stroma ("back to back" aspect). Often, it associates intestinal metaplasia in neighbouring mucosa. Depending on glandular architecture, cellular pleomorphism and mucosecretion, adenocarcinoma may present 3 degrees of differentiation: well, moderate and poorly differentiated. Diffuse type adenocarcinoma (mucinous, colloid, linitis plastica, leather-bottle stomach) tumour cells are discohesive and secrete mucus, which is delivered in the interstitium, producing large pools of mucus/colloid (optically "empty" spaces). It is poorly differentiated. If the mucus remains inside the tumour cell, it pushes the nucleus to the periphery: "*signet-ring cell*".
- Around 5% of gastric malignancies are lymphomas (MALTomas, or MALT lymphoma).[52]
- Carcinoid and stromal tumors may occur.



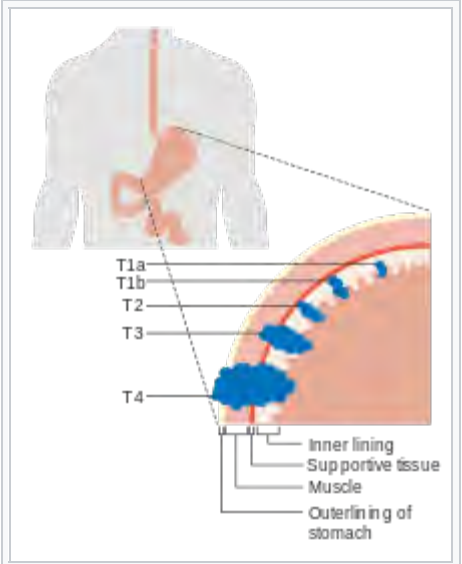
Poor to moderately differentiated adenocarcinoma of the stomach. H&E stain.



Gastric signet ring cell carcinoma. H&E stain.

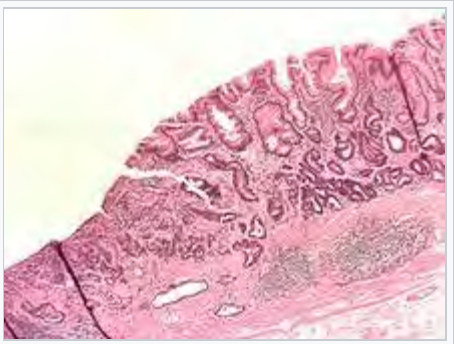
## Staging [edit]

If cancer cells are found in the tissue sample, the next step is to stage, or find out the extent of the disease. Various tests determine whether the cancer has spread and, if so, what parts of the body are affected. Because stomach cancer can spread to the liver, the pancreas, and other organs near the stomach as well as to the lungs, the doctor may order a CT scan, a PET scan,[53] an endoscopic ultrasound exam, or other tests to check these areas. Blood tests for tumor markers, such as carcinoembryonic antigen (CEA) and carbohydrate antigen (CA) may be ordered, as their levels correlate to extent of metastasis, especially to the liver, and the cure rate.



T stages of stomach cancer

Staging may not be complete until after surgery. The surgeon removes nearby lymph nodes and possibly samples of tissue from other areas in the abdomen for examination by a pathologist.



Adenocarcinoma of the stomach and intestinal metaplasia. H&E stain.

The clinical stages of stomach cancer are:[54][55]

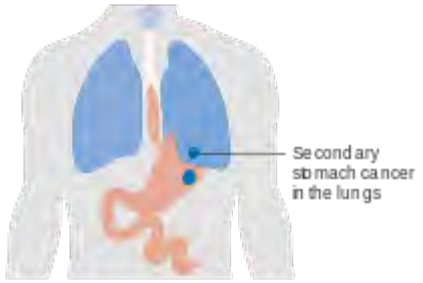
- **Stage 0.** Limited to the inner lining of the stomach. Treatable by endoscopic mucosal resection when found very early (in routine screenings); otherwise by gastrectomy and lymphadenectomy without need for chemotherapy or

radiation.

- **Stage I.** Penetration to the second or third layers of the stomach **(Stage 1A)** or to the second layer and nearby lymph nodes **(Stage 1B)**. Stage 1A is treated by surgery, including removal of the omentum. Stage 1B may be treated with chemotherapy (5-fluorouracil) and radiation therapy.
- **Stage II.** Penetration to the second layer and more distant lymph nodes, or the third layer and only nearby lymph nodes, or all four layers but not the lymph nodes. Treated as for Stage I, sometimes with additional neoadjuvant chemotherapy.
- **Stage III.** Penetration to the third layer and more distant lymph nodes, or penetration to the fourth layer and either nearby tissues or nearby or more distant lymph nodes. Treated as for Stage II; a cure is still possible in some cases.
- **Stage IV.** Cancer has spread to nearby tissues and more distant lymph nodes, or has metastasized to other organs. A cure is very rarely possible at this stage. Some other techniques to prolong life or improve symptoms are used, including laser treatment, surgery, and/or stents to keep the digestive tract open, and chemotherapy by drugs such as 5-fluorouracil, cisplatin, epirubicin, etoposide, docetaxel, oxaliplatin, capecitabine or irinotecan.

The TNM staging system is also used.[56]

In a study of open-access endoscopy in Scotland, patients were diagnosed 7% in Stage I 17% in Stage II, and 28% in Stage III.[57] A Minnesota population was diagnosed 10% in Stage I, 13% in Stage II, and 18% in Stage III.[58] However, in a high-risk population in the Valdivia Province of southern Chile, only 5% of patients were diagnosed in the first two stages and 10% in stage III.[59]



Stomach cancer metastasized to the lungs

## Prevention [edit]

Getting rid of *H. pylori* in those who are infected decreases the risk of stomach cancer, at least in those who are Asian.[60] A 2014 meta-analysis of observational studies found that a diet high in fruits, mushrooms, garlic, soybeans, and green onions was associated with a lower risk of stomach cancer in the Korean population.[61] Low doses of vitamins, especially from a healthy diet, decrease the risk of stomach cancer.[62] A previous review of antioxidant supplementation did not find supporting evidence and possibly worse outcomes.[63][64]

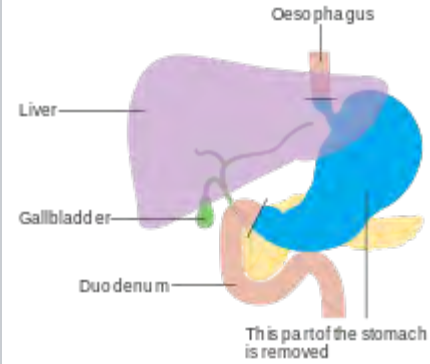
## Management [edit]

Cancer of the stomach is difficult to cure unless it is found at an early stage (before it has begun to spread). Unfortunately, because early stomach cancer causes few symptoms, the disease is usually advanced when the diagnosis is made.[65]

Treatment for stomach cancer may include surgery,[66] chemotherapy, and/or radiation therapy.[67] New treatment approaches such as biological therapy and improved ways of using current methods are being studied in clinical trials.[68]

### Surgery [edit]

Surgery remains the only curative therapy for stomach cancer.[8] Of the different surgical techniques, endoscopic mucosal resection (EMR) is a treatment for early gastric cancer (tumor only involves the mucosa) that was pioneered in Japan and is available in the United States at some centers.[8] In this procedure, the tumor, together with the inner lining of stomach (mucosa), is removed from the wall of the stomach using an electrical wire loop through the endoscope. The advantage is that it is a much smaller operation than removing the stomach.[8] Endoscopic



Anatomy before Roux-en-y surgery to resect stomach cancer.

submucosal dissection (ESD) is a similar technique pioneered in Japan, used to resect a large area of mucosa in one piece.[8] If the pathologic examination of the resected specimen shows incomplete resection or deep invasion by tumor, the patient would need a formal stomach resection.[8] A 2016 Cochrane review found low quality evidence of no difference in short-term mortality between laparoscopic and open gastrectomy (removal of stomach), and that benefits or harms of laparoscopic gastrectomy cannot be ruled out.[69]

Those with metastatic disease at the time of presentation may receive palliative surgery and while it remains controversial, due to the possibility of complications from the surgery itself and the fact that it may delay chemotherapy the data so far is mostly positive, with improved survival rates being seen in those treated with this approach.[8][70]

### Chemotherapy [edit]

The use of chemotherapy to treat stomach cancer has no firmly established standard of care. Unfortunately, stomach cancer has not been particularly sensitive to these drugs, and chemotherapy, if used, has usually served to palliatively reduce the size of the tumor, relieve symptoms of the disease and increase survival time. Some drugs used in stomach cancer treatment have included: 5-FU (fluorouracil) or its analog capecitabine, BCNU (carmustine), methyl-CCNU (semustine) and doxorubicin (Adriamycin), as well as mitomycin C, and more recently cisplatin and taxotere, often using drugs in various combinations. The relative benefits of these different drugs, alone and in combination, are unclear.[71] Clinical researchers have explored the benefits of giving chemotherapy before surgery to shrink the tumor, or as adjuvant therapy after surgery to destroy remaining cancer cells.[8]

### Targeted therapy [edit]

Recently, treatment with human epidermal growth factor receptor 2 (*HER2*) inhibitor, trastuzumab, has been demonstrated to increase overall survival in inoperable locally advanced or metastatic gastric carcinoma over-expressing the HER2/neu gene.[8] In particular, *HER2* is overexpressed in 13-22% of patients with gastric cancer.[68][72] Of note, *HER2* overexpression in gastric neoplasia is heterogeneous and comprises a minority of tumor cells (less than 10% of gastric cancers overexpress *HER2* in more than 5% of tumor cells). Hence, this heterogeneous expression should be taken into account for *HER2* testing, particularly in small samples such as biopsies, requiring the evaluation of more than one bioptic sample.[72]

### Radiation [edit]

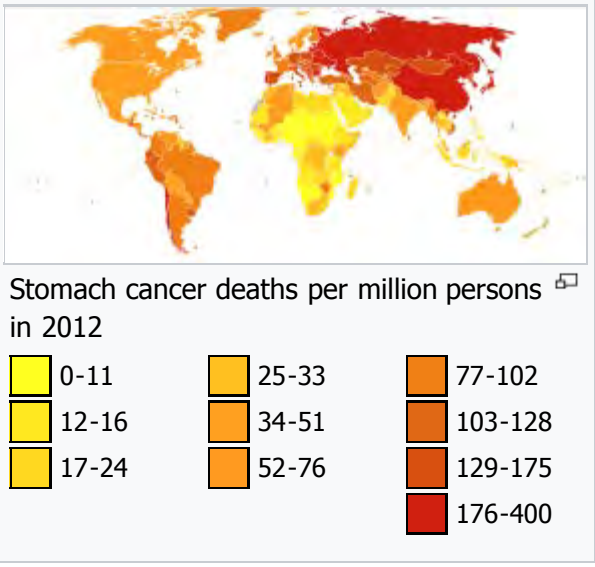
Radiation therapy (also called radiotherapy) may be used to treat stomach cancer, often as an adjuvant to chemotherapy and/or surgery.[8]

## Prognosis [edit]

The prognosis of stomach cancer is generally poor, due to the fact the tumour has often metastasised by the time of discovery and the fact that most people with the condition are elderly (median age is between 70 and 75 years) at presentation.[73] The five-year survival rate for stomach cancer is reported to be less than 10 percent.[8]

## Epidemiology [edit]

Worldwide, stomach cancer is the fifth most common cancer with 952,000 cases diagnosed in 2012.[10] It is more common in men and in developing countries.[74][75] In 2012, it represented 8.5% of cancer cases in men, making it the fourth most common cancer in men.[76] In 2012 number of deaths were 700,000 having decreased slightly from 774,000 in 1990 making it the third leading cause of cancer death after lung cancer and liver cancer.[77][78]



Less than 5% of stomach cancers occur in people under 40 years of age with 81.1% of that 5% in the age-group of 30 to 39 and 18.9% in the age-group of 20 to 29.[79]

In 2014, stomach cancer accounted for 0.61% of deaths (13,303 cases) in the United States.[80] In China, stomach cancer accounted for 3.56% of all deaths (324,439 cases).[81] The highest rate of stomach cancer was in Mongolia, at 28 cases per 100,000 people.[82]

In the United Kingdom, stomach cancer is the fifteenth most common cancer (around 7,100 people were diagnosed with stomach cancer in 2011), and it is the tenth most common cause of cancer death (around 4,800 people died in 2012).[83]

Incidence and mortality rates of gastric cancer vary greatly in Africa. The GLOBOCAN system is currently the most widely used method to compare these rates between countries, but African incidence and mortality rates are seen to differ among countries possibly due to the lack of universal access to a registry system for all countries.[84] Variation as drastic as estimated rates from 0.3/100000 in Botswana to 20.3/100000 in Mali have been observed.[84] In Uganda, the incidence of gastric cancer has increased from the 1960s measurement of 0.8/100000 to 5.6/100000.[84] Gastric cancer, though present, is relatively low when compared to countries with high incidence like Japan or China. One suspected cause of the variation within Africa and between other countries is due to different strains of the Helicobacter pylori bacteria. The trend commonly seen is that H. pylori infection increases the risk for gastric cancer, however this is not the case in Africa giving this phenomenon the name the "African enigma."[85] Although this bacteria is found in Africa, evidence has supported that different strains with mutations in the bacterial genotype may contribute to the difference in cancer development between African countries and others outside of the continent.[85] However, increasing access to health care and treatment measures have been commonly associated with the rising incidence, particularly in Uganda.[84]

## Other animals [edit]

The stomach is a muscular organ of the gastrointestinal tract that holds food and begins the digestive process by secreting gastric juice. The most common cancers of the stomach are adenocarcinomas but other histological types have been reported. Signs vary but may include vomiting (especially if blood is present), weight loss, anemia, and lack of appetite. Bowel movements may be dark and tarry in nature. In order to determine whether cancer is present in the stomach, special X-rays and/or abdominal ultrasound may be performed. Gastroscopy, a test using an instrument called endoscope to examine the stomach, is a useful diagnostic tool that can also take samples of the suspected mass for histopathological analysis to confirm or rule out cancer. The most definitive method of cancer diagnosis is through open surgical biopsy.[86] Most stomach tumors are malignant with evidence of spread to lymph nodes or liver, making treatment difficult. Except for lymphoma, surgery is the most frequent treatment option for stomach cancers but it is associated with significant risks.

# Amblyopia

From Wikipedia, the free encyclopedia

**Amblyopia**, also called **lazy eye**, is a disorder of sight due to the eye and brain not working well together. It results in decreased vision in an eye that otherwise typically appears normal. It is the most common cause of decreased vision in a single eye among children and younger adults.[1]

The cause of amblyopia can be any condition that interferes with focusing during early childhood.[1][2] This can occur from poor alignment of the eyes, an eye being irregularly shaped such that focusing is difficult, one eye being more nearsighted or farsighted than the other, or clouding of the lens of an eye.[1] After the underlying cause is fixed, vision is not fully restored as the mechanism also involves the brain.[2][3] Amblyopia can be difficult to detect and therefore vision testing is recommended for all children around the ages of four to five.[4]

Early detection improves treatment success.[4] Eye glasses may be all the treatment needed for some children.[4][5] If this is not sufficient, treatments which force the child to use the weaker eye are used. This is done by either using a patch or putting atropine in the stronger eye. Without treatment amblyopia typically persists into adulthood. Evidence regarding treatments for adults is poor.[1]

Amblyopia was first described in the 1600s.[6] It begins by the age of five.[4] In adults the disorder is estimated to affect 1–5% of the population.[7] While treatment improves vision it does not typically restore it to normal in the affected eye.[4] The condition may make people ineligible to be pilots or police officers.[4] The word "amblyopia" is from Greek αμβλυωπία, meaning "blunt vision".[6]

## Signs and symptoms [edit]

Many people with amblyopia, especially those who only have a mild form, are not aware they have the condition until tested at older ages, since the vision in their stronger eye is normal. People typically have poor stereo vision, however, since it requires both eyes. Those with amblyopia further may have, on the affected eye, poor pattern recognition, poor visual acuity, and low sensitivity to contrast and motion.[8]

Amblyopia is characterized by several functional abnormalities in spatial vision, including reductions in visual acuity (VA), contrast sensitivity function (CSF), and vernier acuity as well as spatial distortion, abnormal spatial interactions, and impaired contour detection. In addition, individuals with amblyopia suffer from binocular abnormalities such as impaired stereoacuity (stereoscopic acuity) and abnormal binocular summation.[9] Also, a crowding phenomenon is present.[10] These deficits are usually specific to the amblyopic eye. However, sub-clinical deficits of the "better" eye have also been demonstrated.[11]

People with amblyopia also have problems of binocular vision such as limited stereoscopic depth perception and usually have difficulty seeing the three-dimensional images in hidden stereoscopic displays such as autostereograms.[12] Perception of depth, however, from monocular cues such as size, perspective, and motion parallax remains normal.

## Types [edit]

Amblyopia has three main causes:

- Strabismic: by strabismus (misaligned eyes)
- Refractive: by anisometropia (high degrees of nearsightedness, farsightedness, or astigmatism in one or both eyes)
- Deprivational: by deprivation of vision early in life by vision-obstructing disorders such as congenital cataract

### Strabismus amblyopia [edit]

Strabismus, sometimes also incorrectly called *lazy eye*, is a condition in which the eyes are misaligned.[13] Strabismus usually results in normal vision in the preferred sighting (or "fellow") eye (the eye that the person prefers to use), but may cause abnormal vision in the deviating or strabismic eye due to the difference between the images projecting to the brain from the two eyes.[14] Adult-onset strabismus usually causes double vision (diplopia), since the two eyes are not fixed on the same object. Children's brains, however, are more neuroplastic, and therefore can more easily adapt by suppressing images from one of the eyes, eliminating the double vision. This plastic response of the brain, however, interrupts the brain's normal development, resulting in the amblyopia. Recent evidence points to a cause of infantile strabismus lying with the input to the visual cortex.[15]

Those with strabismic amblyopia tend to show ocular motion deficits when reading, even when they use the nonamblyopic eye. In particular, they tend to make more saccades per line than persons with normal stereo vision, and to have a reduced reading speed, especially when reading a text with small font size.[16][17]

Strabismic amblyopia is treated by clarifying the visual image with glasses, or encouraging use of the amblyopic eye with an eyepatch over the dominant eye or pharmacologic penalization of the better eye. Penalization usually consists of applying atropine drops to temporarily dilate the pupil, which leads to blurring of vision in the good eye. This helps to prevent the bullying and teasing associated with wearing a patch, although sometimes application of the eye drops is more challenging. The ocular alignment itself may be treated with surgical or non-surgical methods, depending on the type and severity of the strabismus.[18]

### Refractive or anisometropic amblyopia [edit]

Refractive amblyopia may result from anisometropia (unequal refractive error between the two eyes).[19][20] Anisometropia exists when there is a difference in the power between the two eyes. The eye which provides the brain with a clearer image typically becomes the dominant eye. The image in the other eye is blurred, which results in abnormal development of one half of the visual system. Refractive amblyopia is usually less severe than strabismic amblyopia and is commonly missed by primary care physicians because of its less dramatic appearance and lack of obvious physical manifestation, such as with strabismus.[21] Given that the refractive correction of anisometropia by means of spectacles typically leads to different image magnification for the two eyes, which may in turn prevent binocular vision, a refractive correction using contact lenses is to be considered. Also pediatric refractive surgery is a treatment option, in particular if conventional approaches have failed due to aniseikonia or lack of compliance or both.[22]

Frequently, amblyopia is associated with a combination of anisometropia and strabismus. In some cases, the vision between the eyes can differ to the point where one eye has twice average vision while the other eye is completely blind.

### Deprivation and occlusion amblyopia [edit]

Deprivation amblyopia (*Amblyopia ex anopsia*) results when the ocular media become opaque, such as is the case with congenital cataract or corneal haziness.[23] These opacities prevent adequate visual input from reaching the eye, and therefore disrupt development. If not treated in a timely fashion, amblyopia may persist even after the cause of the opacity is removed. Sometimes, drooping of the eyelid (ptosis) or some other problem causes the upper eyelid to physically occlude a child's vision, which may cause amblyopia quickly. Occlusion amblyopia may be a complication of a hemangioma that blocks some or all of the eye. Other possible causes of deprivation and occlusion amblyopia include obstruction in the vitreous and aphakia.[24] Deprivation amblyopia accounts for less than 3% of all individuals affected by amblyopia.[24]

## Pathophysiology [edit]

Amblyopia is a developmental problem in the brain, not any intrinsic, organic neurological problem in the eyeball (although organic problems can lead to amblyopia which can continue to exist after the organic problem has resolved by medical intervention).[25] The part of the brain receiving images from the affected eye is not stimulated properly and does not develop to its full visual potential. This has been confirmed by direct brain examination. David H. Hubel and Torsten Wiesel won the Nobel Prize in Physiology or Medicine in 1981 for their work in showing the extent of the damage to ocular dominance columns produced in kittens by sufficient visual deprivation during the so-called "critical period." The maximum "critical period" in humans is from birth to two years old.[26]

## Diagnosis [edit]

Amblyopia is diagnosed by identifying low visual acuity in one or both eyes, out of proportion to the structural abnormality of the eye and excluding other visual disorders as causes for the lowered visual acuity.

It can be defined as an inter-ocular difference of two lines or more in acuity (e.g. on Snellen chart) when the eye optics is maximally corrected.[27]

In young children, visual acuity is difficult to measure and can be estimated by observing the reactions of the patient reacts when one eye is covered, including observing the patient's ability to follow objects with one eye.

Stereotests like the Lang stereotest are not reliable exclusion tests for amblyopia: A patient who passes the Lang stereotest test is unlikely to have strabismic amblyopia, but could nonetheless have refractive or deprivational amblyopia.[28] It has been suggested that binocular retinal birefringence scanning may be

able to identify, already in very young children, amblyopia that is associated with strabismus, microstrabismus, or reduced fixation accuracy.

It is essential to diagnose and treat amblyopia as early as possible in order to keep the vision loss to a minimum.

## Treatment [edit]

Treatment of strabismic or anisometropic amblyopia consists of correcting the optical deficit (wearing the necessary spectacle prescription) and often forcing use of the amblyopic eye, by patching the good eye, or instilling topical atropine in the good eye, or both.[13]:130[29]

Concerning patching versus atropine, there is a drawback in using atropine: the drops can have a side effect of creating nodules in the eye which a correctional ointment can counteract. One should also be wary of over-patching or over-penalizing the good eye when treating amblyopia, as this can create so-called "reverse amblyopia".[18][30] Eye patching is usually done on a part-time schedule of about 4–6 hours a day. Treatment is continued as long as vision improves. It is not worthwhile continuing to patch for more than 6 months if there is no improvement.[31]

Treatment of individuals age 9 through adult is possible through applied perceptual learning.[32][33]

*Deprivation amblyopia* is treated by removing the opacity as soon as possible followed by patching or penalizing the good eye to encourage the use of the amblyopic eye.[18] The earlier the treatment is initiated, the easier and faster the treatment is and the less psychologically damaging. There is also a greater chance of achieving 20/20 vision if treatment is initiated as early as possible.[34]

One of the German public health insurance providers, Barmer, has changed its policy to cover, as of 1 April 2014, the costs for an app for amblyopic children whose condition has so far not improved through patching. The app offers dedicated eye exercises which the patient performs while wearing an eyepatch.[35]

### Older age [edit]

Although the best outcome is achieved if treatment is started before age 8, research has shown that children older than age 12 and some adults can show improvement in the affected eye. Children from 9 to 11 who wore an eye patch and performed near point activities (vision therapy) were four times as likely to show a two line improvement on a standard 11 line eye chart than children with amblyopia who did not receive treatment. Adolescents aged 13 to 17 showed improvement as well, albeit in smaller amounts than younger children. It is uncertain whether such improvements are only temporary, however, particularly if treatment is discontinued.[18][36]

There is tentative evidence that perceptual training may be beneficial in adults.[37][38][39]

Virtual reality computer games where each eye receives different signals of the virtual world that the player's brain must combine in order to successfully play the game have shown some promise in improving both monocularity in the affected eye as well as binocularity.[40][41]

## Epidemiology [edit]

Between 2% and 5% of the population in western countries have amblyopia.[27][42] In the U.K., 90% of visual health appointments in the child are concerning amblyopia.[43]

Depending on the chosen criterion for diagnosis, between 1% and 4% of the children have amblyopia.[44]

## Research [edit]

A 2009 study,[45] widely reported in the popular press,[46] has suggested that repetitive transcranial

magnetic stimulation may temporarily improve contrast sensitivity and spatial resolution in the affected eye of adults with amblyopia. This approach is still under development,[47] and the results await verification by other researchers. It has also been suggested that comparable results can be achieved using different types of brain stimulation[48] such as anodal transcranial direct current stimulation[49] and theta burst rTMS.[50]

A 2013 study concluded that there is converging evidence that decorrelated binocular experience plays a pivotal role in the genesis of amblyopia and the associated residual deficits.[51] Another study of 2013[52] suggests that playing a version of the popular game Tetris that is modified such that each eye sees separate components of the game may also help to treat this condition in adults.[53] Furthermore, it has been proposed that the effects of this kind of therapy may be further enhanced by non-invasive brain stimulation[48] as shown by a recent study using anodal tDCS.[54]

A 2014 Cochrane Review sought to determine the effectiveness of occlusion treatment on patients with sensory deprivation amblyopia, however no trials were found eligible to be included in the review.[24] However, it is suggested that good outcomes from occlusion treatment for sensory deprivation amblyopia rely on compliance with the treatment.

# Cataract

From Wikipedia, the free encyclopedia
(Redirected from Cataracts)

*For other uses, see Cataract (disambiguation).*

A **cataract** is a clouding of the lens in the eye which leads to a decrease in vision. Cataracts often develop slowly and can affect one or both eyes. Symptoms may include faded colors, blurry vision, halos around light, trouble with bright lights, and trouble seeing at night.[1] This may result in trouble driving, reading, or recognizing faces.[2] Poor vision caused by cataracts may also result in an increased risk of falling and depression.[3] Cataracts are the cause of half of blindness and 33% of visual impairment worldwide.[4][5]

Cataracts are most commonly due to aging but may also occur due to trauma or radiation exposure, be present from birth, or occur following eye surgery for other problems.[1][6] Risk factors include diabetes, smoking tobacco, prolonged exposure to sunlight, and alcohol. Either clumps of protein or yellow-brown pigment may be deposited in the lens reducing the transmission of light to the retina at the back of the eye. Diagnosis is by an eye examination.[1]

Prevention includes wearing sunglasses and not smoking. Early on the symptoms may be improved with glasses. If this does not help, surgery to remove the cloudy lens and replace it with an artificial lens is the only effective treatment. Surgery is only needed if the cataracts are causing problems and generally results in an improved quality of life.[1][7] Cataract surgery is not readily available in many countries, which is especially true for women, those living in rural areas, and those who do not know how to read.[6][8]

About 20 million people are blind due to cataracts.[6] It is the cause of approximately 5% of blindness in the United States and nearly 60% of blindness in parts of Africa and South America.[8] Blindness from cataracts occurs in about 10 to 40 per 100,000 children in the developing world, and 1 to 4 per 100,000 children in the developed world.[9] Cataracts become more common with age. More than half the people in the United States had cataracts by the age of 80.[1]

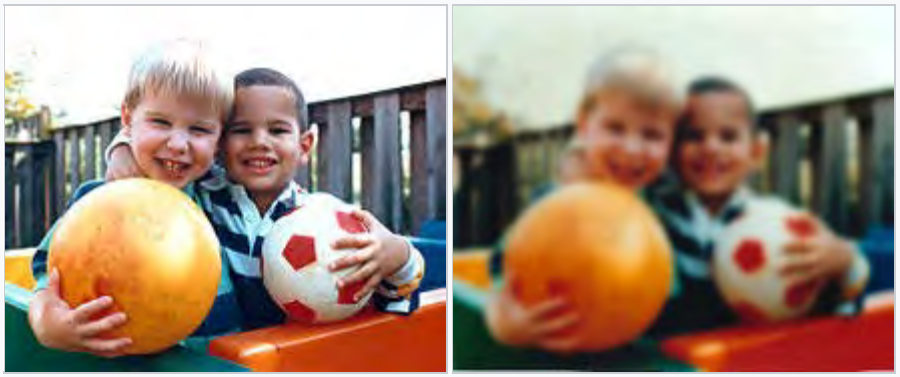
## Signs and symptoms [edit]

Signs and symptoms vary depending on the type of cataract, though considerable overlap occurs. People with nuclear sclerotic or brunescent cataracts often notice a reduction of vision. Those with posterior subcapsular cataracts usually complain of glare as their major symptom.[10]



An example of normal vision on the left versus vision with cataracts on the right

The severity of cataract formation, assuming no other eye disease is present, is judged primarily by a visual acuity test. The appropriateness of surgery depends on a patient's particular functional and visual needs and other risk factors, all of which may vary widely.[11]

## Causes [edit]

### Age [edit]

Age is the most common cause.[1][6] Lens proteins denature and degrade over time, and this process is accelerated by diseases such as diabetes mellitus and hypertension. Environmental factors, including toxins, radiation, and ultraviolet light, have cumulative effects, which are worsened by the loss of protective and restorative mechanisms due to alterations in gene expression and chemical processes within the eye.[12]

Edit links

Blunt trauma causes swelling, thickening, and whitening of the lens fibers. While the swelling normally resolves with time, the white color may remain. In severe blunt trauma, or in injuries that penetrate the eye, the capsule in which the lens sits can be damaged. This damage allows fluid from other parts of the eye to rapidly enter the lens leading to swelling and then whitening, obstructing light from reaching the retina at the back of the eye. Cataracts may develop in 0.7 to 8.0% of cases following electrical injuries.[13] Blunt trauma can also result in star- or petal-shaped cataracts.[14]

## Radiation [edit]

Ultraviolet light, specifically UVB, has been shown to cause cataracts, and some evidence indicates sunglasses worn at an early age can slow its development in later life.[15] Microwave radiation has also been found to cause cataracts. The mechanism is unclear, but it may include changes in heat-sensitive enzymes that normally protect cell proteins in the lens. Another possible mechanism is direct damage to the lens from pressure waves induced in the aqueous humor.

Cataracts have been associated with ionizing radiation such as X-rays. The addition of damage to the DNA of the lens cells has been considered.[16] Finally, electric and heat injuries denature and whiten the lens as a result of direct protein coagulation.[12] This same process makes the clear albumen of an egg become white and opaque after cooking. Cataracts of this type are often seen in glassblowers and furnace workers. Lasers of sufficient power output are known to damage the eyes and skin.

## Genetics [edit]

The genetic component is strong in the development of cataracts,[17] most commonly through mechanisms that protect and maintain the lens. The presence of cataracts in childhood or early life can occasionally be due to a particular syndrome. Examples of chromosome abnormalities associated with cataracts include 1q21.1 deletion syndrome, cri-du-chat syndrome, Down syndrome, Patau's syndrome, trisomy 18 (Edward's syndrome), and Turner's syndrome, and in the case of neurofibromatosis type 2, juvenile cataract on one or both sides may be noted. Examples of single-gene disorder include Alport's syndrome, Conradi's syndrome, myotonic dystrophy, and oculocerebrorenal syndrome or Lowe syndrome.

## Skin diseases [edit]

The skin and the lens have the same embryological origin and so can be affected by similar diseases.[18] Those with atopic dermatitis and eczema occasionally develop shield ulcers cataracts. Ichthyosis is an autosomal recessive disorder associated with cuneiform cataracts and nuclear sclerosis. Basal-cell nevus and pemphigus have similar associations.

## Smoking and alcohol [edit]

Cigarette smoking has been shown to double the rate of nuclear sclerotic cataracts and triple the rate of posterior subcapsular cataracts.[19] Evidence is conflicting over the effect of alcohol. Some surveys have shown a link, but others which followed people over longer terms have not.[20]

## Inadequate vitamin C [edit]

Low vitamin C intake and serum levels have been associated with greater cataract rates.[21] However, use of supplements of vitamin C has not demonstrated benefit.[22]

## Medications [edit]

Some medications, such as inhaled corticosteroids, may increase the risk of cataract development.[23] People with schizophrenia often have risk factors for lens opacities (such as diabetes, hypertension, and [24] [25]

poor nutrition) but antipsychotic medications are unlikely to contribute to cataract formation. Miotics and triparanol may increase the risk.[26]

### Post-operative [edit]

Nearly every person who undergoes a vitrectomy—without ever having had cataract surgery—will experience progression of nuclear sclerosis after the operation.[27] This may be because the native vitreous humor is different to the solutions used to replace the vitreous (vitreous substitutes), such as BSS Plus.[28] This may also be because the native vitreous humour contains ascorbic acid which helps neutralize oxidative damage to the lens and because traditional vitreous substitutes do not contain ascorbic acid.[29][30] As such, for phakic patients requiring a vitrectomy it is becoming increasingly common for ophthalmologists to offer the vitrectomy with a combined prophylactic cataract surgery procedure to prophylactically prevent cataract formation.[31]

### Other diseases [edit]

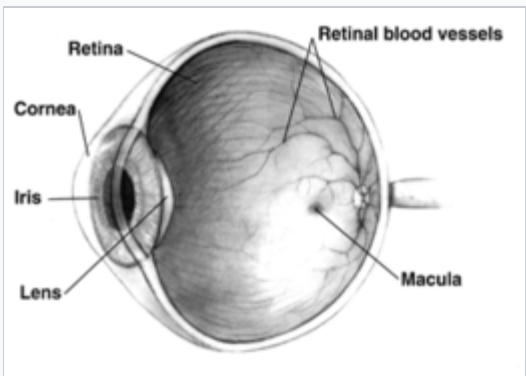
## Classification [edit]

Cataracts may be partial or complete, stationary or progressive, or hard or soft. The main types of age-related cataracts are nuclear sclerosis, cortical, and posterior subcapsular.

Nuclear sclerosis is the most common type of cataract, and involves the central or 'nuclear' part of the lens. This eventually becomes hard, or 'sclerotic', due to condensation on the lens nucleus and the deposition of brown pigment within the lens. In its advanced stages it is called a brunescent cataract. This type of cataract can present with a shift to nearsightedness, causing problems with distance vision though reading is less affected.[32]

Cortical cataracts are due to the lens cortex (outer layer) becoming opaque. They occur when changes in the fluid contained in the periphery of the lens causes fissuring. When these cataracts are viewed through an ophthalmoscope, or other magnification



Cross-sectional view, showing the position of the human lens

system, the appearance is similar to white spokes of a wheel.
Symptoms often include problems with glare and light scatter at night.[32]

Posterior subcapsular cataracts are cloudy at the back of the lens adjacent to the capsule (or bag) in which the lens sits. Because light becomes more focused toward the back of the lens, they can cause disproportionate symptoms for their size.

An immature cataract has some transparent protein, but with a mature cataract, all the lens protein is opaque. In a hypermature or Morgagnian cataract, the lens proteins have become liquid. Congenital cataract, which may be detected in adulthood, has a different classification and includes lamellar, polar, and sutural cataracts.[33][34]

Cataracts can be classified by using the lens opacities classification system LOCS III. In this system, cataracts are classified based on type as nuclear, cortical, or posterior. The cataracts are further classified based on severity on a scale from 1 to 5. The LOCS III system is highly reproducible.[35]

## Prevention [edit]

Risk factors such as UVB exposure and smoking can be addressed, but are unlikely to make a large difference to visual function. Although no means of preventing cataracts has been scientifically proven, wearing sunglasses that counteract ultraviolet light may slow their development.[36][37] While adequate intake of antioxidants (such as vitamins A, C, and E) has been thought to protect against the risk of cataracts, clinical trials have shown no benefit from supplements;[22] though evidence is mixed, but weakly positive, for a potential protective effect of the nutrients lutein and zeaxanthin.[38] Statin use is somewhat associated with a lower risk of nuclear sclerotic cataracts.[39]

## Treatment [edit]

### Surgical [edit]

*Main article: Cataract surgery*

Cataract removal can be performed at any stage and no longer requires ripening of the lens. Surgery is usually 'outpatient' and performed using local anesthesia. About 9 of 10 patients can achieve a corrected vision of 20/40 or better after surgery.[32]

Cataract surgery, using a temporal-approach phacoemulsification probe (in right hand) and "chopper" (in left hand) being done under operating microscope at a navy medical center

Several recent evaluations found that cataract surgery can meet expectations only when significant functional impairment due to cataracts exists prior to surgery. Visual function estimates such as VF-14 have been found to give more realistic estimates than visual acuity testing alone.[32][40] In some developed countries, a trend to overuse cataract surgery has been noted, which may lead to disappointing results.[41]

Phacoemulsification is the most widely used cataract surgery in the developed world.[42][43] This procedure uses ultrasonic energy to emulsify the cataract lens. Phacoemulsification typically comprises six steps:

- Anaesthetic – The eye is numbed with either a subtenon injection around the eye (see: retrobulbar block) or topical anesthetic eye drops. The former also provides paralysis of the eye muscles.
- Corneal incision – Two cuts are made at the margin of the clear cornea to allow insertion of instruments into the eye.
- Capsulorhexis – A needle or small pair of forceps is used to create a

Slit lamp photo of posterior capsular opacification visible a few months after implantation of intraocular lens in eye, seen on retroillumination

circular hole in the capsule in which the lens sits.
- Phacoemulsification – A handheld ultrasonic probe is used to break up and emulsify the lens into liquid using the energy of ultrasound waves. The resulting 'emulsion' is sucked away.
- Irrigation and aspiration – The cortex, which is the soft outer layer of the cataract, is aspirated or sucked away. Fluid removed is continually replaced with a saline solution to prevent collapse of the structure of the anterior chamber (the front part of the eye).
- Lens insertion – A plastic, foldable lens is inserted into the capsular bag that formerly contained the natural lens. Some surgeons also inject an antibiotic into the eye to reduce the risk of infection. The final step is to inject salt water into the corneal wounds to cause the area to swell and seal the incision.

Extracapsular cataract extraction (ECCE) consists of removing the lens manually, but leaving the majority of the capsule intact.[44] The lens is expressed through a 10- to 12-mm incision which is closed with sutures at the end of surgery. ECCE is less frequently performed than phacoemulsification, but can be useful when dealing with very hard cataracts or other situations where emulsification is problematic. Manual small incision cataract surgery (MSICS) has evolved from ECCE. In MSICS, the lens is removed through a self-sealing scleral tunnel wound in the sclera which, ideally, is watertight and does not require suturing. Although "small", the incision is still markedly larger than the portal in phacoemulsion. This surgery is increasingly popular in the developing world where access to phacoemulsification is still limited.

Intracapsular cataract extraction (ICCE) is rarely performed.[45] The lens and surrounding capsule are removed in one piece through a large incision while pressure is applied to the vitreous membrane. The surgery has a high rate of complications.

## Prognosis [edit]

### Postoperative care [edit]

Slit lamp photo of anterior capsular opacification visible a few months after implantation of intraocular lens in eye, magnified view

The postoperative recovery period (after removing the cataract) is usually short. The patient is usually ambulatory on the day of surgery, but is advised to move cautiously and avoid straining or heavy lifting for about a month. The eye is usually patched on the day of surgery and use of an eye shield at night is often suggested for several days after surgery.[11]

In all types of surgery, the cataractous lens is removed and replaced with an artificial lens, known as an intraocular lens, which stays in the eye permanently. Intraocular lenses are usually monofocal, correcting for either distance or near vision. Multifocal lenses may be implanted to improve near and distance vision simultaneously, but these lenses may increase the chance of unsatisfactory vision.[12]

### Complications [edit]

Serious complications of cataract surgery include retinal detachment and endophthalmitis.[46] In both cases, patients notice a sudden decrease in vision. In endophthalmitis, patients often describe pain. Retinal detachment frequently presents with unilateral visual field defects, blurring of vision, flashes of light, or floating spots.

The risk of retinal detachment was estimated as about 0.4% within 5.5

A South African woman experiences newfound eyesight after a patch was removed after surgery to remove an eye cataract.

years, corresponding to a 2.3-fold risk increase compared to naturally expected incidence, with older studies reporting a substantially higher risk. The incidence is increasing over time in a somewhat linear manner, and the risk increase lasts for at least 20 years after the procedure. Particular risk factors are younger age, male sex, longer axial length, and complications during surgery. In the highest risk group of patients, the incidence of pseudophakic retinal detachment may be as high as 20%.[47][48]

The risk of endophthalmitis occurring after surgery is less than one in 1000.[49]

Corneal edema and cystoid macular edema are less serious but more common, and occur because of persistent swelling at the front of the eye in corneal edema or back of the eye in cystoid macular edema.[50] They are normally the result of excessive inflammation following surgery, and in both cases, patients may notice blurred, foggy vision. They normally improve with time and with application of anti-inflammatory drops. The risk of either occurring is around one in 100.

Posterior capsular opacification, also known as after-cataract, is a condition in which months or years after successful cataract surgery, vision deteriorates or problems with glare and light scattering recur, usually due to thickening of the back or posterior capsule surrounding the implanted lens, so-called 'posterior lens capsule opacification'. Growth of natural lens cells remaining after the natural lens was removed may be the cause, and the younger the patient, the greater the chance of this occurring. Management involves cutting a small, circular area in the posterior capsule with targeted beams of energy from a laser, called Nd:YAG laser capsulotomy, after the type of laser used. The laser can be aimed very accurately, and the small part of the capsule which is cut falls harmlessly to the bottom of the inside of the eye. This procedure leaves sufficient capsule to hold the lens in place, but removes enough to allow light to pass directly through to the retina. Serious side effects are rare.[51] Posterior capsular opacification is common and occurs following up to one in four operations, but these rates are decreasing following the introduction of modern intraocular lenses together with a better understanding of the causes.

Vitreous touch syndrome is a possible complication of intracapsular cataract extraction.[52]

## Epidemiology [edit]

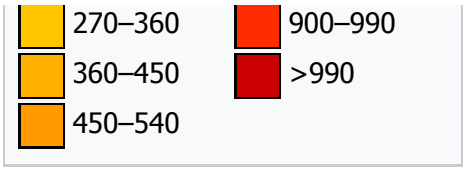
Age-related cataracts are responsible for 51% of world blindness, about 20 million people.[54] Globally, cataracts cause moderate to severe disability in 53.8 million (2004), 52.2 million of whom are in low and middle income countries.[55]

In many countries, surgical services are inadequate, and cataracts remain the leading cause of blindness.[54] Even where surgical services are available, low vision associated with cataracts may still be prevalent as a result of long waits for, and barriers to, surgery, such as cost, lack of information and transportation problems.

In the United States, age-related lens changes have been reported in 42% between the ages of 52 and 64,[56] 60% between the ages 65 and 74,[57] and 91% between the ages of 75 and 85.[56] Cataracts affect nearly 22 million Americans age 40 and older. By age 80, more than half of all Americans have cataracts. Direct medical costs for cataract treatment are estimated at $6.8 billion annually.[58]

Disability-adjusted life years for cataracts per 100,000 inhabitants in 2004:[53]

| | |
|---|---|
| no data | 540–630 |
| <90 | 630–720 |
| 90–180 | 720–810 |
| 180–270 | 810–900 |



In the eastern Mediterranean region, cataracts are responsible for over 51% of blindness. Access to eye care in many countries in this region is limited.[59]

## History [edit]

*See also: Cataract surgery § History*

The first references to cataracts and their treatment in Ancient Rome are found in 29 AD in *De Medicinae*, the work of the Latin encyclopedist Aulus Cornelius Celsus.[60] Archaeological evidence of eye surgery in the Roman era also exists.[61]

Other early accounts are found in Sanskrit. Cataract surgery was described by the Indian physician, Suśruta (about 200 AD).[62]

Muslim ophthalmologist Ammar ibn Ali, in his *Choice of Eye Diseases*, written *circa* 1000, wrote of his invention of a syringe and the technique of cataract extraction while experimenting with it on a patient.[63]

### Etymology [edit]

"Cataract" is derived from the Latin *cataracta*, meaning "waterfall", and from the Ancient Greek καταρράκτης (*katarrhaktēs*), "down-rushing",[64] from καταράσσω (*katarassō*) meaning "to dash down"[65] (from *kata-*, "down"; *arassein*, "to strike, dash").[66] As rapidly running water turns white, so the term may have been used metaphorically to describe the similar appearance of mature ocular opacities. In Latin, *cataracta* had the alternative meaning "portcullis"[67] and the name possibly passed through French to form the English meaning "eye disease" (early 15th century), on the notion of "obstruction".[68] Early Persian physicians called the term *nazul-i-ah*, or "descent of the water"—vulgarised into waterfall disease or cataract—believing such blindness to be caused by an outpouring of corrupt humour into the eye.[69]

## Research [edit]

N-Acetylcarnosine drops have been investigated as a medical treatment for cataracts. The drops are believed to work by reducing oxidation and glycation damage in the lens, particularly reducing crystallin crosslinking.[70][71] Some benefit has been shown in small manufacturer sponsored randomized controlled trials but further independent corroboration is still required.[72]

Femtosecond laser mode-locking, used during cataract surgery, was originally used to cut accurate and predictable flaps in LASIK surgery, and has been introduced to cataract surgery. The incision at the junction of the sclera and cornea and the hole in capsule during capsulorhexis, traditionally made with a handheld blade, needle, and forceps, are dependent on skill and experience of the surgeon. Sophisticated three-dimensional images of the eyes can be used to guide lasers to make these incisions. Nd:YAG laser can also then break up the cataract as in phacoemulsification.[73]

Stem cells have been used in a clinical trial for lens regeneration in twelve children under the age of two with cataracts present at birth.[74] The children were followed for six months, so it is unknown what the long-term results will be, and it is unknown if this procedure would work in adults.[74]

# Color blindness

From Wikipedia, the free encyclopedia

(Redirected from Color blind)

*"Colorblind" redirects here. For color blindness in other species, see Color vision. For other uses, see Colorblind (disambiguation).*

**Color blindness**, also known as **color vision deficiency**, is the decreased ability to see color or differences in color.[2] Color blindness can make some educational activities difficult. Buying fruit, picking clothing, and reading traffic lights can also be more challenging. Problems, however, are generally minor and most people adapt. People with total color blindness may also have decreased visual acuity and be uncomfortable in bright environments.[2]

The most common cause of color blindness is a fault in the development of one or more of the three sets of color sensing cones in the eye. Males are more likely to be color blind than females as the genes responsible for the most common forms of color blindness are on the X chromosome. As females have two X chromosomes, a defect in one is typically compensated for by the other, while males only have one X chromosome. Color blindness can also result from physical or chemical damage to the eye, optic nerve, or parts of the brain. Diagnosis is typically with the Ishihara color test; however a number of other testing methods also exist.[2]

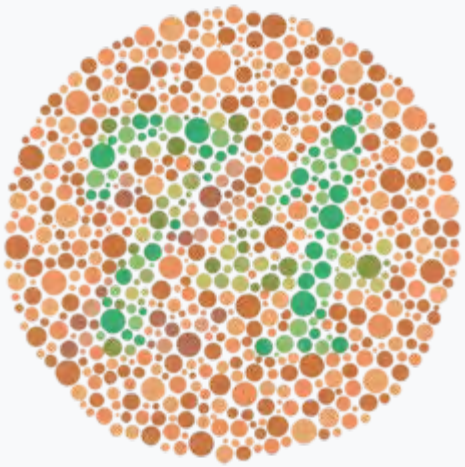
There is no cure for color blindness.[2] Diagnosis may allow a person's teacher to change their method of teaching to accommodate the decreased ability to recognize color.[1] Special lenses may help people with red–green color blindness when under bright conditions. There are also mobile apps that can help people identify colors.[2]

Red–green color blindness is the most common form, followed by blue–yellow color blindness and total color blindness.[2] Red–green color blindness affects up to 8% of males and 0.5% of females of Northern European descent. The ability to see color also decreases in old age.[2] Being color blind may make people ineligible for certain jobs in certain countries. This may include pilot, train driver, and armed forces. The effect of color blindness on artistic ability, however, is controversial. The ability to draw appears to be unchanged and a number of famous artists are believed to have been color blind.[1]

Contents

**Color blindness**

**Synonyms** ... vision[1]



Example of an Ishihara color test plate. Depending on the computer displays, people with normal vision should see the number "74". Many people who are color blind see it as "21", and those with total color blindness may not see any numbers.

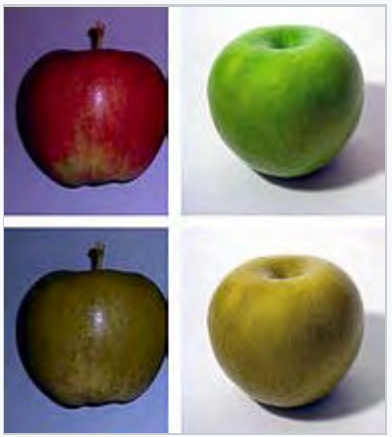
## Signs and symptoms [edit]

In almost all cases, color blind people retain blue–yellow discrimination, and most color-blind individuals are anomalous trichromats rather than complete dichromats. In practice, this means that they often retain a limited discrimination along the red–green axis of color space, although their ability to separate colors in this dimension is severely reduced. Color blindness very rarely means complete monochromatism.[*citation needed*]

Dichromats often confuse red and green items. For example, they may find it difficult to distinguish a Braeburn apple from a Granny Smith and in some cases, the red and green of traffic lights without other clues—for example, shape or position. The vision of dichromats may also be compared to images produced by a color printer that has run out of the ink in one of its three color cartridges (for protanopes and deuteranopes, the red cartridge, and for tritanopes, the yellow cartridge). Dichromats tend to learn to use texture and shape clues and so are often able to penetrate camouflage that has been designed to deceive individuals with color-normal vision.[3]



Simulation of the normal (above) and dichromatic (below) perception of red and green apples[*citation needed*]

Colors of traffic lights are confusing to some dichromats, as there is insufficient apparent difference between the red/amber traffic lights, and that of sodium street lamps; also, the green can be confused with a grubby white lamp. This is a risk factor on high-speed undulating roads where angular cues cannot be used. British Rail color lamp signals use more easily identifiable colors: The red is blood red, the amber is yellow and the green is a bluish color. Most British road traffic lights are mounted vertically on a black rectangle with a white border (forming a "sighting board") and so dichromats can look for the position of the light within the rectangle—top,

Horizontal traffic light in Halifax, Nova Scotia, Canada

middle or bottom. In the eastern provinces of Canada horizontally mounted traffic lights are generally differentiated by shape to facilitate identification for those with color blindness. In the United States, this is not done by shape but by position, as the red light is always on the left if the light is horizontal, or on top if the light is vertical. However, a single flashing light (red indicating cars must stop, yellow for caution/yield) is indistinguishable, but these are rare.

Normal sight

Deuteranopia sight

Tritanopia sight

Monochromacy sight

## Causes [edit]

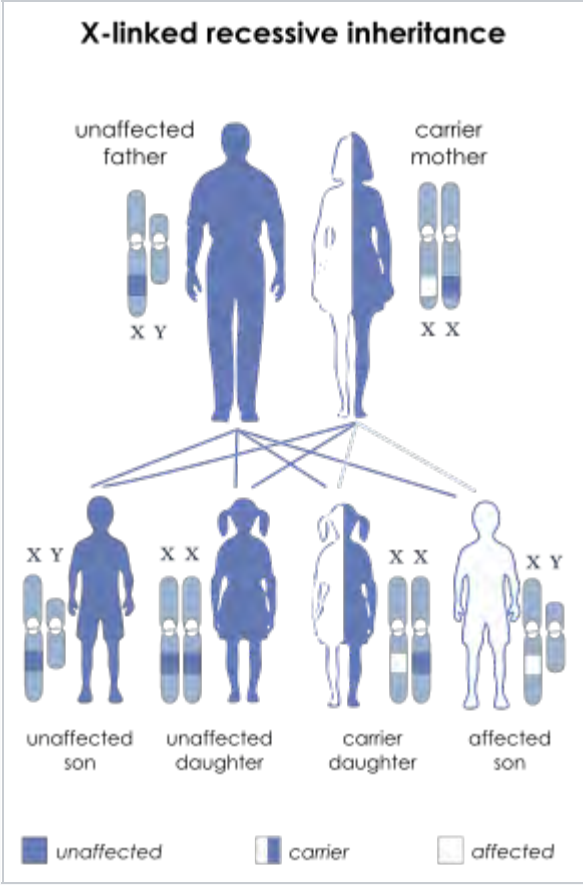
Color vision deficiencies can be classified as acquired or inherited.

- Acquired: Diseases, drugs (e.g., Plaquenil), and chemicals may cause color blindness.[4][5]
- Inherited: There are three types of inherited or congenital color vision deficiencies: monochromacy, dichromacy, and anomalous trichromacy.
  - Monochromacy, also known as "total color blindness", is the lack of ability to distinguish colors (and thus the person views everything as if it were on a black and white television); caused by cone defect or absence. Monochromacy occurs when two or all three of the cone pigments are missing and color and lightness vision is reduced to one dimension.
    - Rod monochromacy (achromatopsia) is an exceedingly rare, nonprogressive inability to distinguish any colors as a result of absent or nonfunctioning retinal cones. It is associated with light sensitivity (photophobia), involuntary eye oscillations (nystagmus), and poor vision.
    - Cone monochromacy is a rare total color blindness that is accompanied by relatively normal vision, electroretinogram, and electrooculogram. Cone monochromacy can also be a result of having more than one type of dichromatic color blindness. People who have, for instance, both protanopia and tritanopia are considered to have cone monochromacy. Since cone monochromacy is the lack of/damage of more than one cone in retinal environment, having two types of dichromacy would be an equivalent.
  - Dichromacy is a moderately severe color vision defect in which one of the three basic color mechanisms is absent or not functioning. It is hereditary and, in the case of protanopia or deuteranopia, sex-linked, affecting predominantly males. Dichromacy occurs when one of the cone pigments is missing and color is reduced to two dimensions. Dichromacy conditions are labeled based on whether the "first" (Greek: *prot-*, referring to the red photoreceptors), "second" (*deuter-*, the green), or "third" (*trit-*, the blue) photoreceptors are affected.
    - Protanopia is a severe type of color vision deficiency caused by the complete absence of red retinal photoreceptors. Protans have difficulties distinguishing between blue and green colors and also between red and green colors. It is a form of dichromatism in which the subject can only perceive light wavelengths from 400 to 650 nm, instead of the usual 700 nm. Pure reds cannot be seen, instead appearing black; purple colors cannot be distinguished from blues; more orange-tinted reds may appear as very dim yellows, and all orange–yellow–green shades of too long a wavelength to stimulate the blue receptors appear as a similar yellow hue. It is hereditary, sex-linked, and present in 1% of males.
    - Deuteranopia is a type of color vision deficiency where the green photoreceptors are absent. It affects hue discrimination in the same way as protanopia, but without the dimming effect. Like protanopia, it is hereditary, sex-linked, and found in about 1% of the male population.[6]
    - Tritanopia is a very rare color vision disturbance in which there are only two cone pigments present and a total absence of blue retinal receptors. Blues appear greenish, yellows and oranges appear pinkish, and purple colors appear deep red. It is related to chromosome 7. Unlike protanopia and deuteranopia, tritanopia and tritanomaly are not sex-linked traits and can be acquired rather than inherited and can be reversed in some cases.
  - Anomalous trichromacy is a common type of inherited color vision deficiency, occurring when one of the three cone pigments is altered in its spectral sensitivity.
    - Protanomaly is a mild color vision defect in which an altered spectral sensitivity of red retinal receptors (closer to green receptor response) results in poor red–green hue discrimination. It is hereditary, sex-linked, and present in 1% of males. The difference with protanopia is that in this case the L-cone is present but malfunctioning, whereas in the earlier the L-cone is completely missing.[7]
    - Deuteranomaly, caused by a similar shift in the green retinal receptors, is by far the most common type of color vision deficiency, mildly affecting red–green hue discrimination in 5% of European males. It is hereditary and sex-linked. The difference with deuteranopia is that in this

case the green sensitive cones are not missing but malfunctioning.[8]
- Tritanomaly is a rare, hereditary color vision deficiency affecting blue–green and yellow–red/pink hue discrimination. It is related to chromosome "7".[9] The difference is that the S-cone is malfunctioning but not missing.[10]

## Genetics [edit]

Color blindness is typically inherited. It is most commonly inherited from mutations on the X chromosome but the mapping of the human genome has shown there are many causative mutations—mutations capable of causing color blindness originate from at least 19 different chromosomes and 56 different genes (as shown online at the Online Mendelian Inheritance in Man (OMIM)). Two of the most common inherited forms of color blindness are protanopia and deuteranopia.[11] One of the common color vision defects is red–green deficiency which is present in about 8 percent of males and 0.5 percent of females of Northern European ancestry.[12]



X-linked recessive inheritance

Some of the inherited diseases known to cause color blindness are:

- cone dystrophy
- cone-rod dystrophy
- achromatopsia (a.k.a. rod monochromatism, stationary cone dystrophy or cone dysfunction syndrome)
- blue cone monochromatism (a.k.a. blue cone monochromacy or X-linked achromatopsia)
- Leber's congenital amaurosis
- retinitis pigmentosa (initially affects rods but can later progress to cones and therefore color blindness).

Inherited color blindness can be congenital (from birth), or it can commence in childhood or adulthood. Depending on the mutation, it can be stationary, that is, remain the same throughout a person's lifetime, or progressive. As progressive phenotypes involve deterioration of the retina and other parts of the eye, certain forms of color blindness can progress to legal blindness, i.e., an acuity of 6/60 (20/200) or worse, and often leave a person with complete blindness.

Color blindness always pertains to the cone photoreceptors in retinas, as the cones are capable of detecting the color frequencies of light.

About 8 percent of males, and 0.5 percent of females, are color blind in some way or another, whether it is one color, a color combination, or another mutation.[13] The reason males are at a greater risk of inheriting an X linked mutation is that males only have one X chromosome (XY, with the Y chromosome carrying altogether different genes than the X chromosome), and females have two (XX); if a woman inherits a normal X chromosome in addition to the one that carries the mutation, she will not display the mutation. Men do not have a second X chromosome to override the chromosome that carries the mutation. If 5% of variants of a given gene are defective, the probability of a single copy being defective is 5%, but the probability that two copies are both defective is $0.05 \times 0.05 = 0.0025$, or just 0.25%.

## Other causes [edit]

Other causes of color blindness include brain or retinal damage caused by shaken baby syndrome, accidents and other trauma which produce swelling of the brain in the occipital lobe, and damage to the retina caused by exposure to ultraviolet light (10–300 nm). Damage often presents itself later on in life.

Color blindness may also present itself in the spectrum of degenerative diseases of the eye, such as age-related macular degeneration, and as part of the retinal damage caused by diabetes. Another factor that may affect color blindness includes a deficiency in Vitamin A.[14]

## Types [edit]

Based on clinical appearance, color blindness may be described as total or partial. Total color blindness is much less common than partial color blindness.[15] There are two major types of color blindness: those who have difficulty distinguishing between red and green, and who have difficulty distinguishing between blue and yellow.[16][17]

- Total color blindness
- Partial color blindness
  - Red–green
    - Dichromacy (protanopia and deuteranopia)
    - Anomalous trichromacy (protanomaly and deuteranomaly)
  - Blue–yellow
    - Dichromacy (tritanopia)
    - Anomalous trichromacy (tritanomaly)
    - Blue–green trichromacy (tritanomaly)

Immunofluorescent imaging is a way to determine red–green color coding. Conventional color coding is difficult for individuals with red–green color blindness (protanopia or deuteranopia) to discriminate. Replacing red with magenta or green with turquoise improves visibility for such individuals.[18]

The different kinds of inherited color blindness result from partial or complete loss of function of one or more of the different cone systems. When one cone system is compromised, dichromacy results. The most frequent forms of human color blindness result from problems with either the middle or long wavelength sensitive cone systems, and involve difficulties in discriminating reds, yellows, and greens from one another. They are collectively referred to as "red–green color blindness", though the term is an over-simplification and is somewhat misleading. Other forms of color blindness are much more rare. They include problems in discriminating blues from greens and yellows from reds/pinks, and the rarest forms of all, complete color blindness or *monochromacy*, where one cannot distinguish any color from grey, as in a black-and-white movie or photograph.

Protanopes, deuteranopes, and tritanopes are dichromats; that is, they can match any color they see with some mixture of just two primary colors (whereas normally humans are trichromats and require three primary colors). These individuals normally know they have a color vision problem and it can affect their lives on a daily basis. Two percent of the male population exhibit severe difficulties distinguishing between red, orange, yellow, and green. A certain pair of colors, that seem very different to a normal viewer, appear to be the same color (or different shades of same color) for such a dichromat. The terms protanopia, deuteranopia, and tritanopia come from Greek and literally mean "inability to see (*anopia*) with the first (*prot-*), second (*deuter-*), or third (*trit-*) [cone]", respectively.

Anomalous trichromacy is the least serious type of color deficiency.[19] People with protanomaly, deuteranomaly, or tritanomaly are trichromats, but the color matches they make differ from the normal. They are called anomalous trichromats. In order to match a given spectral yellow light, protanomalous observers need more red light in a red/green mixture than a normal observer, and deuteranomalous observers need more green. From a practical standpoint though, many protanomalous and deuteranomalous people have very little difficulty carrying out tasks that require normal color vision. Some may not even be aware that their color perception is in any way different from normal.

Protanomaly and deuteranomaly can be diagnosed using an instrument called an anomaloscope, which mixes spectral red and green lights in variable proportions, for comparison with a fixed spectral yellow. If this is done in front of a large audience of males, as the proportion of red is increased from a low value, first a small proportion of the audience will declare a match, while most will see the mixed light as greenish; these are the deuteranomalous observers. Next, as more red is added the majority will say that a match

has been achieved. Finally, as yet more red is added, the remaining, protanomalous, observers will declare a match at a point where normal observers will see the mixed light as definitely reddish.[*citation needed*]

## Red–green color blindness [edit]

Protanopia, deuteranopia, protanomaly, and deuteranomaly are commonly inherited forms of red–green color blindness which affect a substantial portion of the human population. Those affected have difficulty with discriminating red and green hues due to the absence or mutation of the red or green retinal photoreceptors. This deficiency does not cause difficulty discerning red from green.[11][20] It is sex-linked: genetic red–green color blindness affects males much more often than females, because the genes for the red and green color receptors are located on the X chromosome, of which males have only one and females have two. Females (46, XX) are red–green color blind only if *both* their X chromosomes are defective with a similar deficiency, whereas males (46, XY) are color blind if their single X chromosome is defective.[*citation needed*]

The gene for red–green color blindness is transmitted from a color blind male to all his daughters who are heterozygote carriers and are usually unaffected. In turn, a carrier woman has a fifty percent chance of passing on a mutated X chromosome region to each of her male offspring. The sons of an affected male will not inherit the trait from him, since they receive his Y chromosome and not his (defective) X chromosome. Should an affected male have children with a carrier or colorblind woman, their daughters may be colorblind by inheriting an affected X chromosome from each parent.[*citation needed*]

Because one X chromosome is inactivated at random in each cell during a woman's development, it is possible for her to have four different cone types, as when a carrier of protanomaly has a child with a deuteranomalic man. Denoting the normal vision alleles by P and D and the anomalous by p and d, the carrier is PD pD and the man is Pd. The daughter is either PD Pd or pD Pd. Suppose she is pD Pd. Each cell in her body expresses either her mother's chromosome pD or her father's Pd. Thus her red–green sensing will involve both the normal and the anomalous pigments for both colors. Such females are tetrachromats, since they require a mixture of four spectral lights to match an arbitrary light.[*citation needed*]

Red–green color blindness can be caused by ethambutol.[21]

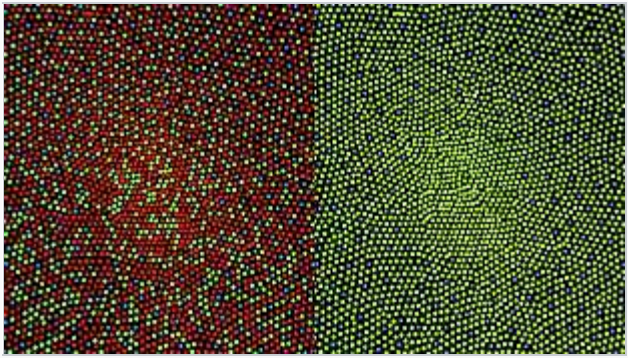


Illustration of the distribution of cone cells in the fovea of an individual with normal color vision (left), and a color blind (protanopic) retina. The center of the fovea holds very few blue-sensitive cones.

- **Protanopia** (1% of males): Lacking the red cones for long-wavelength sensitive retinal cones, those with this condition are unable to distinguish between colors in the green–yellow–red section of the spectrum. They have a neutral point at a cyan-like wavelength around 492 nm (see spectral color for comparison) – that is, they cannot discriminate light of this wavelength from white. For a protanope, the brightness of red, orange, and yellow are much reduced compared to normal. This dimming can be so pronounced that reds may be confused with black or dark gray, and red traffic lights may appear to be extinguished. They may learn to distinguish reds from yellows primarily on the basis of their apparent brightness or lightness, not on any perceptible hue difference. Violet, lavender, and purple are indistinguishable from various shades of blue because their reddish components are so dimmed as to be invisible. For example, pink flowers, reflecting both red light and blue light, may appear just blue to the protanope. A very few people have been found who have one normal eye and one protanopic eye. These *unilateral dichromats* report that with only their protanopic eye open, they see wavelengths shorter than neutral point as blue and those longer than it as yellow. This is a rare form of color blindness.

- **Deuteranopia** (1% of males): Lacking the green cones for medium-wavelength cones, those affected

are again unable to distinguish between colors in the green–yellow–red section of the spectrum. Their neutral point is at a slightly longer wavelength, 498 nm, a more greenish hue of cyan. A deuteranope suffers the same hue discrimination problems as protanopes, but without the abnormal dimming. Purple colors are not perceived as something opposite to spectral colors; all these appear similarly. This form of colorblindness is also known as *Daltonism* after John Dalton (his diagnosis was confirmed as deuteranopia in 1995, some 150 years after his death, by DNA analysis of his preserved eyeball). Equivalent forms for daltonism in Romanic languages such as *daltonismo* (Spanish, Portuguese and Italian), *daltonisme* (French), *daltonism* (Romanian) are still used to describe color blindess in a broad sense or deuteranopia in a more restricted sense. Deuteranopic unilateral dichromats report that with only their deuteranopic eye open, they see wavelengths shorter than neutral point as blue and longer than it as yellow.[22]

- **Protanomaly** (1% of males, 0.01% of females):[23] Having a mutated form of the long-wavelength (red) pigment, whose peak sensitivity is at a shorter wavelength than in the normal retina, protanomalous individuals are less sensitive to red light than normal. This means that they are less able to discriminate colors, and they do not see mixed lights as having the same colors as normal observers. They also suffer from a darkening of the red end of the spectrum. This causes reds to reduce in intensity to the point where they can be mistaken for black. Protanomaly is a fairly rare form of color blindness, making up about 1% of the male population. Both protanomaly and deuteranomaly are carried on the X chromosome.

- **Deuteranomaly** (most common—6% of males, 0.4% of females):[23] These individuals have a mutated form of the medium-wavelength (green) pigment. The medium-wavelength pigment is shifted towards the red end of the spectrum resulting in a reduction in sensitivity to the green area of the spectrum. Unlike protanomaly the intensity of colors is unchanged. The deuteranomalous person is considered "green weak". For example, in the evening, dark green cars appear to be black to Deuteranomalous people. Similar to the protanomates, deuteranomates are poor at discriminating small differences in hues in the red, orange, yellow, green region of the spectrum. They make errors in the naming of hues in this region because the hues appear somewhat shifted towards green. One very important difference between deuteranomalous individuals and protanomalous individuals is deuteranomalous individuals do *not* have the loss of "brightness" problem.

## Blue–yellow color blindness [edit]

Those with tritanopia and tritanomaly have difficulty discriminating between bluish and greenish hues, as well as yellowish and reddish hues.

Color blindness involving the inactivation of the short-wavelength sensitive cone system (whose absorption spectrum peaks in the bluish-violet) is called **tritanopia** or, loosely, blue–yellow color blindness. The tritanope's neutral point occurs near a yellowish 570 nm; green is perceived at shorter wavelengths and red at longer wavelengths.[24] Mutation of the short-wavelength sensitive cones is called **tritanomaly**. Tritanopia is equally distributed among males and females. Jeremy H. Nathans (with the Howard Hughes Medical Institute) demonstrated that the gene coding for the blue receptor lies on chromosome 7, which is shared equally by males and females. Therefore, it is not sex-linked. This gene does not have any neighbor whose DNA sequence is similar. Blue color blindness is caused by a simple mutation in this gene.

- **Tritanopia** (less than 1% of males and females): Lacking the short-wavelength cones, those affected see short-wavelength colors (blue, indigo and a spectral violet) greenish and drastically dimmed, some of these colors even as black. Yellow is indistinguishable from pink, and purple colors are perceived as various shades of red. This form of color blindness is not sex-linked.

- **Tritanomaly** (equally rare for males and females [0.01% for both]):[23] Having a mutated form of the short-wavelength (blue) pigment. The short-wavelength pigment is shifted towards the green area of the spectrum. This is the rarest form of anomalous trichromacy color blindness. Unlike the other anomalous trichromacy color deficiencies, the mutation for this color blindness is carried on chromosome

7. Therefore, it is equally prevalent in both male & female populations. The OMIM gene code for this mutation is 304000 "Colorblindness, Partial Tritanomaly".[25]

### Total color blindness [edit]

Total color blindness is defined as the inability to see color. Although the term may refer to acquired disorders such as cerebral achromatopsia also known as color agnosia, it typically refers to congenital color vision disorders (i.e. more frequently rod monochromacy and less frequently cone monochromacy).[26][27]

In cerebral achromatopsia, a person cannot perceive colors even though the eyes are capable of distinguishing them. Some sources do not consider these to be true color blindness, because the failure is of perception, not of vision. They are forms of visual agnosia.[27]

Monochromacy is the condition of possessing only a single channel for conveying information about color. Monochromats possess a complete inability to distinguish any colors and perceive only variations in brightness. It occurs in two primary forms:

1. Rod monochromacy, frequently called *achromatopsia*, where the retina contains no cone cells, so that in addition to the absence of color discrimination, vision in lights of normal intensity is difficult. While normally rare, achromatopsia is very common on the island of Pingelap, a part of the Pohnpei state, Federated States of Micronesia, where it is called *maskun*: about 10% of the population there has it, and 30% are unaffected carriers. The island was devastated by a storm in the 18th century (an example of a genetic bottleneck) and one of the few male survivors carried a gene for achromatopsia. The population grew to several thousand before foreign troops introduced diseases to the island in the 1940s.
2. Cone monochromacy is the condition of having both rods and cones, but only a single kind of cone. A cone monochromat can have good pattern vision at normal daylight levels, but will not be able to distinguish hues. Blue cone monochromacy (X chromosome) is caused by lack of functionality of L and M cones (red and green). It is encoded at the same place as red–green color blindness on the X chromosome. Peak spectral sensitivities are in the blue region of the visible spectrum (near 440 nm). People with this condition generally show nystagmus ("jiggling eyes"), photophobia (light sensitivity), reduced visual acuity, and myopia (nearsightedness).[28] Visual acuity usually falls to the 20/50 to 20/400 range.

## Mechanism [edit]

*See also: Trichromatic color vision*

The typical human retina contains two kinds of light cells: the rod cells (active in low light) and the cone cells (active in normal daylight). Normally, there are three kinds of cone cells, each containing a different pigment, which are activated when the pigments absorb light. The spectral sensitivities of the cones differ; one is most sensitive to short wavelengths, one to medium wavelengths, and the third to medium-to-long wavelengths within the visible spectrum, with their peak sensitivities in the blue, green, and yellow-green regions of the spectrum, respectively. The absorption spectra of the three systems overlap, and combine to cover the visible spectrum. These receptors are known as short (S), medium (M),and long (L) wavelength cones, but are also often referred to as blue, green, and red cones, although this terminology is inaccurate.[29]

The receptors are each responsive to a wide range of wavelengths. For example, the long wavelength "red" receptor has its peak sensitivity in the yellow-green, some way from the red end (longest wavelength) of the visible spectrum. The sensitivity of normal color vision actually depends on the overlap between the absorption ranges of the three systems: different colors are recognized when the different types of cone are stimulated to different degrees. Red light, for example, stimulates the long wavelength cones much more than either of the others, and reducing the wavelength causes the other two cone systems to be increasingly stimulated, causing a gradual change in hue.

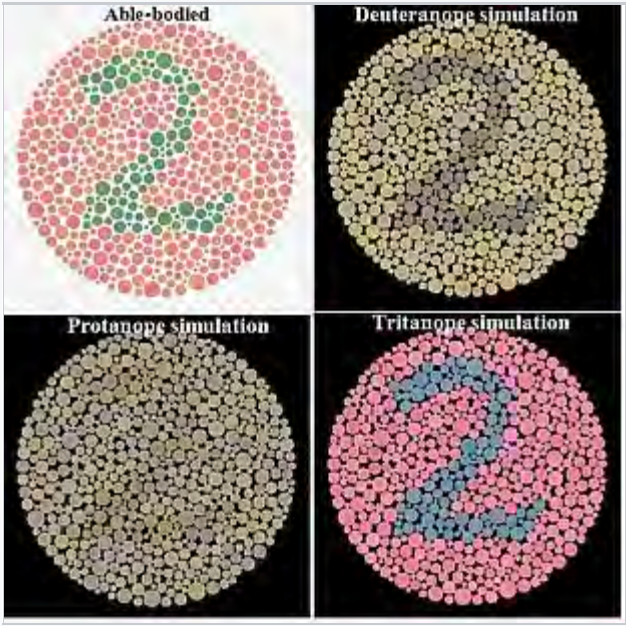
Many of the genes involved in color vision are on the X chromosome, making color blindness much more common in males than in females because males only have one X chromosome, while females have two. Because this is an X-linked trait, an estimated 2–3% of women have a 4th color cone[30] and can be

considered tetrachromats. One such woman has been reported to be a true or functional tetrachromat, as she can discriminate colors most other people can't.[31][32]

## Diagnosis [edit]

The Ishihara color test, which consists of a series of pictures of colored spots, is the test most often used to diagnose red–green color deficiencies.[33] A figure (usually one or more Arabic digits) is embedded in the picture as a number of spots in a slightly different color, and can be seen with normal color vision, but not with a particular color defect. The full set of tests has a variety of figure/background color combinations, and enable diagnosis of which particular visual defect is present. The anomaloscope, described above, is also used in diagnosing anomalous trichromacy.

> Position yourself about 75cm from your monitor so that the colour test image you are looking at is at eye level, read the description of the image and see what you can see!! It is not necessary in all cases to use the entire set of images. In a large scale examination the test can be simplified to 6 tests; test, one of tests 2 or 3, one of tests 4, 5, 6 or 7, one of tests 8 or 9, one of tests 10, 11, 12 or 13 and one of tests 14 or 15.[*this quote needs a citation*]



An Ishihara test image as seen by subjects with normal color vision and by those with a variety of color deficiencies

Because the Ishihara color test contains only numerals, it may not be useful in diagnosing young children, who have not yet learned to use numerals. In the interest of identifying these problems early on in life, alternative color vision tests were developed using only symbols (square, circle, car).

Besides the Ishihara color test, the US Navy and US Army also allow testing with the Farnsworth Lantern Test. This test allows 30% of color deficient individuals, whose deficiency is not too severe, to pass.

Another test used by clinicians to measure chromatic discrimination is the Farnsworth-Munsell 100 hue test. The patient is asked to arrange a set of colored caps or chips to form a gradual transition of color between two anchor caps.[34]

The HRR color test (developed by Hardy, Rand, and Rittler) is a red–green color test that, unlike the Ishihara, also has plates for the detection of the tritan defects.[35]

Most clinical tests are designed to be fast, simple, and effective at identifying broad categories of color blindness. In academic studies of color blindness, on the other hand, there is more interest in developing flexible tests to collect thorough datasets, identify copunctal points, and measure just noticeable differences.[36]

## Management [edit]

There is generally no treatment to cure color deficiencies. "The American Optometric Association reports a contact lens on one eye can increase the ability to differentiate between colors, though nothing can make you truly see the deficient color."[37]

### Lenses [edit]

Optometrists can supply colored spectacle lenses or a single red-tint contact lens to wear on the non-dominant eye, but although this may improve discrimination of some colors, it can make other colors more difficult to distinguish. A 1981 review of various studies to evaluate the effect of the X-chrom contact lens concluded that, while the lens may allow the wearer to achieve a better score on certain color vision tests, it did not correct color vision in the natural environment.[38] A case history using the X-Chrom lens for a rod monochromat is reported[39] and an X-Chrom manual is online.[40]

Lenses that filter certain wavelengths of light can allow people with a cone anomaly, but not dichromacy, to see a better spectrum of colors, especially those with classic "red/green" color blindness. They work by notching out wavelengths that strongly stimulate both red and green cones in a deuter- or protanomalous person, improving the distinction between the two cones' signals. As of 2013, sunglasses that enhance colors for many colorblind people are available commercially.[41][42][43]

### Apps [edit]

Many applications for iPhone and iPad have been developed to help colorblind people to view the colors in a better way. Many applications launch a sort of simulation of colorblind vision to make normal-view people understand how the color-blinds see the world. Others allow a correction of the image grabbed from the camera with a special "daltonizer" algorithm.

The GNOME desktop environment provides colorblind accessibility using the gnome-mag and the libcolorblind software. Using a gnome applet, the user may switch a color filter on and off, choosing from a set of possible color transformations that will displace the colors in order to disambiguate them. The software enables, for instance, a colorblind person to see the numbers in the Ishihara test.

## Epidemiology [edit]

Color blindness affects a large number of individuals, with protanopia and deuteranopia being the most common types.[11] In individuals with Northern European ancestry, as many as 8 percent of men and 0.4 percent of women experience congenital color deficiency.[45]

**Rates of color blindness**[*clarification needed*][44]

| | Males | Females |
|---|---|---|
| **Dichromacy** | 2.4% | 0.03% |
| Protanopia (red deficient: L cone absent) | 1.3% | 0.02% |
| Deuteranopia (green deficient: M cone absent) | 1.2% | 0.01% |
| Tritanopia (blue deficient: S cone absent) | 0.001% | 0.03% |
| **Anomalous trichromacy** | 6.3% | 0.37% |
| Protanomaly (red deficient: L cone defect) | 1.3% | 0.02% |
| Deuteranomaly (green deficient: M cone defect) | 5.0% | 0.35% |
| Tritanomaly (blue deficient: S cone defect) | 0.0001% | 0.0001% |

The number affected varies among groups. Isolated communities with a restricted gene pool sometimes produce high proportions of color blindness, including the less usual types. Examples include rural Finland, Hungary, and some of the Scottish islands. In the United States, about 7 percent of the male population—or about 10.5 million men—and 0.4 percent of the female population either cannot distinguish red from green, or see red and green differently from how others do (Howard Hughes Medical Institute, 2006 [*clarification needed*]). More than 95 percent of all variations in human color vision involve the red and green receptors in male eyes. It is very rare for males or females to be "blind" to the blue end of the spectrum.[46]

### Red–green color blindness [edit]

| Population | N | % |
|---|---|---|
| Arabs (Druzes) | 337 | 10.0 |
| | | |

| | | |
|---|---|---|
| Aboriginal Australians | 4,455 | 1.9 |
| Belgians | 9,540 | 7.4 |
| Bosnians | 4,836 | 6.2 |
| Britons | 16,180 | 6.6 |
| Chinese | 1,164 | 6.9 |
| Dutch | 3,168 | 8.0 |
| Eskimo | 297 | 2.5 |
| Fiji Islanders | 608 | 0.8 |
| French | 1,243 | 8.6 |
| Germans | 7,861 | 7.7 |
| Hutu | 1,000 | 2.9 |
| Indians (Andhra Pradesh) | 292 | 7.5 |
| Iranians | 16,180 | 6.6 |
| Japanese | 259,000 | 4.0 |
| Navajo | 571 | 2.3 |
| Norwegians | 9,047 | 9.0 |
| Mexicans | 571 | 2.3 |
| Russians | 1,343 | 9.2 |
| Scots | 463 | 7.8 |
| Swiss | 2,000 | 8.0 |
| Tibetans | 241 | 5.0 |
| Tswana | 407 | 2.0 |
| Tutsi | 1,000 | 2.5 |
| Vojvodinians | 4,750 | 7.4 |
| DR Congolese | 929 | 1.7 |

[47]

## History [edit]

The first scientific paper on the subject of color blindness, *Extraordinary facts relating to the vision of colours*, was published by the English chemist John Dalton in 1798[48] after the realization of his own color blindness. Because of Dalton's work, the general condition has been called *daltonism*, although in English this term is now used only for deuteranopia.

## Society and culture [edit]

### Design implications [edit]

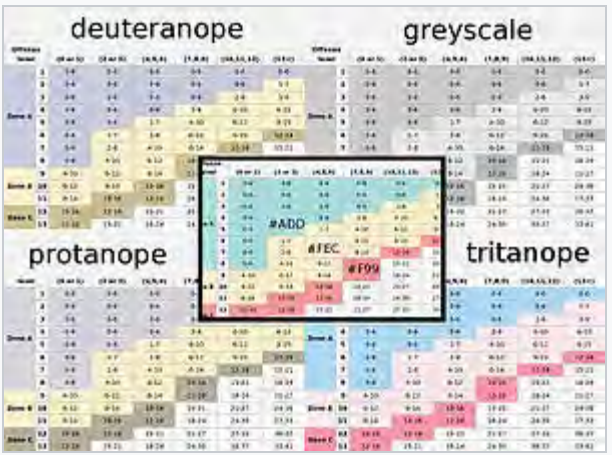
> This section **needs additional citations for verification**. Please help improve this article by adding citations to reliable sources.

An 1895 illustration of normal vision and various kinds of color blindness

Color codes present particular problems for those with color deficiencies as they are often difficult or impossible for them to perceive.

Good graphic design avoids using color coding or using color contrasts alone to express information;[49] this not only helps color blind people, but also aids understanding by normally sighted people.

Designers need to take into account that color-blindness is highly sensitive to differences in material. For example, a red–green colorblind person who is incapable of distinguishing colors on a map printed on paper may have no such difficulty when viewing the map on a computer screen or television. In addition, some color blind people find it easier to distinguish problem colors on artificial materials, such as plastic or in acrylic paints, than on natural materials, such as paper or wood. Third, for some color blind people, color can only be distinguished if there is a sufficient "mass" of color: thin lines might appear black, while a thicker line of the same color can be perceived as having color.[*citation needed*]



Testing the colors of a web chart, *(center)*, to ensure that no information is lost to the various forms of color-blindness.

Designers should also note that red–blue and yellow–blue color combinations are generally safe. So instead of the ever-popular "red means bad and green means good" system, using these combinations can lead to a much higher ability to use color coding effectively. This will still cause problems for those with monochromatic color blindness, but it is still something worth considering.[50]

When the need to process visual information as rapidly as possible arises, for example in an emergency situation, the visual system may operate only in shades of gray, with the extra information load in adding color being dropped.[*citation needed*] This is an important possibility to consider when designing, for example, emergency brake handles or emergency phones.

## Occupations [edit]

Color blindness may make it difficult or impossible for a person to engage in certain occupations. Persons with color blindness may be legally or practically barred from occupations in which color perception is an essential part of the job (*e.g.,* mixing paint colors), or in which color perception is important for safety (*e.g.,* operating vehicles in response to color-coded signals). This occupational safety principle originates

from the Lagerlunda train crash of 1875 in Sweden. Following the crash, Professor Alarik Frithiof Holmgren, a physiologist, investigated and concluded that the color blindness of the engineer (who had died) had caused the crash. Professor Holmgren then created the first test using different-colored skeins to exclude people from jobs in the transportation industry on the basis of color blindness.[51] However, there is a claim that there is no firm evidence that color deficiency did cause the collision, or that it might have not been the sole cause.[52]

Color vision is important for occupations using telephone or computer networking cabling, as the individual wires inside the cables are color-coded using green, orange, brown, blue and white colors.[53] Electronic wiring, transformers, resistors, and capacitors are color-coded as well, using black, brown, red, orange, yellow, green, blue, violet, gray, white, silver, gold.[54]

## Driving [edit]

Some countries (for example, Romania) have refused to grant driving licenses to individuals with color blindness. In Romania, there is an ongoing campaign to remove the legal restrictions that prohibit colorblind citizens from getting drivers' licenses.[55]

The usual justification for such restrictions is that drivers of motor vehicles must be able to recognize color-coded signals, such as traffic lights or warning lights.[50]

## Piloting aircraft [edit]

While many aspects of aviation depend on color coding, only a few of them are critical enough to be interfered with by some milder types of color blindness. Some examples include color-gun signaling of aircraft that have lost radio communication, color-coded glide-path indications on runways, and the like. Some jurisdictions restrict the issuance of pilot credentials to persons who suffer from color blindness for this reason. Restrictions may be partial, allowing color-blind persons to obtain certification but with restrictions, or total, in which case color-blind persons are not permitted to obtain piloting credentials at all.[*citation needed*]

In the United States, the Federal Aviation Administration requires that pilots be tested for normal color vision as part of their medical clearance in order to obtain the required medical certificate, a prerequisite to obtaining a pilot's certification. If testing reveals color blindness, the applicant may be issued a license with restrictions, such as no night flying and no flying by color signals—such a restriction effectively prevents a pilot from holding certain flying occupations, such as that of an airline pilot, although commercial pilot certification is still possible, and there are a few flying occupations that do not require night flight and thus are still available to those with restrictions due to color blindness (e.g., agricultural aviation). The government allows several types of tests, including medical standard tests (*e.g.,* the Ishihara, Dvorine, and others) and specialized tests oriented specifically to the needs of aviation. If an applicant fails the standard tests, they will receive a restriction on their medical certificate that states: "Not valid for night flying or by color signal control". They may apply to the FAA to take a specialized test, administered by the FAA. Typically, this test is the "color vision light gun test". For this test an FAA inspector will meet the pilot at an airport with an operating control tower. The color signal light gun will be shone at the pilot from the tower, and they must identify the color. If they pass they may be issued a waiver, which states that the color vision test is no longer required during medical examinations. They will then receive a new medical certificate with the restriction removed. This was once a Statement of Demonstrated Ability (SODA), but the SODA was dropped, and converted to a simple waiver (letter) early in the 2000s.[56]

Research published in 2009 carried out by the City University of London's Applied Vision Research Centre, sponsored by the UK's Civil Aviation Authority and the US Federal Aviation Administration, has established a more accurate assessment of color deficiencies in pilot applicants' red–green and yellow–blue color range which could lead to a 35% reduction in the number of prospective pilots who fail to meet the minimum medical threshold.[57]

## Art [edit]

Inability to distinguish color does not necessarily preclude the ability to become a celebrated artist. The 20th century expressionist painter Clifton Pugh, three-time winner of Australia's Archibald Prize, on biographical, gene inheritance and other grounds has been identified as a protanope.[58] 19th century French artist Charles Méryon became successful by concentrating on etching rather than painting after he was diagnosed as having a red–green deficiency.[59]

### Rights of the color blind [edit]

A famous traffic light on Tipperary Hill in Syracuse, New York, is upside-down due to the sentiments of its Irish American community, but has been criticized due to the potential hazard it poses for color-blind persons.[60]

### Brazil [edit]

A Brazilian court ruled that people with color blindness are protected by the Inter-American Convention on the Elimination of All Forms of Discrimination against Person with Disabilities.[61][62][63]

At trial, it was decided that the carriers of color blindness have a right of access to wider knowledge, or the full enjoyment of their human condition.

## Research [edit]

Some tentative evidence finds that color blind people are better at penetrating certain color camouflages. Such findings may give an evolutionary reason for the high rate of red–green color blindness.[3] There is also a study suggesting that people with some types of color blindness can distinguish colors that people with normal color vision are not able to distinguish.[64] In World War II, color blind observers were used to penetrate camouflage.[65]

In September 2009, the journal *Nature* reported that researchers at the University of Washington and University of Florida were able to give trichromatic vision to squirrel monkeys, which normally have only dichromatic vision, using gene therapy.[66]

In 2003, a cybernetic device called eyeborg was developed to allow the wearer to hear sounds representing different colors.[67] Achromatopsic artist Neil Harbisson was the first to use such a device in early 2004; the eyeborg allowed him to start painting in color by memorizing the sound corresponding to each color. In 2012, at a TED Conference, Harbisson explained how he could now perceive colors outside the ability of human vision.[68] Portuguese Designer Miguel Neiva developed a code system, named Coloradd, based on five basic shapes that, when combined, make it easier to identify various colors for colorblind people. Its use is currently[*when?*] expanding in Portugal (hospitals, transportation, education) and in other countries.

# Conjunctivitis

From Wikipedia, the free encyclopedia

*"Pinkeye" redirects here. For other uses, see Pinkeye (disambiguation).*

**Conjunctivitis**, also known as **pink eye**, is inflammation of the outermost layer of the white part of the eye and the inner surface of the eyelid.[1] It makes the eye appear pink or reddish. There may also be pain, burning, scratchiness, or itchiness. The affected eye may have increased tears or be "stuck shut" in the morning. Swelling of the white part of the eye may also occur.[2] Itching of the eye is more common in cases due to allergies.[3] Conjunctivitis can affect one or both eyes.[2]

The most common infectious causes are viral followed by bacterial.[3] The viral infection may occur along with other symptoms of a common cold. Viral and bacterial cases are easily spread between people.[2] Allergies to pollen or animal hair is also a common cause.[3] Diagnosis is often based on signs and symptoms. Occasionally a sample of the discharge is sent for culture.[2]

Prevention is partly by handwashing. Treatment depends on the underlying cause.[2] In the majority of viral cases, there is no specific treatment.[3] Most cases due to a bacterial infection will also resolve without treatment; however, antibiotics can shorten the illness.[2][3] Those who wear contact lens and those with either gonorrhea or chlamydia as the cause should be treated. Allergic cases can be treated with antihistamine or mast cell inhibitor drops.[3]

About 3 to 6 million people get conjunctivitis each year in the United States.[2][3] In adults viral causes are more common, while in children bacterial causes are more common.[3] Typically people get better in one or two weeks.[2][3] If there is visual loss, significant pain, sensitivity to light, signs of herpes, or a person is not improving after a week, further diagnosis and treatment may be required.[3] Conjunctivitis in a newborn, known as neonatal conjunctivitis, may also require specific treatment.[2]

## Signs and symptoms [edit]

Red eye, swelling of conjunctiva and watering of the eyes are symptoms common to all forms of conjunctivitis. However, the pupils should be normally reactive, and the visual acuity normal.

### Viral [edit]

Viral conjunctivitis is often associated with an infection of the upper respiratory tract, a common cold, and/or a sore throat. Its symptoms include excessive watering and itching. The infection usually begins with one eye, but may spread easily to the other.

Conjunctivitis due to a viral infection resulting in some bleeding

Viral conjunctivitis shows a fine, diffuse pinkness of the conjunctiva, which is easily mistaken for the ciliary infection of iris (iritis), but there are usually corroborative signs on microscopy, particularly numerous lymphoid follicles on the tarsal conjunctiva, and sometimes a punctate keratitis.

Some other viruses that can infect the eye include Herpes simplex virus and Varicella zoster.[4]

### Allergic [edit]

Allergic conjunctivitis is inflammation of the conjunctiva (the membrane covering the white part of the eye) due to allergy.[5] Allergens differ among patients.

Symptoms consist of redness (mainly due to vasodilation of the peripheral small blood vessels), swelling of the conjunctiva, itching, and increased lacrimation (production of tears). If this is combined with rhinitis, the condition is termed "allergic rhinoconjunctivitis". The symptoms are due to release of histamine and other active substances by mast cells, which stimulate dilation of blood vessels, irritate nerve endings, and increase secretion of tears.

An eye with allergic conjunctivitis showing conjunctival

### Bacterial [edit]

edema

An eye with bacterial conjunctivitis

Bacterial conjunctivitis causes the rapid onset of conjunctival redness, swelling of the eyelid, and mucopurulent discharge. Typically, symptoms develop first in one eye, but may spread to the other eye within 2–5 days.Bacterial conjunctivitis due to common pyogenic (pus-producing) bacteria causes marked grittiness/irritation and a stringy, opaque, greyish or yellowish mucopurulent discharge that may cause the lids to stick together, especially after sleep. Severe crusting of the infected eye and the surrounding skin may also occur. The gritty and/or scratchy feeling is sometimes localized enough for patients to insist they must have a foreign body in the eye. The more acute pyogenic infections can be painful.[*citation needed*] Common bacteria responsible for non-acute bacterial conjunctivitis are Staphylococci, Streptococci,[6] Haemophilus sp. Less commonly Chlamydia trachomatis is involved.[7]

Bacteria such as *Chlamydia trachomatis* or *Moraxella* can cause a non-exudative but persistent conjunctivitis without much redness. Bacterial conjunctivitis may cause the production of membranes or pseudomembranes that cover the conjunctiva. Pseudomembranes consist of a combination of inflammatory cells and exudates, and are loosely adherent to the conjunctiva, while true membranes are more tightly adherent and cannot be easily peeled away. Cases of bacterial conjunctivitis that involve the production of membranes or pseudomembranes are associated with Neisseria gonorrhoeae, β-hemolytic streptococci, and C. diphtheriae. *Corynebacterium diphtheriae* causes membrane formation in conjunctiva of non-immunized children.[*citation needed*]

## Chemical [edit]

Chemical eye injury is due to either an acidic or alkali substance getting in the eye.[8] Alkalis are typically worse than acidic burns.[9] Mild burns will produce conjunctivitis, while more severe burns may cause the cornea to turn white.[9] Litmus paper is an easy way to rule out the diagnosis by verifying that the pH is within the normal range of 7.0—7.2.[8] Large volumes of irrigation is the treatment of choice and should continue until the pH is 6—8.[9] Local anaesthetic eye drops can be used to decrease the pain.[9]

Irritant or toxic conjunctivitis show primarily marked redness. If due to splash injury, it is often present in only the lower conjunctival sac. With some chemicals, above all with caustic alkalis such as sodium hydroxide, there may be necrosis of the conjunctiva with a deceptively white eye due to vascular closure, followed by sloughing of the dead epithelium. This is likely to be associated with slit-lamp evidence of anterior uveitis.

## Other [edit]

Inclusion conjunctivitis of the newborn (ICN) is a conjunctivitis that may be caused by the bacteria *Chlamydia trachomatis*, and may lead to acute, purulent conjunctivitis.[10] However, it is usually self-healing.[10]

Conjunctivitis is identified by irritation and redness of the conjunctiva. Except in obvious pyogenic or toxic/chemical conjunctivitis, a slit lamp (biomicroscope) is needed to have any confidence in the diagnosis. Examination of the tarsal conjunctiva is usually more diagnostic than the bulbar conjunctiva.

An eye with chlamydial conjunctivitis

# Causes [edit]

Conjunctivitis when caused by an infection is most commonly caused by a viral infection.[11] Bacterial infections, allergies, other irritants and dryness are also common causes. Both bacterial and viral infections are contagious and passed from person

to person, but can also spread through contaminated objects or water.

The most common cause of viral conjunctivitis is adenoviruses (see: Adenoviral keratoconjunctivitis).[12] Herpetic keratoconjunctivitis (caused by herpes simplex viruses) can be serious and requires treatment with acyclovir. Acute hemorrhagic conjunctivitis is a highly contagious disease caused by one of two enteroviruses, Enterovirus 70 and Coxsackievirus A24. These were first identified in an outbreak in Ghana in 1969, and have spread worldwide since then, causing several epidemics.[13]

The most common causes of acute bacterial conjunctivitis are *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*.[12] Though very rare, hyperacute cases are usually caused by *Neisseria gonorrhoeae* or *N. meningitidis*. Chronic cases of bacterial conjunctivitis are those lasting longer than 3 weeks, and are typically caused by *Staphylococcus aureus*, *Moraxella lacunata*, or gram-negative enteric flora.

Conjunctivitis may also be caused by allergens such as pollen, perfumes, cosmetics, smoke,[14] dust mites, Balsam of Peru,[15] and eye drops.[16]

Conjunctivitis is part of the triad of reactive arthritis, which is thought to be caused by autoimmune cross-reactivity following certain bacterial infections. Reactive arthritis is highly associated with HLA-B27. Conjunctivitis is associated with the autoimmune disease relapsing polychondritis.[17][18]

## Diagnosis [edit]

Cultures are not often taken or needed as most cases resolve either with time or typical antibiotics. Swabs for bacterial culture are necessary if the history and signs suggest bacterial conjunctivitis but there is no response to topical antibiotics. Viral culture may be appropriate in epidemic case clusters.

A patch test is used to identify the causative allergen in the case where conjunctivitis is caused by allergy.[19]

Conjunctival scrapes for cytology can be useful in detecting chlamydial and fungal infections, allergy, and dysplasia, but are rarely done because of the cost and the general lack of laboratory staff experienced in handling ocular specimens. Conjunctival incisional biopsy is occasionally done when granulomatous diseases (*e.g.*, sarcoidosis) or dysplasia are suspected.

### Classification [edit]

Classification can be either by cause or by extent of the inflamed area.

### Causes [edit]

- Allergic conjunctivitis, caused by allergens such as pollen, perfumes, cosmetics, smoke,[14] dust mites, Balsam of Peru (used in food and drink for flavoring, in perfumes and toiletries for fragrance, and in medicine and pharmaceutical items for healing properties),[15] and eye drops.[16] A patch test is used to diagnose it and identify the causative allergen.[19]
- Bacterial conjunctivitis
- Viral conjunctivitis
- Chemical conjunctivitis
- Neonatal conjunctivitis is often defined separately due to different organisms
- Autoimmune

### By extent of involvement [edit]

Blepharoconjunctivitis is the dual combination of conjunctivitis with blepharitis (inflammation of the eyelids).

Keratoconjunctivitis is the combination of conjunctivitis and keratitis (corneal inflammation).

### Differential diagnosis [edit]

There are more serious conditions that can present with a red eye such as infectious keratitis, angle closure glaucoma, or iritis. These conditions require the urgent attention of an ophthalmologist. Signs of such conditions include decreased vision, significantly increased sensitivity to light, inability to keep eye open, a pupil that does not respond to light, or a severe headache with nausea.[20] Fluctuating blurring is common, due to tearing and mucoid discharge. Mild photophobia is common. However, if any of these symptoms are prominent, it is important to consider other diseases such as glaucoma, uveitis, keratitis and even meningitis or carotico-cavernous fistula.

A more comprehensive differential diagnosis for the red or painful eye includes:[20]

- corneal abrasion
- subconjunctival hemorrhage
- pinguecula
- blepharitis
- dacryocystitis
- keratoconjunctivitis sicca (dry eye)
- keratitis
- herpes simplex
- herpes zoster
- episcleritis - an inflammatory condition that produces a similar appearance to conjunctivitis, but without discharge or tearing.
- uveitis
- acute angle-closure glaucoma
- enophthalmitis

## Prevention [edit]

The best effective prevention is hygiene and not rubbing the eyes by infected hands. Vaccination against adenovirus, haemophilus influenzae, pneumococcus, and neisseria meningitidis is also effective.[*citation needed*]

Povidone-iodine eye solution has been found to prevent conjunctivitis following birth.[21] As it is less expensive it is being more commonly used for this purpose globally.[21]

## Management [edit]

Conjunctivitis resolves in 65% of cases without treatment, within two to five days. The prescription of antibiotics is not necessary in most cases.[22]

### Viral [edit]

Viral conjunctivitis usually resolves on its own and does not require any specific treatment.[11] Antihistamines (e.g., diphenhydramine) or mast cell stabilizers (e.g., cromolyn) may be used to help with the symptoms.[11] Povidone iodine has been suggested as a treatment, but as of 2008 evidence to support it was poor.[23]

### Allergic [edit]

For the allergic type, cool water poured over the face with the head inclined downward constricts capillaries, and artificial tears sometimes relieve discomfort in mild cases. In more severe cases, nonsteroidal anti-inflammatory medications and antihistamines may be prescribed. Persistent allergic conjunctivitis may also require topical steroid drops.

### Bacterial [edit]

Bacterial conjunctivitis usually resolves without treatment.[11] Topical antibiotics may be needed only if no improvement is observed after three days.[24] In people who received no antibiotics, recovery was in 4.8 days, with immediate antibiotics it was 3.3 days, and with delayed antibiotics 3.9 days. No serious effects were noted either with or without treatment.[25] As they do speed healing in bacterial conjunctivitis, their use is also reasonable.[26]

In those who wear contact lenses, are immunocompromised, have disease which is thought to be due to chlamydia or gonorrhea, have a fair bit of pain, or who have lots of discharge, antibiotics are recommended.[11] Gonorrhea or chlamydia infections require both oral and topical antibiotics.[11]

When appropriate, the choice of antibiotic varies, differing based on the cause (if known) or the likely cause of the conjunctivitis. Fluoroquinolones, sodium sulfacetamide, or trimethoprim/polymyxin may be used, typically for 7–10 days.[12] Cases of meningococcal conjunctivitis can also be treated with systemic penicillin, as long as the strain is sensitive to penicillin.

When investigated as a treatment, Povidone-iodine ophthalmic solution has also been observed to have some effectiveness against bacterial and chlamydial conjunctivitis, with a possible role suggested in locations where topical antibiotics are unavailable or costly.[27]

### Chemical [edit]

Conjunctivitis due to chemicals is treated via irrigation with Ringer's lactate or saline solution. Chemical injuries (particularly alkali burns) are medical emergencies, as they can lead to severe scarring and intraocular damage. People with chemically induced conjunctivitis should not touch their eyes, regardless of whether or not their hands are clean, as they run the risk of spreading the condition to another eye.

## Epidemiology [edit]

Conjunctivitis is the most common eye disease.[28]

## History [edit]

A former superintendent of the Regional Institute of Ophthalmology in the city of Madras (the present-day Chennai) in India, Kirk Patrick, was the first to have found the adenovirus that caused conjunctivitis, leading to the name "Madras eye" for the disease.[29]

# Retinal detachment

From Wikipedia, the free encyclopedia
(Redirected from Detached retina)

**Retinal detachment** is a disorder of the eye in which the retina separates from the layer underneath.[1] Symptoms include an increase in the number of floaters, flashes of light, and worsening of the outer part of the visual field.[1][2] This may be described as a curtain over part of the field of vision.[2] In about 7% of cases both eyes are affected.[3] Without treatment permanent loss of vision may occur.[4]

The mechanism most commonly involves a break in the retina that then allows the fluid in the eye to get behind the retina. A break in the retina can occur from a posterior vitreous detachment, injury to the eye, or inflammation of the eye. Other risk factors include being short sighted and previous cataract surgery. Retinal detachments also rarely occur due to a choroidal tumor.[1] Diagnosis is by either looking at the back of the eye with an ophthalmoscope or by ultrasound.[1][4]

In those with a retinal tear, efforts to prevent it becoming a detachment include cryotherapy using a cold probe or photocoagulation using a laser. Treatment of retinal detachment should be carried out in a timely manner. This may include scleral buckling where silicone is sutured to the outside of the eye, pneumatic retinopexy where gas is injected into the eye, or vitrectomy where the vitreous is partly removed and replaced with either gas or oil.[1]

Retinal detachments affect between 0.6 and 1.8 people per 10,000 per year.[3] About 0.3% of people are affected at some point in their life.[5] It is most common in people who are in their 60s or 70s. Males are more often affected than females. The long term outcomes depend on the duration of the detachment and whether the macula was detached.[1] If treated before the macula detaches outcomes are generally good.[1][5]

## Signs and symptoms [edit]

A rhegmatogenous retinal detachment is commonly preceded by a posterior vitreous detachment which gives rise to these symptoms:

- flashes of light (photopsia) – very brief in the extreme peripheral (outside of center) part of vision
- a sudden dramatic increase in the number of floaters
- a ring of floaters or hairs just to the temporal (skull) side of the central vision

Although most posterior vitreous detachments do not progress to retinal detachments, those that do produce the following symptoms:

- a dense shadow that starts in the peripheral vision and slowly progresses towards the central vision
- the impression that a veil or curtain was drawn over the field of vision
- straight lines (scale, edge of the wall, road, etc.) that suddenly appear curved (positive Amsler grid test)
- central visual loss

In the event of an appearance of sudden flashes of light or floaters, an eye doctor needs to be consulted immediately.[6] A shower of floaters or any loss of vision, too, is a medical emergency.

## Risk factors [edit]

Risk factors for retinal detachment include severe myopia, retinal tears, trauma, family history, as well as complications from cataract surgery.[5][7]

Retinal detachment can be mitigated in some cases when the warning signs[8] are caught early. The most effective means of prevention and risk reduction is through education of the initial signs, and encouragement for people to seek ophthalmic medical attention if they have symptoms suggestive of a posterior vitreous detachment.[9] Early examination allows detection of retinal tears which can be treated with laser or cryotherapy. This reduces the risk of retinal detachment in those who have tears from around 1:3 to 1:20. For this reason, the governing bodies in some sports require regular eye examination.

Trauma-related cases of retinal detachment can occur in high-impact sports or in high speed sports. Although some recommend avoiding activities that increase pressure in the eye, including diving and skydiving, there is little evidence to support this recommendation, especially in the general population. Nevertheless, ophthalmologists generally advise people with high degrees of myopia to try to avoid exposure to activities that have the potential for trauma, increase pressure on or within the eye itself, or include rapid acceleration and deceleration, such as bungee jumping or roller coaster rides.

Intraocular pressure spikes occur during any activity accompanied by the Valsalva maneuver, including weightlifting.[10] An epidemiological study suggests that heavy manual lifting at work may be associated with increased risk of rhegmatogenous retinal detachment, but this relationship is not strong.[11][12] In this study, obesity also appeared to increase the risk of retinal detachment. A high Body Mass Index (BMI) and elevated blood pressure have been identified as a risk factor in non-myopic individuals.[13]

Genetic factors promoting local inflammation and photoreceptor degeneration may also be involved in the development of the disease.[14]

Other risk factors include the following:

- Glaucoma[*citation needed*]
- AIDS[15]
- Cataract surgery[16]
- Diabetic retinopathy[15][17]
- Eclampsia[18]
- Family history of retinal detachment[19]
- Homocysteinuria[20]
- Malignant hypertension[15][18]
- Metastatic cancer, which spreads to the eye (eye cancer)[21]
- Retinoblastoma[22]
- Severe myopia[7]
- Smoking and passive smoking[23][24]
- Stickler syndrome[15]
- Von Hippel-Lindau disease[25]

## Diagnosis [edit]

Retinal detachment can be examined by fundus photography or ophthalmoscopy. Fundus photography generally needs a considerably larger instrument than the ophthalmoscope, but has the advantage of availing the image to be examined by a specialist at another location and/or time, as well as providing photo documentation for future reference. Modern fundus photographs generally recreate considerably larger areas of the fundus than what can be seen at any one time with handheld ophthalmoscopes.

A physician using a "three-mirror glass" to diagnose retinal detachment

Ultrasound has diagnostic accuracy similar to that of examination by an ophthalmologist.[26] The recent meta-analysis[*which?*] shows the diagnostic accuracy of emergency department (ED) ocular ultrasonography is high. The sensitivity and specificity ranged from 97% to 100% and 83% to 100%. The typical feature of retinal detachment when viewed on ultrasound is "flying angel sign". It shows the detached retina moving with a fixed point under the B mode, linear probe 10MHz.[27]

Retinal detachment, flying angel sign on ultrasound

### Types [edit]

- Rhegmatogenous retinal detachment – A rhegmatogenous retinal detachment occurs due to a break in the retina (called a *retinal tear*) that allows fluid to pass from the vitreous space into the subretinal space between the sensory retina and the retinal pigment epithelium. Retinal breaks are divided into three types – holes, tears and dialyses. Holes form due to retinal atrophy especially within an area of lattice degeneration. Tears are due to vitreoretinal traction. Dialyses are very peripheral and circumferential, and may be either tractional or atrophic. The atrophic form most often occurs as idiopathic dialysis of the young.
- Exudative, serous, or secondary retinal detachment – An exudative retinal detachment occurs due to inflammation, injury or vascular abnormalities that results in fluid accumulating underneath the retina without the presence of a hole, tear, or break. In evaluation of retinal detachment it is critical to exclude exudative detachment as surgery will make the situation worse, not better. Although rare, exudative detachment can be caused by the growth of a tumor on the layers of tissue beneath the retina, namely the choroid. This cancer is called a choroidal melanoma.
- Tractional retinal detachment – A tractional retinal detachment occurs when fibrous or fibrovascular

tissue, caused by an injury, inflammation or neovascularization, pulls the sensory retina from the retinal pigment epithelium.

A minority of retinal detachments result from trauma, including blunt blows to the orbit, penetrating trauma, and concussions to the head. A retrospective Indian study of more than 500 cases of rhegmatogenous detachments found that 11% were due to trauma, and that gradual onset was the norm, with over 50% presenting more than one month after the inciting injury.[28]

# Treatment [edit]

There are several methods of treating a detached retina, each of which depends on finding and closing the breaks that have formed in the retina. All three of the procedures follow the same three general principles:

1. Find all retinal breaks
2. Seal all retinal breaks
3. Relieve present (and future) vitreoretinal traction

## Cryopexy and laser photocoagulation [edit]

Cryotherapy (freezing) or laser photocoagulation are occasionally used alone to wall off a small area of retinal detachment so that the detachment does not spread.

## Scleral buckle surgery [edit]

Scleral buckle surgery is an established treatment in which the eye surgeon sews one or more silicone bands (or tyres) to the sclera (the white outer coat of the eyeball). The bands push the wall of the eye inward against the retinal hole, closing the break or reducing fluid flow through it and reducing the effect of vitreous traction thereby allowing the retina to re-attach. Cryotherapy (freezing) is applied around retinal breaks prior to placing the buckle. Often subretinal fluid is drained as part of the buckling procedure. The buckle remains in situ. The most common side effect of a scleral operation is myopic shift. That is, the operated eye will be more short sighted after the operation. Radial scleral buckle is indicated for U-shaped tears or Fishmouth tears, and posterior breaks. Circumferential scleral buckle is indicated for multiple breaks, anterior breaks and wide breaks. Encircling buckles are indicated for breaks covering more than 2 quadrants of retinal area, lattice degeneration located on more than 2 quadrant of retinal area, undetectable breaks, and proliferative vitreous retinopathy.

## Pneumatic retinopexy [edit]

This operation is generally performed in the doctor's office under local anesthesia. It is another method of repairing a retinal detachment in which a gas bubble ($SF_6$ or $C_3F_8$ gas) is injected into the eye after which laser or freezing treatment is applied to the retinal hole. The patient's head is then positioned so that the bubble rests against the retinal hole. Patients may have to keep their heads tilted for several days to keep the gas bubble in contact with the retinal hole. The surface tension of the gas/water interface seals the hole in the retina, and allows the retinal pigment epithelium to pump the subretinal space dry and "suck the retina back into place". This strict positioning requirement makes the treatment of the retinal holes and detachments that occurs in the lower part of the eyeball impractical. This procedure is usually combined with cryopexy or laser photocoagulation. Pneumatic retinopexy has significantly lower success rates compared to scleral buckle surgery and vitrectomy. Some initially successful cases will fail during the weeks and months after surgery. In some of the failed cases, an area of the retina which was healthy and attached prior to the initial pneumatic retinopexy repair procedure develops new tears and/or becomes detached. A recent Cochrane Review compared outcomes from patients receiving retinal reattachment from pneumatic retinopexy versus scleral buckle.[29] Though the quality of evidence from two randomized controlled trials was low, eyes having received the pneumatic retinopexy procedure were more likely to have a recurrence of retinal detachment by follow-up, and were 11% less likely to achieve retinal reattachment, compared to scleral buckle.[29]

### Vitrectomy [edit]

Vitrectomy is an increasingly used treatment for retinal detachment. It involves the removal of the vitreous gel and is usually combined with filling the eye with either a gas bubble ($SF_6$ or $C_3F_8$ gas) or silicone oil (PDMS). An advantage of using gas in this operation is that there is no myopic shift after the operation and gas is absorbed within a few weeks. PDMS, if used, needs to be removed after a period of 2–8 months depending on surgeon's preference. Silicone oil is more commonly used in cases associated with proliferative vitreo-retinopathy (PVR). A disadvantage is that a vitrectomy always leads to more rapid progression of a cataract in the operated eye. In many places vitrectomy is the most commonly performed operation for the treatment of retinal detachment. A recent Cochrane Review assessing various tamponade agents for patients with retinal detachment associated with PVR found that patients treated with $C_3F_8$ gas and standard silicone oil had visual and anatomic advantages over patients using $SF_6$.[30] Heavy silicone oil did not show any advantages over regular silicone oil.[30]

## Prognosis [edit]

85 percent of cases will be successfully treated with one operation with the remaining 15 percent requiring 2 or more operations. After treatment patients gradually regain their vision over a period of a few weeks, although the visual acuity may not be as good as it was prior to the detachment, particularly if the macula was involved in the area of the detachment.

Up until the early 20th century, the prognosis for rhegmatogenous retinal detachment was very poor, and no effective treatments were available. Currently, about 95 percent of cases of retinal detachment can be repaired successfully.[31] Treatment failures usually involve either the failure to recognize all sites of detachment, the formation of new retinal breaks, or proliferative vitreoretinopathy.[31]

Involvement of the macula portends a worse prognosis. In cases where the macula is not involved (detached), 90 percent of patients have 20/40 vision or better after reattachment surgery.[31] Some damage to vision may occur during reattachment surgery, and 10 percent of patients with normal vision experience some vision loss after a successful reattachment surgery.

## Epidemiology [edit]

The incidence of retinal detachment in otherwise normal eyes is around 5 new cases in 100,000 persons per year.[32] Detachment is more frequent in middle-aged or elderly populations, with rates of around 20 in 100,000 per year.[33] The lifetime risk in normal individuals is about 1 in 300.[5] Asymptomatic retinal breaks are present in about 6% of eyes in both clinical and autopsy studies.[34][*needs update*]

- Retinal detachment is more common in people with severe myopia (above 5–6 diopters), in whom the retina is more thinly stretched. In such patients, lifetime risk rises to 1 in 20.[35][*not in citation given*] About two-thirds of cases of retinal detachment occur in myopics. Myopic retinal detachment patients tend to be younger than non-myopic ones.
- Retinal detachment is more frequent after surgery for cataracts. The estimated long-term prevalence of retinal detachment after cataract surgery is in the range of 5 to 16 per 1000 cataract operations,[36] but is much higher in patients who are highly myopic, with a prevalence of up to 7% being reported in one study.[37] One study found that the probability of experiencing retinal detachment within 10 years of cataract surgery may be about 5 times higher than in the absence of treatment.[38]
- Tractional retinal detachments can also occur in patients with proliferative diabetic retinopathy[39] or those with proliferative retinopathy of sickle cell disease.[40] In proliferative retinopathy, abnormal blood vessels (neovascularization) grow within the retina and extend into the vitreous. In advanced disease, the vessels can pull the retina away from the back wall of the eye, leading to tractional retinal detachment.

Although retinal detachment usually occurs in just one eye, there is a 15% chance of it developing in the

other eye, and this risk increases to 25–30% in patients who have had a retinal detachment and cataracts extracted from both eyes.[35]

# Sjögren's syndrome

From Wikipedia, the free encyclopedia

*Not to be confused with Sjögren–Larsson syndrome, a skin disorder.*

**Sjögren's syndrome** (**SS**) is a long-term autoimmune disease in which the moisture-producing glands of the body are affected.[2] This results primarily in the development of a dry mouth and dry eyes.[3] Other symptoms can include dry skin, a chronic cough, vaginal dryness, numbness in the arms and legs, feeling tired, muscle and joint pains, and thyroid problems.[2] Those affected are at an increased risk (5%) of lymphoma.[3][4]

While the exact cause is unclear it is believed to involve a combination of genetics and an environmental trigger such as exposure to a virus or bacteria.[2] It can occur independently of other health problems (primary Sjögren's syndrome) or as a result of another connective tissue disorder (secondary Sjögren's syndrome).[5] The inflammation that results progressively damages the glands.[4] Diagnosis is by biopsy of moisture-producing glands and blood tests looking for specific antibodies.[3] On biopsy there is typically lymphocyte within the glands.[3]

Treatment is directed at the person's symptoms. For dry eyes artificial tears, medications to reduce inflammation, or surgery to shut the tear ducts, may be tried. For a dry mouth, chewing gum, sipping water, or a saliva substitute may be used. In those with joint or muscle pain, ibuprofen may be used. Medications that can cause dryness may also be stopped such as antihistamines.[2]

The disease was described in 1933 by Henrik Sjögren after whom it is named; however, a number of earlier descriptions of people with the symptoms exist.[5] Between 0.2% and 1.2% of the population are affected, with half having the primary form and half the secondary form.[4] Females are affected about ten times as often as males and it commonly begins in middle age;[3][5] however, anyone can be affected.[3] Among those without other autoimmune disorders, life expectancy is unchanged.[6]

## Signs and symptoms [edit]

The hallmark symptom of SS is a generalized dryness, typically including dry mouth and keratoconjunctivitis sicca (dry eyes), part of what are known as sicca symptoms. Sicca syndrome also incorporates vaginal dryness and chronic bronchitis. SS may cause skin, nose, and vaginal dryness, and may affect other organs of the body, including the muscles (myositis), kidneys, blood vessels, lungs, liver, biliary system, pancreas, peripheral nervous system (distal axonal sensorimotor neuropathy or small fiber peripheral neuropathy) and brain. Some patients have gastric issues such as GERD, achlorhydria and/or gastroparesis, and chronic pain with accompanying fatigue and brain fog.

Skin dryness in some people with SS may be the result of lymphocytic infiltration into skin glands. The symptoms may develop insidiously, with the diagnosis often not considered for several years, because the complaints of sicca may be otherwise attributed to medications, a dry environment, aging, or may be regarded as not of severity warranting the level of investigation necessary to establish the presence of the specific underlying autoimmune disorder condition.[7]

SS can damage vital organs of the body with symptoms that may plateau or worsen, or go into remission as with other autoimmune diseases. Some people may experience only the mild symptoms of dry eyes and mouth, while others have symptoms of severe disease. Many patients can treat problems symptomatically. Others are forced to cope with blurred vision, constant eye discomfort, recurrent mouth infections, swollen parotid glands, dysphonia (vocal disorders including hoarseness), and difficulty in swallowing and eating. Debilitating fatigue and joint pain can seriously impair quality of life. Some patients can develop renal involvement (autoimmune tubulointerstitial nephritis) leading to proteinuria (excess protein in urine), urinary concentrating defect, and distal renal tubular acidosis.

### Associated conditions [edit]

SS is associated with a number of other medical conditions, many of which are autoimmune or rheumatic disorders, such as celiac disease,[8][9] fibromyalgia, autoimmune thyroiditis, multiple sclerosis and spondyloarthropathy,[10] and several malignancies, principally non-Hodgkin lymphoma.[10][11]

## Cause [edit]

Although the cause of SS is unknown, it is believed to be under the influence of a combination of genetic, environmental, and several other factors, as is the case with many other autoimmune disorders.[12]

### Genetic factors [edit]

The observation of high rates of autoimmune disorders in families of SS is linked with a genetic predisposition to the syndrome.[13] Studies on the polymorphisms of human leukocyte antigen (HLA)-DR and HLA-DQ gene regions in SS patients show differential susceptibility to the syndrome due to different types of the resulting autoantibody production.[13]

### Hormonal factors [edit]

Since SS is associated with a high prevalence in women, sex hormones, especially estrogen, are believed to affect humoral and cell-mediated immune responses affecting susceptibility to the syndrome.[13] Androgens are generally considered to prevent autoimmunity.[14] Studies on mice models suggest estrogen deficiency stimulates presentation of autoantigens, inducing SS-like symptoms.[13]

### Microchimerism factors [edit]

Microchimerism of fetal cells (offspring lymphoid cells in maternal circulation) may generate autoimmunity in women who have been previously pregnant.[14][15] Generation of an autoimmune potential via microchimerism may lead to a switch from a silent form of autoimmunity with age-dependent decrease in self-tolerance.[14]

### Environmental factors [edit]

Viral proteins, engulfed molecules, or degraded self-structures may initiate autoimmunity by molecular mimicry and increase the chances of SS development.[14] Epstein-Barr virus, hepatitis C, and human T-cell leukemia virus-1 are among the most studied infectious agents in SS.[14] Damaged self-structures targeted for apoptosis may be mistakenly exposed to the immune system, triggering autoimmunity in exocrine glands which are often prone to autoimmune responses.[14]

## Pathogenesis [edit]

The pathogenetic mechanisms of SS have not been fully elucidated, resulting in the lack of pathophysiology knowledge of the management of this autoimmune exocrinopathy. Although the numerous factors contributing to the progression of this disease have made it difficult to find out the exact origin and cause, major advances over the past decade have contributed to a proposed set of pathogenic events that occur prior to the diagnosis of SS.[16]

SS was originally proposed to be a specific, self-perpetuating immune system-mediated loss of exocrine glands, specifically acinar and ductal cells. Although this explains the more obvious symptoms (e.g., the lack of salivary and lacrimal fluid), it does not explain the more widespread systemic effects seen in the progression of the disease.

In the presence of a susceptible genetic background, both environmental and hormonal factors are thought to be capable of triggering the infiltration of lymphocytes, specifically CD4+ T cells, B cells, and plasma cells, causing glandular dysfunction in the salivary and lacrimal glands.[16]

SS is associated with increased levels in cerebrospinal fluid (CSF) of IL-1RA, an interleukin 1 antagonist. This suggests that the disease begins with increased activity in the interleukin 1 system, followed by an autoregulatory up-regulation of IL-1RA to reduce the successful binding of interleukin 1 to its receptors. Interleukin 1 likely is the marker for fatigue, but increased IL-1RA is observed in the CSF and is associated with increased fatigue through cytokine-induced sickness behavior.[17] SS, though, is characterized by decreased levels of IL-1ra in saliva, which could be responsible for mouth inflammation and dryness.[18] Patients with secondary SS also often exhibit signs and symptoms of their primary rheumatic disorders, such as systemic lupus erythematosus, rheumatoid arthritis, or systemic sclerosis.

### Genetic predisposition [edit]

The genetic locus most significantly associated with primary SS is the major histocompatibility complex/human leukocyte antigen (MHC/HLA) region, as demonstrated by the preliminary results of the first genome-wide

association study (GWAS).[19] This GWAS included data from a discovery cohort of 395 patients of European ancestry with primary SS, and 1,975 healthy control individuals, and from a replication study that comprised 1,234 cases and 4,779 healthy controls. Associations with polymorphisms located at six independent loci were also detected; *IRF5, STAT4, BLK, IL12A, TNIP1,* and *CXCR5*. This also suggested the activation of the innate immune system, notably through the IFN system, B-cell activation through *CXCR5*-directed recruitment to lymphoid follicles and B-cell receptor (BCR) activation involving *BLK*, and T-cell activation owing to HLA susceptibility and the IL-12-IFN-γ-axis.[20]

Patients of different ethnic origin carry different HLA susceptibility alleles, of which, HLA-DR and HLA-DQ are involved in the pathogenesis of SS. For example, patients from Northern and Western Europe and from North America show a high prevalence of *B8, DRw52,* and *DR3* genes.[21] HLA class II alleles are associated with the presence of specific subsets of autoantibodies, rather than with the disease itself.[22] Autoantibodies refer to the loss of B-cell tolerance leading to production of antibodies directed against diverse organ-specific and organ nonspecific antigens.[16] Association between HLA and SS is restricted to patients with anti-SSA/Ro or anti-SSB/La antibodies. Seropositivity for anti-Ro and anti-La is associated with greater severity and longer duration of disease, and findings of their high abundance from the salivary glands of SS patients suggests their imperative role in the pathogenesis of SS.[23]

Beyond genetics, epigenetic abnormality related to DNA methylation, histone acetylation, or microRNA expression probably have key roles in the pathogenesis of autoimmune diseases, including SS, though research in this area is very limited and minimal.[24]

## Environmental triggers [edit]

Environmental factors, such as glandular viral infection, could prompt epithelial cells to activate the HLA-independent innate immune system through toll-like receptors.[25] Although a number of infectious, exogenous agents have been implicated in the pathogenesis of SS, such as Epstein-Barr virus (EBV), human T-lymphotropic virus 1, and hepatitis C virus, their association with appears weak. While EBV is present in the salivary glands of normal individuals, a high incidence of EBV reactivation in SS patients has been reported with increased levels of EBV DNA. This indicates viral reactivation and inability of lymphoid infiltrates to control EBV replication in SS, leading to the initiation or perpetuation of an immune response in target organs. Nonetheless, it remains to be clarified exactly how reactivation of EBV is induced in lesions of patients with SS, and which specific molecular mechanisms are involved in the process of viral reactivation.[26]

## Inflammation [edit]

Epithelial cells in SS lesions are active participants in the induction and perpetuation of the inflammatory process. Environmental and hormonal factors, in concert with an appropriate genetic background, are believed to trigger SS, which dysregulates epithelial cells and allows aberrant homing and activation of dendritic cells (DCs), T cells, and B cells.[27] Dendritic cells are antigen-presenting cells which process antigen material and present it to other T cells. Following the migration of lymphocytes into the glands in response to chemokines and specific adhesion molecules, T cells interact with epithelial cells. Epithelial cells are further activated by proinflammatory cytokines (IL-1β, IFN-γ, and TNF), which are produced by adjacent T cells. The early accumulation of plasmacytoid dendritic cells in the target tissues, which produce high levels of type 1 IFNs, seems to be important, as these cells can further dysregulate the immune response through abnormal retention of lymphocytes in the tissues and their subsequent activation. IFN-α stimulates the production of B-cell activating factor (BAFF) by epithelial cells, DCs, and T cells. BAFF stimulates aberrant B-cell maturation, leading to the emergence of self-reactive B cells, which locally produce autoantibodies, in a germinal centre-like structure (GC-like), which is also the location of lymphomagenesis (origin of lymphoma).[16]

## Programmed cell death [edit]

Dysregulation of apoptosis (programmed cell death) is believed to play a role in the pathogenesis of a variety of autoimmune diseases, though its role in SS is controversial. Both the Fas and Fas ligand proteins are overexpressed in primary SS patients, while expression of BCL-1, which is known to downregulate apoptosis, was found to be significantly reduced in acinar and ductal epithelial cells of SS patients compared to healthy people.[28][29] *In situ* studies did not show increased apoptosis among glandular epithelial cells, but did show reduced apoptosis among infiltrating mononuclear cells. Reduced apoptosis was also implicated in the

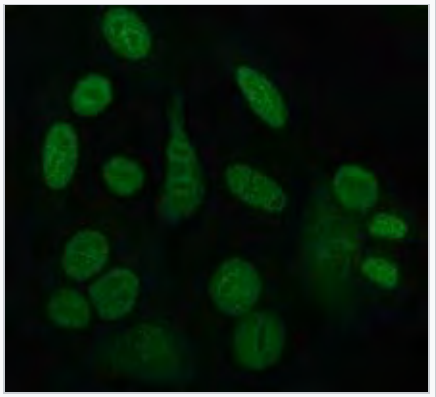
accumulation of autoreactive B-cells found in the glands. The relationship of autoantibodies expressed in SS with apoptosis is still being researched.[12]

### Hormonal factors [edit]

Sex hormones seem to influence humoral and cell-mediated immune response, with estrogen being considered one of the biggest factors responsible for sex-immunologic dimorphism.[30] Estrogen deficiency appears to play a role in development of SS.[31] It has been hypothesized that androgen administration to the ocular surface may serve as an effective therapy for dry eyes.[32]

## Diagnosis [edit]

Diagnosing SS is complicated by the range of symptoms a patient may manifest, and the similarity between symptoms of SS and those of other conditions. Also, patients who have symptoms of SS approach different specialities regarding their symptoms which make the diagnosis difficult. Since the symptoms of this autoimmune disorder such as dry eyes and dry mouth are very common among people, and mostly observed from the age of 40 and above, it is often mistaken as age-related, thus ignored. However, some medications can also cause symptoms that are similar to those of SS. The combination of several tests, which can be done in a series, can eventually lead to the diagnosis of SS.[15][33]



Speckled Immunofluorescence staining pattern of antinuclear antibodies on HEp-20-10 cells

SS is usually classified as either 'primary' or 'secondary'. Primary Sjögren's syndrome occurs by itself and secondary Sjögren's syndrome occurs when another connective tissue disease is present.

Blood tests can be done to determine if a patient has high levels of antibodies that are indicative of the condition, such as antinuclear antibody (ANA) and rheumatoid factor (because SS frequently occurs secondary to rheumatoid arthritis), which are associated with autoimmune diseases. Typical SS ANA patterns are SSA/Ro and SSB/La, of which SSB/La is far more specific; SSA/Ro is associated with numerous other autoimmune conditions, but are often present in SS. However, SSA and SSB tests are frequently not positive in SS.

The rose bengal test uses a stain that measures state and function of the lacrimal glands. This test involves placing the non-toxic dye rose bengal on the eyes. The dye's distinctive colour helps in determining the state and functioning of tear film and the rate of tear evaporation. Any distinctive colour change observed will be indicative of SS, but many related diagnostic tools will be used to confirm the condition of SS.[33]

Schirmer's test measures the production of tears: a strip of filter paper is held inside the lower eyelid for five minutes, and its wetness is then measured with a ruler. Producing less than 5 mm (0.20 in) of liquid is usually indicative of SS. This measurement analysis varies among people depending on other eye-related conditions and medications in use when the test is taken.[33] A slit-lamp examination can reveal dryness on the surface of the eye.

Symptoms of dry mouth and dryness in the oral cavity are caused by the reduced production of saliva from the salivary glands (parotid gland, submandibular gland, and sublingual gland). To check the status of salivary glands and the production of saliva, a salivary flow-rate test is performed, in which the person is asked to spit as much as they can into a cup, and the resulting saliva sample is collected and weighed. This test's results can determine whether the salivary glands are functioning adequately. Not enough saliva produced could mean the person has SS.[33] An alternative test is non-stimulated whole saliva flow collection, in which the person spits into a test tube every minute for 15 minutes. A resultant collection of less than 1.5 ml (0.053 imp fl oz; 0.051 US fl oz) is considered a positive result.[34]

A lip/salivary gland biopsy takes a tissue sample that can reveal lymphocytes clustered around salivary glands, and damage to these glands due to inflammation. This test involves removing a sample of tissue from a person's inner lip/salivary gland and examining it under a microscope. In addition, a sialogram, a special X-ray test, is performed to see if any blockage is present in the salivary gland ducts (i.e. parotid duct) and the amount of saliva that flows into the mouth.[33]

Also, a radiological procedure is available as a reliable and accurate test for SS. A contrast agent is injected into the parotid duct, which opens from the cheek into the vestibule of the mouth opposite the neck of the upper second molar tooth. Histopathology studies should show focal lymphocytic sialadenitis. Objective evidence of salivary gland involvement is tested through ultrasound examinations, the level of unstimulated whole salivary flow, a parotid sialography or salivary scintigraphy, and autoantibodies against Ro (SSA) and/or La (SSB) antigens.

SS can be excluded from people with past head and neck radiation therapy, acquired immunodeficiency syndrome, pre-existing lymphoma, sarcoidosis, graft-versus-host disease, and use of anticholinergic drugs.

## Prevention [edit]

There is no prevention mechanism for SS due to its complexity as an autoimmune disorder. However, lifestyle changes can reduce the risk factors of getting SS or reduce the severity of the condition with patients who have already been diagnosed. Diet is strongly associated with inflammation that is mostly seen in many autoimmune related diseases including SS. An experimental study show that SS patients show high sensitivity to gluten that directly relates to inflammation.[35] Moderate exercise is also found to be helpful in SS patients mainly reducing the effect of lung inflammation.[36]

## Treatment [edit]

Neither a cure for SS nor a specific treatment is known to permanently restore gland secretion. Instead, treatment is generally symptomatic and supportive.

### Eye care [edit]

Moisture replacement therapies such as artificial tears may ease the symptoms of dry eyes. Some patients with more severe problems use goggles to increase local humidity or have punctal plugs inserted to help retain tears on the ocular surface for a longer time.

Additionally, cyclosporine (Restasis) is available by prescription to help treat chronic dry eye by suppressing the inflammation that disrupts tear secretion. Prescription drugs are also available that help to stimulate salivary flow, such as cevimeline (Evoxac) and pilocarpine. Salagen, a manufactured form of pilocarpine, can be used to help produce tears, as well as saliva in the mouth and intestines. It is derived from the jaborandi plant.

### Vaginal dryness [edit]

In women with SS, vaginal dryness, vulvodynia and dyspareunia (painful sexual intercourse) are often reported; personal lubricants are recommended to help lessen irritation or pain that may result from dryness in the vaginal and vulvar areas.[33]

### Musculoskeletal [edit]

Nonsteroidal anti-inflammatory drugs (NSAIDs) may be used to treat musculoskeletal symptoms. For individuals with severe complications, corticosteroids or immunosuppressive drugs may be prescribed, and sometimes IVIG (intravenous immunoglobulin). Also, disease-modifying antirheumatic drugs (DMARDs) such as methotrexate may be helpful. Hydroxychloroquine (Plaquenil) is another option and is generally considered safer than methotrexate. However, these prescribed drugs have a range of side effects such as nausea, loss of appetite, dizziness, hair loss, stomach aches/cramps, headache, liver toxicity, and increased risk of infections. Also, people who take drugs to suppress the immune system are more likely to develop cancer later.[33]

### Systemic [edit]

For systemic symptoms, including fatigue, joint pain, myositis and neuropathy, biologic immunosuppressant drugs such as Rituxan and Benlysta that work via B-cell pathology are often used and have less toxic profiles than traditional immunosuppressive regimens.

### Dental care [edit]

Preventive dental treatment is also necessary (and often overlooked by the patient), as the lack of saliva associated with xerostomia creates an ideal environment for the proliferation of bacteria that cause cavities.[37] Treatments include at-home topical fluoride application to strengthen tooth enamel and frequent teeth cleanings by a dental hygienist. Existing cavities must also be treated, as cavities that extend into the tooth can not be effectively treated through teeth cleaning alone, and are at a high risk of spreading into the pulp of the tooth, leading to the loss of vitality and need for extraction or root canal therapy. This treatment regimen is the same as that used for all xerostomia patients, such as those undergoing head and neck radiation therapy which often damages the salivary glands, as they are more susceptible to radiation than other body tissues.

Unfortunately, many patients, not realizing the need for dental treatment, do not see a dentist until most of their teeth are beyond the point of restoration. It is not uncommon for a dentist to see a xerostomia patient with severe, untreatable cavities in almost every tooth. In severe cases, the only viable treatment may be to extract all of the patient's teeth and treat with prosthetics such as dentures or implants.

## Prognosis [edit]

Published studies on the survival of SS patients are limited in varied respects, perhaps owing to the relatively small sample sizes, and secondary SS is associated with other autoimmune diseases. However, results from a number of studies indicated, compared to other autoimmune diseases, SS is associated with a notably high incidence of malignant non-Hodgkin lymphoma (NHL).[16] NHL is the cancer derived from white blood cells. About 5% of patients with SS will develop some form of lymphoid malignancy.[38] Patients with severe cases are much more likely to develop lymphomas than patients with mild or moderate cases.[39] The most common lymphomas are salivary extranodal marginal zone B cell lymphomas (MALT lymphomas in the salivary glands)[40] and diffuse large B-cell lymphoma.[39]

Lymphomagenesis in primary SS patients is considered as a multistep process, with the first step being chronic stimulation of autoimmune B cells, especially B cells that produce rheumatoid factor at sites targeted by the disease.[41][42] This increases the frequency of oncogenic mutation, leading to any dysfunction at checkpoints of autoimmune B-cell activation to transform into malignancy. A study's finding has concluded the continuous stimulation of autoimmune B cells, leading to subtle germinal abnormalities in genes having specific consequences in B cells, which underlies the susceptibility to lymphoma.[43]

Apart from this notably higher incidence of malignant NHL, SS patients show only modest or clinically insignificant deterioration in specific organ-related function, which explains the only slight increases in mortality rates of SS patients in comparison with the remainder of the population.[16]

## Complications [edit]

Among the complications discussed above, women with anti-Ro/SSA and anti-La/SSA antibodies who become pregnant, have an increased rate of neonatal lupus erythematosus with congenital heart block requiring a pacemaker.[44] Type I cryoglobulinemia is a known complication of SS.[45]

## Epidemiology [edit]

SS is the third most common rheumatic autoimmune disorder, behind rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE).[46] There are no geographical differences in the rates of SS.[47] SS has been reported in all areas of the world, although regional rates have not been well studied.[47][48] Depending on the criteria for determining prevalence, studies estimate the prevalence of SS at 500,000 to 2 million people in the United States. Moreover, other broader studies of prevalence of SS range widely with some reports of up to a prevalence of 3% of the population.[46] A few studies that have been conducted on the incidence of SS report that the incidence of the syndrome varies between 3 and 6 per 100,000 per year.[46][49]

Nine out of ten SS patients are reported to be women.[12][48] In addition to prevalence in women, having a first-degree relative with an autoimmune disease and previous pregnancies have been identified as

epidemiological risk factors.[50] Differences in prevalence due to race and ethnicity are unknown.

Although SS occurs in all age groups, the average age of onset is between ages 40 and 60, although experts note that up to half of all cases may be left undiagnosed or unreported.[12][46][51][52] The prevalence of SS generally increases with age.[46]

SS has been known to be reported in 30-50% of people with rheumatoid arthritis, as well as 10-25% with systemic lupus erythematosus.[12]

## History [edit]

Henrik Samuel Conrad Sjögren

Johann von Mikulicz-Radecki (1850–1905) is generally credited with the first description of SS. In 1892, he described a 42-year-old man with enlargement of the parotid and lacrimal glands associated with a round-cell infiltrate and acinar atrophy.[33][53] However, the criteria Mikulicz established for diagnosis, often led to misdiagnosis of Mikulicz's syndrome. Many conditions, such as tuberculosis, infections, sarcoidosis, and lymphoma present with similar conditions to those listed under Mikulicz's syndrome.[33] Nevertheless, the term "Mikulicz's syndrome" is still used occasionally to describe the appearance of lymphocytic infiltrates on salivary-gland biopsies.[33]

In 1930, Henrik Sjögren (1899–1986), an ophthalmologist in Jönköping, Sweden, observed a patient with low secretions from the lacrimal and salivary glands.[54] Sjögren introduced the term keratoconjunctivitis sicca for the symptom of dry eyes (keratoconjunctivitis). In 1933, he published his doctoral thesis, describing 19 females, most of whom were postmenopausal and had arthritis, showing clinical and pathological manifestations of the syndrome.[53] Sjögren clarifies that keratoconjunctivitis sicca, resulting from water deficiency, had no relation to xerophthalmia, resulting from vitamin A deficiency.[53] Sjögren's thesis was not well received as the Board of Examiners criticized some clinical aspects.[54]

After extensive research and data collection, Sjögren published an essential paper in 1951, describing 80 patients with keratoconjunctivitis sicca, 50 of whom also had arthritis.[54] His subsequent follow-up conference trips pertaining to his paper led to an international interest in SS.[54] The term *keratoconjunctivitis sicca* was coined by Sjögren himself began to be identified as SS in literature,[54] although it can now have more general usage.

## Research [edit]

Research on multifactorial autoimmune diseases such as SS focuses on expanding the knowledge surrounding the disorder, improving diagnostic tools and finding ways to prevent, manage, and cure the disorder. The United Kingdom Primary Sjögren's Syndrome Registry, a tissue biobank of samples taken for research, supported by the Medical Research Council, UK was established in 2010.[55]

As an autoimmune disease, susceptibility to SS is greatly influenced by the human leukocyte antigen.[56] DQA1*05:01, DQB1*02:01, and DRB1*03:01 alleles were identified as risk factors, while DQA1*02:01, DQA1*03:01 and DQB1*05:01 alleles were found to be protective factors for the disease.[57] The relationship between alleles and specific race was also established.[58] HLA-DQ2 and HLA-B8 are generally found in Caucasian patients, while HLA-DR5 is related to Greek and Israeli patients.[58] Multiple genome-wide association scans may be conducted in the future to identify key risk variants.[56]

Viruses that can trigger the immune response of the syndrome include

Singer-actress Carrie Ann Inaba is the National Awareness Ambassador and Spokesperson for the Sjogren's Syndrome Foundation.

human T-lymphotropic virus type 1 (HTLV-1), Epstein-Barr virus (EBV), human immunodeficiency virus (HIV) and hepatitis C virus (HCV).[58] The UK Primary Sjögren's Syndrome Registry supports clinical trials and genetic studies of SS and is open to patients wishing to participate in research studies and researchers studying the disease.[55]

Some research showed that the lack of vitamin A and vitamin D are associated with this disease.[58] Vitamin D deficiency was found to be related to neurological manifestations and the presence of lymphoma among patients. On the other hand, vitamin A levels were inversely associated with extra-glandular manifestations of the disease.[58]

Saliva is a potential diagnostic tool of SS because the salivary component is changed after onset of the disease.[59] With the new miniaturization technology, called 'lab on a chip', the diagnosis can be more convenient.[59]

With regard to therapeutics, multiple monoclonal antibodies were under investigation in 2007.[60] The most promising seemed to be the anti-CD20 rituximab and the anti-CD22 epratuzumab, while the anti-TNF-α and IFN-α seemed less effective.[60]

In 2014, the Sjögren's Syndrome Foundation announced a five-year goal to cut the time to diagnoses in half.[61]

## Notable cases [edit]

- Shannon Boxx (U.S. Olympic soccer player) has both SS and lupus.[62]
- Carrie Ann Inaba (singer-actress) is the National Awareness Ambassador & Spokesperson for the Sjogren Syndrome Foundation.[63]
- Venus Williams (world champion tennis player) has been diagnosed with SS and said she had struggled with fatigue for years.[64]

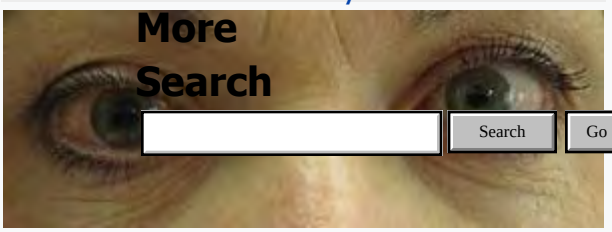
# Glaucoma

From Wikipedia, the free encyclopedia

**Glaucoma** is a group of eye diseases which result in damage to the optic nerve and vision loss.[1] The most common type is open-angle glaucoma with less common types including closed-angle glaucoma and normal-tension glaucoma. Open-angle glaucoma develops slowly over time and there is no pain. Side vision may begin to decrease followed by central vision resulting in blindness if not treated.[1] Closed-angle glaucoma can present gradually or suddenly.[2] The sudden presentation may involve severe eye pain, blurred vision, mid-dilated pupil, redness of the eye, and nausea.[1][2] Vision loss from glaucoma, once it has occurred, is permanent.[1]

Risk factors for glaucoma include increased pressure in the eye, a family history of the condition, migraines, high blood pressure, and obesity.[1] For eye pressures a value of greater than 21 mmHg or 2.8 kPa is often used with higher pressures leading to a greater risk.[2][3] However, some may have high eye pressure for years and never develop damage.[2] Conversely, optic nerve damage may occur with normal pressure, known as normal-tension glaucoma.[4] The mechanism of open-angle glaucoma is believed to be slow exit of aqueous humor through the trabecular meshwork while in closed-angle glaucoma the iris blocks the trabecular meshwork.[2] Diagnosis is by a dilated eye examination.[1] Often the optic nerve shows an abnormal amount of cupping.[2]

**Glaucoma**



Acute angle closure glaucoma of the right eye. Note the mid-sized pupil, which was nonreactive to light, and redness of the whites of the eyes.

[edit on Wikidata]

If treated early it is possible to slow or stop the progression of disease with medication, laser treatment, or surgery.[1] The goal of these treatments is to decrease eye pressure. A number of different classes of glaucoma medication are available. Laser treatments may be effective in both open-angle and closed-angle glaucoma. A number of types of glaucoma surgeries may be used in people who do not respond sufficiently to other measures.[2] Treatment of closed-angle glaucoma is a medical emergency.[1]

About 11 to 67 million people have glaucoma globally.[2][5] The disease affects about 2 million people in the United States.[2] It occurs more commonly among older people.[1] Closed-angle glaucoma is more common in women.[2] Glaucoma has been called the "silent thief of sight" because the loss of vision usually occurs slowly over a long period of time.[6] Worldwide, glaucoma is the second-leading cause of blindness after cataracts.[2][7] The word "glaucoma" is from ancient Greek *glaukos* which means blue, green, or gray.[8] In English, the word was used as early as 1587 but did not become commonly used until after 1850, when the development of the ophthalmoscope allowed people to see the optic nerve damage.[9]

Video explanation

## Signs and symptoms [edit]

Open-angle glaucoma is painless and does not have acute attacks, thus the lack of clear symptoms make screening via regular eye check-ups important. The only signs are gradually progressive visual field loss, and optic nerve changes (increased cup-to-disc ratio on fundoscopic examination).

About 10% of people with closed angles present with acute angle closure characterized by sudden ocular pain, seeing halos around lights, red eye, very high intraocular pressure (>30 mmHg), nausea and vomiting, suddenly decreased vision, and a fixed, mid-dilated pupil. It is also associated with an oval pupil in some cases. Acute angle closure is an emergency.

Photo showing conjunctival vessels dilated at the corneal edge (ciliary flush, circumcorneal flush) and hazy cornea characteristic of acute angle closure glaucoma

## Causes [edit]

Of the several causes for glaucoma, ocular hypertension (increased pressure within the eye) is the most important risk factor in most glaucomas, but in some populations, only 50% of people with primary open-angle glaucoma actually have elevated ocular pressure.[10]

Open-angle glaucoma accounts for 90% of glaucoma cases in the United States. Closed-angle glaucoma accounts for less than 10% of glaucoma cases in the United States, but as many as half of glaucoma cases in other nations (particularly East Asian countries).

A normal range of vision

The same view with advanced vision loss from glaucoma

## Dietary [edit]

No clear evidence indicates vitamin deficiencies cause glaucoma in humans. It follows, then, that oral vitamin supplementation is not a recommended treatment for glaucoma.[11] Caffeine increases intraocular pressure in those with glaucoma, but does not appear to affect normal individuals.[12]

## Ethnicity [edit]

Many people of East Asian descent are prone to developing angle closure glaucoma due to shallower anterior chamber depths, with the majority of cases of glaucoma in this population consisting of some form of angle closure.[13] Higher rates of glaucoma have also been reported for Eskimo populations, compared to white populations, in Canada and Greenland.[14]

## Genetics [edit]

Positive family history is a risk factor for glaucoma. The relative risk of having primary open-angle glaucoma (P.O.A.G.) is increased about two- to four-fold for people who have a sibling with glaucoma.[15] Glaucoma, particularly primary open-angle glaucoma, is associated with mutations in several genes, including *MYOC*, *ASB10*, *WDR36*, *NTF4*, and *TBK1*,[16] although most cases of glaucoma do not involve these genetic mutations. Normal-tension glaucoma, which comprises one-third of POAG, is also associated with genetic mutations (including *OPA1* and *OPTN* genes).[17]

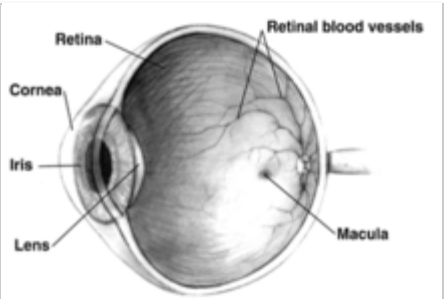
Various rare congenital/genetic eye malformations are associated with glaucoma. Occasionally, failure of the normal third-trimester gestational atrophy of the hyaloid canal and the tunica vasculosa lentis is associated with other anomalies. Angle closure-induced ocular hypertension and glaucomatous optic neuropathy may also occur with these anomalies,[18][19][20] and has been modelled in mice.[21]

## Other [edit]

Other factors can cause glaucoma, known as "secondary glaucoma", including prolonged use of steroids (steroid-induced glaucoma); conditions that severely restrict blood flow to the eye, such as severe diabetic retinopathy and central retinal vein occlusion (neovascular glaucoma); ocular trauma (angle-recession glaucoma); and inflammation of the middle layer of the pigmented vascular eye structure (uveitis), known as uveitic glaucoma.

# Pathophysiology [edit]

The underlying cause of open-angle glaucoma remains unclear. Several theories exist on its exact etiology. However, the major risk factor for most glaucomas and the focus of treatment is increased intraocular pressure. Intraocular pressure is a function of production of liquid aqueous humor by the ciliary processes of the eye, and its drainage through the trabecular meshwork. Aqueous humor flows from the ciliary processes into the posterior chamber, bounded posteriorly by the lens



Human eye cross-sectional view

and the zonules of Zinn, and anteriorly by the iris. It then flows through the pupil of the iris into the anterior chamber, bounded posteriorly by the iris and anteriorly by the cornea. From here, the trabecular meshwork drains aqueous humor via Schlemm's canal into scleral plexuses and general blood circulation.[22]

In open/wide-angle glaucoma, flow is reduced through the trabecular meshwork, due to the degeneration and obstruction of the trabecular meshwork, whose original function is to absorb the aqueous humor. Loss of aqueous humor absorption leads to increased resistance and thus a chronic, painless buildup of pressure in the eye.[23]

In close/narrow-angle, the iridocorneal angle is completely closed because of forward displacement of the final roll and root of the iris against the cornea, resulting in the inability of the aqueous fluid to flow from the posterior to the anterior chamber and then out of the trabecular network. This accumulation of aqueous humor causes an acute increase in pressure and pain.

The inconsistent relationship of glaucomatous optic neuropathy with increased intraocular pressure has provoked hypotheses and studies on anatomic structure, eye development, nerve compression trauma, optic nerve blood flow, excitatory neurotransmitter, trophic factor, retinal ganglion cell/axon degeneration, glial support cell, immune system, aging mechanisms of neuron loss, and severing of the nerve fibers at the scleral edge.[24][25][26][27][28][29][30][31][32][33][34][35]

## Diagnosis [edit]

Screening for glaucoma is usually performed as part of a standard eye examination performed by optometrists and ophthalmologists. Testing for glaucoma should include measurements of the intraocular pressure via tonometry,[36] anterior chamber angle examination or gonioscopy, and examination of the optic nerve to look for any visible damage to it, or change in the cup-to-disc ratio and also rim appearance and vascular change. A formal visual field test should be performed. The retinal nerve fiber layer can be assessed with imaging techniques such as optical coherence tomography, scanning laser polarimetry, and/or scanning laser ophthalmoscopy (Heidelberg retinal tomogram).[37][38][39]

Owing to the sensitivity of all methods of tonometry to corneal thickness, methods such as Goldmann tonometry should be augmented with pachymetry to measure the central corneal thickness (CCT). A thicker-than-average cornea can result in a pressure reading higher than the 'true' pressure whereas a thinner-than-average cornea can produce a pressure reading lower than the 'true' pressure.

Because pressure measurement error can be caused by more than just CCT (i.e., corneal hydration, elastic properties, etc.), it is impossible to 'adjust' pressure measurements based only on CCT measurements. The frequency doubling illusion can also be used to detect glaucoma with the use of a frequency doubling technology perimeter.[40]

Examination for glaucoma also could be assessed with more attention given to sex, race, history of drug use, refraction, inheritance and family history.[37]

**Glaucoma tests**[41][42][43]

| | What test examines | How it is accomplished |
|---|---|---|
| Tonometry | Inner eye pressure | The eye is numbed via eye drops. The examiner then uses a tonometer to measure the inner pressure of the eye through pressure applied by a puff of warm air or a tiny tool. |

| | | |
|---|---|---|
| Ophthalmoscopy (dilated eye examination) | Shape and color of the optic nerve | The pupil is dilated via the application of eye drops. Using a small magnification device with a light on the end, the examiner can examine the magnified optic nerve. |
| Perimetry (visual field test) | Complete field of vision | The patient looks straight ahead and is asked to indicate when light passes the patient's peripheral field of vision. This allows the examiner to map the patient's field of vision. |
| Gonioscopy | Angle in the eye where the iris meets the cornea | Eyedrops are used to numb the eye. A hand-held contact lens with a mirror is placed gently on the eye to allow the examiner to see the angle between the cornea and the iris. |
| Pachymetry | Thickness of the cornea | The examiner places a pachymeter gently on the front of the eye to measure its thickness. |
| Nerve fiber analysis | Thickness of the nerve fiber layer | Using one of several techniques, the nerve fibers are examined. |

Glaucoma has been classified into specific types:[44]

## Primary glaucoma and its variants [edit]

Primary glaucoma (H40.1-H40.2)

- Primary open-angle glaucoma, also known as chronic open-angle glaucoma, chronic simple glaucoma, glaucoma simplex
  - High-tension glaucoma
  - Low-tension glaucoma
- Primary angle closure glaucoma, also known as primary closed-angle glaucoma, narrow-angle glaucoma, pupil-block glaucoma, acute congestive glaucoma
  - Acute angle closure glaucoma (*aka* AACG)[45]
  - Chronic angle closure glaucoma
  - Intermittent angle closure glaucoma
  - Superimposed on chronic open-angle closure glaucoma ("combined mechanism" – uncommon)

Variants of primary glaucoma

- Pigmentary glaucoma
- Exfoliation glaucoma, also known as pseudoexfoliative glaucoma or glaucoma capsulare
- Primary juvenile glaucoma

**Primary angle closure glaucoma** is caused by contact between the iris and trabecular meshwork, which in turn obstructs outflow of the aqueous humor from the eye. This contact between iris and trabecular meshwork (TM) may gradually damage the function of the meshwork until it fails to keep pace with aqueous production, and the pressure rises. In over half of all cases, prolonged contact between iris and TM causes the formation of synechiae (effectively "scars").

These cause permanent obstruction of aqueous outflow. In some cases, pressure may rapidly build up in the eye, causing pain and redness (symptomatic, or so-called "acute" angle closure). In this situation, the vision may become blurred, and halos may be seen around bright lights. Accompanying symptoms may include a headache and vomiting.

Diagnosis is made from physical signs and symptoms: pupils mid-dilated and unresponsive to light, cornea edematous (cloudy), reduced vision, redness, and pain. However, the majority of cases are asymptomatic. Prior to the very severe loss of vision, these cases can only be identified by examination, generally by an eye care professional.

Once any symptoms have been controlled, the first line (and often definitive) treatment is laser iridotomy. This may be performed using either Nd:YAG or argon lasers, or in some cases by conventional incisional surgery. The goal of treatment is to reverse and prevent, contact between the iris and trabecular meshwork. In early to moderately advanced cases, iridotomy is successful in opening the angle in around

75% of cases. In the other 25%, laser iridoplasty, medication (pilocarpine) or incisional surgery may be required.

**Primary open-angle glaucoma** is when optic nerve damage results in a progressive loss of the visual field.[46] This is associated with increased pressure in the eye. Not all people with primary open-angle glaucoma have eye pressure that is elevated beyond normal, but decreasing the eye pressure further has been shown to stop progression even in these cases.

The increased pressure is caused by trabecular blockage. Because the microscopic passageways are blocked, the pressure builds up in the eye and causes imperceptible very gradual vision loss. Peripheral vision is affected first, but eventually the entire vision will be lost if not treated.

Diagnosis is made by looking for cupping of the optic nerve. Prostaglandin agonists work by opening uveoscleral passageways. Beta-blockers, such as timolol, work by decreasing aqueous formation. Carbonic anhydrase inhibitors decrease bicarbonate formation from ciliary processes in the eye, thus decreasing the formation of Aqueous humor. Parasympathetic analogs are drugs that work on the trabecular outflow by opening up the passageway and constricting the pupil. Alpha 2 agonists (brimonidine, apraclonidine) both decrease fluid production (via. inhibition of AC) and increase drainage.

## Developmental glaucoma [edit]

Developmental glaucoma (Q15.0)

- Primary congenital glaucoma
- Infantile glaucoma
- Glaucoma associated with hereditary or familial diseases

## Secondary glaucoma [edit]

Secondary glaucoma (H40.3-H40.6)

- Inflammatory glaucoma
  - Uveitis of all types
  - Fuchs heterochromic iridocyclitis
- Phacogenic glaucoma
  - Angle-closure glaucoma with mature cataract
  - Phacoanaphylactic glaucoma secondary to rupture of lens capsule
  - Phacolytic glaucoma due to phacotoxic meshwork blockage
  - Subluxation of lens
- Glaucoma secondary to intraocular hemorrhage
  - Hyphema
  - Hemolytic glaucoma, also known as erythroclastic glaucoma
- Traumatic glaucoma
  - Angle recession glaucoma: Traumatic recession on anterior chamber angle
  - Postsurgical glaucoma
    - Aphakic pupillary block
    - Ciliary block glaucoma
- Neovascular glaucoma (see below for more details)
- Drug-induced glaucoma
  - Corticosteroid induced glaucoma
  - Alpha-chymotrypsin glaucoma. Postoperative ocular hypertension from use of alpha chymotrypsin.
- Glaucoma of miscellaneous origin
  - Associated with intraocular tumors
  - Associated with retinal detachments
  - Secondary to severe chemical burns of the eye

- Associated with essential iris atrophy
- Toxic glaucoma

**Neovascular glaucoma**, an uncommon type of glaucoma, is difficult or nearly impossible to treat, and is often caused by proliferative diabetic retinopathy (PDR) or central retinal vein occlusion (CRVO). It may also be triggered by other conditions that result in ischemia of the retina or ciliary body. Individuals with poor blood flow to the eye are highly at risk for this condition.

Neovascular glaucoma results when new, abnormal vessels begin developing in the angle of the eye that begin blocking the drainage. Patients with such condition begin to rapidly lose their eyesight. Sometimes, the disease appears very rapidly, especially after cataract surgery procedures. A new treatment for this disease, as first reported by Kahook and colleagues, involves the use of a novel group of medications known as anti-VEGF agents. These injectable medications can lead to a dramatic decrease in new vessel formation and, if injected early enough in the disease process, may lead to normalization of intraocular pressure. Currently, there are no high-quality controlled trials demonstrating a beneficial effect of anti-VEGF treatments in lowering IOP in people with neovascular glaucoma.[47]

**Toxic glaucoma** is open angle glaucoma with an unexplained significant rise of intraocular pressure following unknown pathogenesis. Intraocular pressure can sometimes reach 80 mmHg (11 kPa). It characteristically manifests as ciliary body inflammation and massive trabecular oedema that sometimes extends to Schlemm's canal. This condition is differentiated from malignant glaucoma by the presence of a deep and clear anterior chamber and a lack of aqueous misdirection. Also, the corneal appearance is not as hazy. A reduction in visual acuity can occur followed neuroretinal breakdown.

Associated factors include inflammation, drugs, trauma and intraocular surgery, including cataract surgery and vitrectomy procedures. Gede Pardianto (2005) reported on four patients who had toxic glaucoma. One of them underwent phacoemulsification with small particle nucleus drops. Some cases can be resolved with some medication, vitrectomy procedures or trabeculectomy. Valving procedures can give some relief, but further research is required.[48]

## Absolute glaucoma [edit]

Absolute glaucoma (H44.5) is the end stage of all types of glaucoma. The eye has no vision, absence of pupillary light reflex and pupillary response, and has a stony appearance. Severe pain is present in the eye. The treatment of absolute glaucoma is a destructive procedure like cyclocryoapplication, cyclophotocoagulation, or injection of 99% alcohol.

## Types [edit]

This section **needs additional citations for verification**. Please help improve this article by adding citations to reliable sources. Unsourced material may be challenged and removed. *(August 2015) (Learn how and when to remove this template message)*

Glaucoma is an umbrella term for eye conditions which damage the optic nerve, and which can lead to a loss of vision.[49] The main cause of damage to the optic nerve is intraocular pressure (IOP), excessive fluid pressure within the eye, which can be due to various reasons including blockage of drainage ducts, and narrowing or closure of the angle between the iris and cornea.

The primary division in categorizing different types of glaucoma is open-angle and closed-angle (or angle-closure) glaucoma. The open angle refers to the angle where the iris meets the cornea being as wide and open as it should be, allowing the fluid from inside the eye to drain, thus relieving the internal pressure. Where this angle is narrowed or closed, pressure can build up, and eventually damage the optic nerve leading to loss of vision.

Primary open-angle glaucoma (also, *primary glaucoma*, *chronic glaucoma*) refers to slow clogging of the drainage canals resulting in increased eye pressure which causes progressive optic nerve damage. This manifests as a gradual loss of the visual field, starting with a loss of peripheral vision, but eventually the entire vision will be lost if not treated.[46] This is the most common type of glaucoma, accounting for 90%

of cases in the United States, but fewer in Asian countries. Onset is slow and painless, and loss of vision is gradual and irreversible.

Narrow-angle glaucoma (also *closed-angle glaucoma*) the iris bows forward, narrowing the angle that drains the eye, increasing pressure within the eye. If untreated, it can lead to the medical emergency of angle-closure glaucoma.

In angle-closure glaucoma (also *closed-angle glaucoma*, *primary angle-closure glaucoma*, *acute glaucoma*) the iris bows forward and causes physical contact between the iris and trabecular meshwork, which blocks the outflow of aqueous humor from within the eye. This contact may gradually damage the draining function of the meshwork until it fails to keep pace with aqueous production, and the intraocular pressure rises. The onset of symptoms is sudden and causes pain and other symptoms that are noticeable; it is treated as a medical emergency. Unlike open-angle glaucoma, angle-closure glaucoma is a result of the angle between the iris and cornea closing. This tends to occur in the far-sighted, who have smaller-than-normal anterior chambers, making physical contact between the iris and trabecular meshwork more likely.

Normal-tension glaucoma (also *NTG*, *low-tension glaucoma*, *normal-pressure glaucoma*) is a condition where the optic nerve is damaged although intraocular pressure (IOP) is in the normal range (12-22mm Hg). Individuals with a family history of NTG, those of Japanese ancestry, and those with a history of systemic heart disease are at higher than average risk of developing NTG. The cause of NTG is unknown.

Secondary glaucoma refers to any case in which another disease, trauma, drug or procedure causes increased eye pressure, resulting in optic nerve damage and vision loss, and may be mild or severe. It can be due to an eye injury, inflammation, a tumor, or advanced cases of cataracts or diabetes. It can also be caused by certain drugs such as steroids. Treatment depends on whether it is open-angle or angle-closure glaucoma.

In pseudoexfoliation glaucoma (also, *PEX*, *exfoliation glaucoma*) the pressure is due to the accumulation of microscopic granular protein fibers, which can block normal drainage of the aqueous humor. PEX is prevalent in Scandinavia, primarily in those over 70, and more commonly in women.

Pigmentary glaucoma (also, pigmentary dispersion syndrome) is caused by pigment cells sloughing off from the back of the iris and floating around in the aqueous humor. Over time, these pigment cells can accumulate in the anterior chamber in such a way that it can begin to clog the trabecular meshwork. It is a rare condition that occurs mostly among Caucasians, mostly males in their mid-20s to 40s, and most are nearsighted.

Primary juvenile glaucoma is a neonate or juvenile abnormality where ocular hypertension is evident at birth or shortly thereafter and is caused by abnormalities in the anterior chamber angle development that blocks the outflow of the aqueous humor.

Uveitic Glaucoma is due to uveitis, the swelling and inflammation of the uvea, the middle layer of the eye. The uvea provides most of the blood supply to the retina. Increased eye pressure in uveitis can result from the inflammation itself or from the steroids used to treat it.

## Screening [edit]

The United States Preventive Services Task Force as of 2013 states there is insufficient evidence to recommend for or against screening for glaucoma.[50] Therefore, there is no national screening program in the US. Screening, however, is recommended starting at age 40 by the American Academy of Ophthalmology.[2]

There is a glaucoma screening program in the UK. Those at risk are advised to have a dilated eye examination at least once a year.[51]

## Treatment [edit]

The modern goals of glaucoma management are to avoid glaucomatous damage and nerve damage, and

preserve visual field and total quality of life for patients, with minimal side effects.[52][53] This requires appropriate diagnostic techniques and follow-up examinations, and judicious selection of treatments for the individual patient. Although intraocular pressure is only one of the major risk factors for glaucoma, lowering it via various pharmaceuticals and/or surgical techniques is currently the mainstay of glaucoma treatment.

Vascular flow and neurodegenerative theories of glaucomatous optic neuropathy have prompted studies on various neuroprotective therapeutic strategies, including nutritional compounds, some of which may be regarded by clinicians as safe for use now, while others are on trial.

## Medication [edit]

*Main article: Glaucoma medication*

Latanoprost

Intraocular pressure can be lowered with medication, usually eye drops. Several classes of medications are used to treat glaucoma, with several medications in each class.

Each of these medicines may have local and systemic side effects. Adherence to medication protocol can be confusing and expensive; if side effects occur, the patient must be willing either to tolerate them or to communicate with the treating physician to improve the drug regimen. Initially, glaucoma drops may reasonably be started in either one or in both eyes.[54]

Poor compliance with medications and follow-up visits is a major reason for vision loss in glaucoma patients. A 2003 study of patients in an HMO found half failed to fill their prescriptions the first time, and one-fourth failed to refill their prescriptions a second time.[55] Patient education and communication must be ongoing to sustain successful treatment plans for this lifelong disease with no early symptoms.

The possible neuroprotective effects of various topical and systemic medications are also being investigated.[11][56][57][58]

- Prostaglandin analogs, such as latanoprost, bimatoprost and travoprost, increase uveoscleral outflow of aqueous humor. Bimatoprost also increases trabecular outflow.
- Topical beta-adrenergic receptor antagonists, such as timolol, levobunolol, and betaxolol, decrease aqueous humor production by the epithelium of the ciliary body.
- Alpha2-adrenergic agonists, such as brimonidine and apraclonidine, work by a dual mechanism, decreasing aqueous humor production and increasing uveoscleral outflow.
- Less-selective alpha agonists, such as epinephrine, decrease aqueous humor production through vasoconstriction of ciliary body blood vessels, useful only in open-angle glaucoma. Epinephrine's mydriatic effect, however, renders it unsuitable for closed-angle glaucoma due to further narrowing of the uveoscleral outflow (i.e. further closure of trabecular meshwork, which is responsible for absorption of aqueous humor).
- Miotic agents (parasympathomimetics), such as pilocarpine, work by contraction of the ciliary muscle, opening the trabecular meshwork and allowing increased outflow of the aqueous humour. Echothiophate, an acetylcholinesterase inhibitor, is used in chronic glaucoma.
- Carbonic anhydrase inhibitors, such as dorzolamide, brinzolamide, and acetazolamide, lower secretion of aqueous humor by inhibiting carbonic anhydrase in the ciliary body.

## Laser [edit]

Argon laser trabeculoplasty (ALT) may be used to treat open-angle glaucoma, but this is a temporary solution, not a cure. A 50-μm argon laser spot is aimed at the trabecular meshwork to stimulate the opening of the mesh to allow more outflow of aqueous fluid. Usually, half of the angle is treated at a time. Traditional laser trabeculoplasty uses a thermal argon laser in an argon laser trabeculoplasty procedure.

A newer type of laser trabeculoplasty uses a "cold" (nonthermal) laser to stimulate drainage in the trabecular meshwork. This newer procedure, selective laser trabeculoplasty (SLT), uses a 532-nm, frequency-doubled, Q-switched Nd:YAG laser, which selectively targets melanin pigment in the trabecular

meshwork cells. Studies show SLT is as effective as ALT at lowering eye pressure. In addition, SLT may be repeated three to four times, whereas ALT can usually be repeated only once.

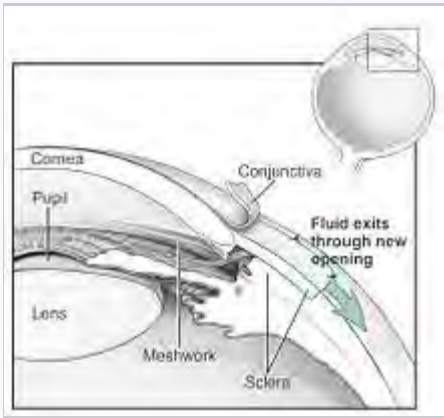
Nd:YAG laser peripheral iridotomy (LPI) may be used in patients susceptible to or affected by angle closure glaucoma or pigment dispersion syndrome. During laser iridotomy, laser energy is used to make a small, full-thickness opening in the iris to equalize the pressure between the front and back of the iris, thus correcting any abnormal bulging of the iris. In people with narrow angles, this can uncover the trabecular meshwork. In some cases of intermittent or short-term angle closure, this may lower the eye pressure. Laser iridotomy reduces the risk of developing an attack of acute angle closure. In most cases, it also reduces the risk of developing chronic angle closure or of adhesions of the iris to the trabecular meshwork.

Diode laser cycloablation lowers IOP by reducing aqueous secretion by destroying secretory ciliary epithelium.[37]

## Surgery [edit]

*Main article: Glaucoma surgery*

Both laser and conventional surgeries are performed to treat glaucoma. Surgery is the primary therapy for those with congenital glaucoma.[59] Generally, these operations are a temporary solution, as there is not yet a cure for glaucoma.



Conventional surgery to treat glaucoma makes a new opening in the trabecular meshwork, which helps fluid to leave the eye and lowers intraocular pressure.

## Canaloplasty [edit]

Canaloplasty is a nonpenetrating procedure using microcatheter technology. To perform a canaloplasty, an incision is made into the eye to gain access to the Schlemm's canal in a similar fashion to a viscocanalostomy. A microcatheter will circumnavigate the canal around the iris, enlarging the main drainage channel and its smaller collector channels through the injection of a sterile, gel-like material called viscoelastic. The catheter is then removed and a suture is placed within the canal and tightened.

By opening the canal, the pressure inside the eye may be relieved, although the reason is unclear, since the canal (of Schlemm) does not have any significant fluid resistance in glaucoma or healthy eyes. Long-term results are not available.[60][61]

## Trabeculectomy [edit]

The most common conventional surgery performed for glaucoma is the trabeculectomy. Here, a partial thickness flap is made in the scleral wall of the eye, and a window opening is made under the flap to remove a portion of the trabecular meshwork. The scleral flap is then sutured loosely back in place to allow fluid to flow out of the eye through this opening, resulting in lowered intraocular pressure and the formation of a bleb or fluid bubble on the surface of the eye.

Scarring can occur around or over the flap opening, causing it to become less effective or lose effectiveness altogether. Traditionally, chemotherapeutic adjuvants, such as mitomycin C (MMC) or 5-fluorouracil (5-FU), are applied with soaked sponges on the wound bed to prevent filtering blebs from scarring by inhibiting fibroblast proliferation. Contemporary alternatives to prevent the scarring of the meshwork opening include the sole or combinative implementation of nonchemotherapeutic adjuvants such as the ologen collagen matrix, which has been clinically shown to increase the success rates of surgical treatment.[62][63][64][65]

Collagen matrix prevents scarring by randomizing and modulating fibroblast proliferation in addition to mechanically preventing wound contraction and adhesion.

## Glaucoma drainage implants [edit]

*Main article: Glaucoma valve*

Professor Anthony Molteno developed the first glaucoma drainage implant, in Cape Town in 1966.[66] Since then, several types of implants have followed on from the original, the Baerveldt tube shunt, or the valved implants, such as the Ahmed glaucoma valve implant or the ExPress Mini Shunt and the later generation pressure ridge Molteno implants. These are indicated for glaucoma patients not responding to maximal medical therapy, with previous failed guarded filtering surgery (trabeculectomy). The flow tube is inserted into the anterior chamber of the eye, and the plate is implanted underneath the conjunctiva to allow a flow of aqueous fluid out of the eye into a chamber called a bleb.

- The first-generation Molteno and other nonvalved implants sometimes require the ligation of the tube until the bleb formed is mildly fibrosed and water-tight.[67] This is done to reduce postoperative hypotony—sudden drops in postoperative intraocular pressure.
- Valved implants, such as the Ahmed glaucoma valve, attempt to control postoperative hypotony by using a mechanical valve.
- Ab interno implants, such as the Xen Gel Stent, are transscleral implants by an ab interno procedure to channel aqueous humor into the non-dissected Tenon's space, creating a subconjunctival drainage area similar to a bleb.[68][69] The implants are transscleral and different from more other ab interno implants that do not create a transscleral drainage, such as iStent, CyPass, or Hydrus.[70]

The ongoing scarring over the conjunctival dissipation segment of the shunt may become too thick for the aqueous humor to filter through. This may require preventive measures using antifibrotic medications, such as 5-fluorouracil or mitomycin-C (during the procedure), or other nonantifibrotic medication methods, such as collagen matrix implant,[71][72] or biodegradable spacer, or later on create a necessity for revision surgery with the sole or combinative use of donor patch grafts or collagen matrix implant.[73][74] And for glaucomatous painful blind eye and some cases of glaucoma, cyclocryotherapy for ciliary body ablation could be considered to be performed.[75]

### Laser-assisted nonpenetrating deep sclerectomy [edit]

The most common surgical approach currently used for the treatment of glaucoma is trabeculectomy, in which the sclera is punctured to alleviate intraocular pressure.

Nonpenetrating deep sclerectomy (NPDS) surgery is a similar, but modified, procedure, in which instead of puncturing the scleral bed and trabecular meshwork under a scleral flap, a second deep scleral flap is created, excised, with further procedures of deroofing the Schlemm's canal, upon which, percolation of liquid from the inner eye is achieved and thus alleviating intraocular pressure, without penetrating the eye. NPDS is demonstrated to cause significantly fewer side effects than trabeculectomy.[*citation needed*] However, NPDS is performed manually and requires higher level of skills that may be assisted with instruments.[*citation needed*] In order to prevent wound adhesion after deep scleral excision and to maintain good filtering results, NPDS as with other non-penetrating procedures is sometimes performed with a variety of biocompatible spacer or devices, such as the Aquaflow collagen wick,[76] ologen Collagen Matrix,[64][77][78] or Xenoplast glaucoma implant.[79]

Laser-assisted NPDS is performed with the use of a $CO_2$ laser system. The laser-based system is self-terminating once the required scleral thickness and adequate drainage of the intraocular fluid have been achieved. This self-regulation effect is achieved as the $CO_2$ laser essentially stops ablating as soon as it comes in contact with the intraocular percolated liquid, which occurs as soon as the laser reaches the optimal residual intact layer thickness.

## Prognosis [edit]

In open-angle glaucoma, the typical progression from normal vision to complete blindness takes about 25 years to 70 years without treatment, depending on the method of estimation used.[80] The intraocular pressure can also have an effect, with higher pressures reducing the time until blindness.[81]

[edit]

# Epidemiology

As of 2010, there were 44.7 million people in the world with open angle glaucoma.[83] The same year, there were 2.8 million people in the United States with open angle glaucoma.[83] By 2020, the prevalence is projected to increase to 58.6 million worldwide and 3.4 million the United States.[83]

Both internationally and in the United States glaucoma is the second-leading cause of blindness.[2] Globally cataracts are a more common cause. Glaucoma is also the leading cause of blindness in African Americans, who have higher rates of primary open angle glaucoma.[84][85] Bilateral vision loss can negatively affect mobility and interfere with driving.[86]

A meta-analysis published in 2009 found that people with primary open angle glaucoma do *not* have increased mortality rates, or increased risk of cardiovascular death.[87]

Disability-adjusted life year for glaucoma per 100,000 inhabitants in 2004[82]

# History [edit]

The association of elevated intraocular pressure (IOP) and the eye disease glaucoma was first described by Englishman Richard Bannister in 1622: "...that the Eye be grown more solid and hard, then naturally it should be...".[88] The invention of the ophthalmoscope by Hermann Helmholtz in 1851 enabled ophthalmologists for the first time to identify the pathological hallmark of glaucoma, the excavation of the optic nerve head due to retinal ganglion cell loss. The first reliable instrument to measure intraocular pressure was invented by Norwegian ophthalmologist Hjalmar August Schiøtz in 1905. About half a century later, Hans Goldmann in Berne, Switzerland, developed his applanation tonometer which still today - despite numerous new innovations in diagnostics - is considered the gold standard of determining this crucial pathogenic factor. In the late 20th century, further pathomechanisms beyond elevated IOP were discovered and became the subject of research like insufficient blood supply - often associated with low or irregular blood pressure - to the retina and optic nerve head.[89] The first drug to reduce IOP, pilocarpine, was introduced in the 1870s. Early surgical techniques like iridectomy and fistulating methods have recently been supplemented by less invasive procedures like small implants, a range of options now widely called MIGS (micro-invasive glaucoma surgery).

## Etymology [edit]

The word "glaucoma" comes from the Greek γλαύκωμα, a derivative of γλαυκός, which commonly described the color of eyes which were not dark (i.e. blue, green, light gray). Eyes described as γλαυκός due to disease might have had a gray cataract in the Hippocratic era, or, in the early Common Era, the greenish pupillary hue sometimes seen in angle-closure glaucoma.[8][90]

# Research [edit]

## Rho kinase inhibitors [edit]

Rho kinase inhibitors, such as ripasudil, work by inhibition of the actin cytoskeleton, resulting in the morphological changes in the trabecular meshwork and increased aqueous outflow. More compounds in this class are being investigated in phase 2 and phase 3 trials.[91]

Play media

scientists track eye movements in glaucoma patients to check vision impairment while driving

## Neuroprotective agents [edit]

A 2013 Cochrane Systematic Review compared the effect of brimonidine and timolol in slowing the progression of open angle glaucoma in adult participants.[92] The results showed that participants assigned to brimonidine showed less visual field progression that those assigned to timolol, though the results were not significant, given the heavy loss-to-followup and limited evidence.[92] The mean intraocular pressures for both groups were similar. Participants in the brimonidine group had a higher occurrence of side effects caused by medication than participants in the timolol group.[92]

## Cannabis [edit]

Studies in the 1970s reported that the use of cannabis may lower intraocular pressure.[93][94][95] In an effort to determine whether marijuana, or drugs derived from it, might be effective as a glaucoma treatment, the US National Eye Institute supported research studies from 1978 to 1984. These studies demonstrated some derivatives of marijuana lowered intraocular pressure when administered orally, intravenously, or by smoking, but not when topically applied to the eye.

In 2003, the American Academy of Ophthalmology released a position statement stating that cannabis was not more effective than prescription medications. Furthermore, no scientific evidence has been found that demonstrates increased benefits and/or diminished risks of cannabis use to treat glaucoma compared with the wide variety of pharmaceutical agents now available.[95][96]

In 2012 the American Glaucoma Society published a position paper discrediting the use of cannabis as a legitimate treatment for elevated intraocular pressure, for reasons including short duration of action and side effects that limit many activities of daily living.[97]

# Macular degeneration

From Wikipedia, the free encyclopedia

**Macular degeneration**, also known as **age-related macular degeneration** (**AMD** or **ARMD**), is a medical condition which may result in blurred or no vision in the center of the visual field.[1] Early on there are often no symptoms. Over time, however, some people experience a gradual worsening of vision that may affect one or both eyes. While it does not result in complete blindness, loss of central vision can make it hard to recognize faces, drive, read, or perform other activities of daily life. Visual hallucinations may also occur but these do not represent a mental illness.[1]

Macular degeneration typically occurs in older people. Genetic factors and smoking also play a role. It is due to damage to the macula of the retina. Diagnosis is by a complete eye exam. The severity is divided into early, intermediate, and late types.[1] The late type is additionally divided into "dry" and "wet" forms with the dry form making up 90% of cases.[1][2]

Prevention includes exercising, eating well, and not smoking.[1] Antioxidant vitamins and minerals do not appear to be useful for prevention.[3] There is no cure or treatment that returns vision already lost. In the wet form, anti-VEGF medication injected into the eye or less commonly laser coagulation or photodynamic therapy may slow worsening.[1] Supplements in those who already have the disease may slow progression.[4]

In 2010 it affected 23.5 million people globally.[5] In 2013 moderate to severe disease affected 13.4 million and it is the fourth most common cause of blindness after cataracts, preterm birth, and glaucoma.[6] It most commonly occurs in people over the age of fifty and in the United States is the most common cause of vision loss in this age group.[1][2] About 0.4% of people between 50 and 60 have the disease, while it occurs in 0.7% of people 60 to 70, 2.3% of those 70 to 80, and nearly 12% of people over 80 years old.[2]

## Signs and symptoms [edit]

Signs and symptoms of macular degeneration include:

**Visual symptoms**

- Distorted vision in the form of metamorphopsia, in which a grid of straight lines appears wavy and parts of the grid may appear blank: Patients often first notice this when looking at things like miniblinds in their home or telephone poles while driving. There may also be central scotomas, shadows or missing areas of vision
- Slow recovery of visual function after exposure to bright light (photostress test)
- Visual acuity drastically decreasing (two levels or more), e.g.: 20/20 to 20/80
- Blurred vision: Those with nonexudative macular degeneration may be asymptomatic or notice a gradual loss of central vision, whereas those with exudative macular degeneration often notice a rapid onset of vision loss (often caused by leakage and bleeding of abnormal blood vessels).
- Trouble discerning colors, specifically dark ones from dark ones and light ones from light ones
- A loss in contrast sensitivity

Normal vision

The same view with age-related macular degeneration (National Eye Institute)

Macular degeneration by itself will not lead to total blindness. For that matter, only a very small number of people with visual impairment are totally blind. In almost all cases, some vision remains, mainly peripheral. Other complicating conditions may possibly lead to such an acute condition (severe stroke or trauma, untreated glaucoma, etc.), but few macular degeneration patients experience total visual loss.[7]

The area of the macula comprises only about 2.1% of the retina, and the remaining 97.9% (the peripheral field) remains unaffected by the disease. Even though the macula provides such a small fraction of the visual field, almost half of the visual cortex is devoted to processing macular information.[8]

The loss of central vision profoundly affects visual functioning. It is quite difficult, for example, to read

without central vision. Pictures that attempt to depict the central visual loss of macular degeneration with a black spot do not really do justice to the devastating nature of the visual loss. This can be demonstrated by printing letters six inches high on a piece of paper and attempting to identify them while looking straight ahead and holding the paper slightly to the side. Most people find this difficult to do.

## Risk factors [edit]

- **Ageing**: Advanced age is the strongest predictor of AMD.[*medical citation needed*] .
- **Family history:**

### Environment and lifestyle [edit]

- **Smoking**: Smoking tobacco increases the risk of AMD by two to three times that of someone who has never smoked, and may be the most important modifiable factor in its prevention. A review of previous studies found "a strong association between current smoking and AMD. ... Cigarette smoking is likely to have toxic effects on the retina."[9]
- **Hypertension** (high blood pressure): In the ALIENOR study 2013, early and late AMD were not significantly associated with systolic or diastolic BP, hypertension, or use of antihypertensive medications, but elevated pulse pressure ((PP) systolic BP minus diastolic BP) was significantly associated with an increased risk of late AMD.[10]
- **Atherosclerosis**:
- **High cholesterol**: Elevated cholesterol may increase the risk of AMD[11]
- **Obesity**: Abdominal obesity is a risk factor, especially among men[12]
- **Fat intake**: Consuming high amounts of certain fats including saturated fats, trans fats and omega-6 fatty acids likely contributes to AMD, while monounsaturated fats are potentially protective.[13] In particular, ω-3 fatty acids may decrease the risk of AMD.[14]
- **Exposure to sunlight**,[*dubious – discuss*] especially blue light: Evidence is conflicting as to whether exposure to sunlight contributes to the development of macular degeneration. A recent study on 446 subjects found it does not.[15] Other research, however, has shown high-energy visible light may contribute to AMD.[16][17]

### Genetics [edit]

Recurrence ratios for siblings of an affected individual are three- to sixfold higher than in the general population.[18] Genetic linkage analysis has identified 5 sets of gene variants at three locations on different chromosomes (1, 6 and 10) as explaining at least 50% of the risk. These genes have roles regulating immune response, inflammatory processes and homeostasis of the retina. Variants of these genes give rise to different kinds of dysfunction in these processes. Over time, this results in accumulation of intracellular and extracellular metabolic debris. This can cause scarring of the retina or breakdown of its vascularization.

Genetic tests are available for some of these gene variations. However, pathogenesis of macular degeneration is a complex interaction between genetics, environment and lifestyle, and presence of unfavorable genetic factors doesn't necessarily predict progression to disease. The three loci where identified gene variants are found are designated:

- Complement Factor H (CFH) on chromosome 1 at location 1q31.3
- HTRA serine peptidase 1/Age Related Maculopathy Susceptibility 2 (HTRA1/ARMS2) on chromosome 10 at location 10q26
- Complement Factor B/Complement Component 2 (CFB/CC2) on chromosome 6 at 6p21.3

### Specific genes [edit]

- **Polymorphisms in genes for complement system proteins**: The genes for the complement system proteins factor H (CFH), factor B (CFB) and factor 3 (C3) are strongly associated with a person's risk for developing AMD. CFH is involved in inhibiting the inflammatory response. The mutation in CFH (*Y402H*) results in reduced ability of CFH to regulate complement on critical surfaces such as the retina

and leads to increased inflammatory response within the macula. Absence of the complement factor H-related genes *R3* and *R1* protects against AMD.[19][20] Two independent studies in 2007 showed a certain common mutation *Arg80Gly* in the C3 gene, which is a central protein of the complement system, is strongly associated with the occurrence of AMD.[21][22] The authors of both papers consider their study to underscore the influence of the complement pathway in the pathogenesis of this disease.

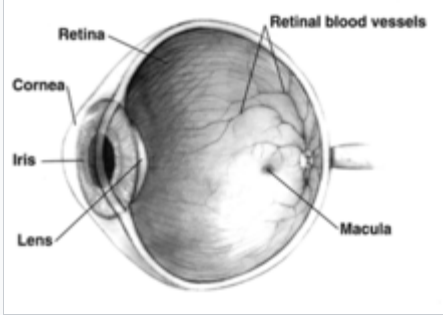
- In two 2006 studies, another gene that has implications for the disease, called *HTRA1* (encoding a secreted serine protease), was identified.[23][24]
- Six mutations of the gene *SERPING1* (Serpin Peptidase Inhibitor, Clade G (C1 Inhibitor), Member 1) are associated with AMD. Mutations in this gene can also cause hereditary angioedema.[25]
- **Fibulin-5 mutation**: Rare forms of the disease are caused by genetic defects in fibulin-5, in an autosomal dominant manner. In 2004, Stone *et al.* performed a screen on 402 AMD patients and revealed a statistically significant correlation between mutations in fibulin-5 and incidence of the disease.

### Mitochondrial related gene polymorphisms [edit]

such as that in the MT-ND2 molecule, predicts wet AMD.[26][27]

## Pathophysiology [edit]

The pathogenesis of age-related macular degeneration is not well known, although a number of theories have been put forward, including oxidative stress, mitochondrial dysfunction, and inflammatory processes.



Human eye cross-sectional view

The imbalance between production of damaged cellular components and degradation leads to the accumulation of detrimental products, for example, intracellular lipofuscin and extracellular drusen. Incipient atrophy is demarcated by areas of retinal pigment epithelium (RPE) thinning or depigmentation that precede geographic atrophy in the early stages of AMD. In advanced stages of AMD, atrophy of the RPE (geographic atrophy) and/or development of new blood vessels (neovascularization) result in death of photoreceptors and central vision loss.

In the dry (nonexudative) form, cellular debris called drusen accumulates between the retina and the choroid, causing atrophy and scarring to the retina. In the wet (exudative) form, which is more severe, blood vessels grow up from the choroid (neovascularization) behind the retina which can leak exudate and fluid and also cause hemorrhaging.

Early work demonstrated a family of immune mediators was plentiful in drusen.[28] Complement factor H (CFH) is an important inhibitor of this inflammatory cascade, and a disease-associated polymorphism in the CFH gene strongly associates with AMD.[29][30][31][32][33] Thus an AMD pathophysiological model of chronic low grade complement activation and inflammation in the macula has been advanced.[34][35] Lending credibility to this has been the discovery of disease-associated genetic polymorphisms in other elements of the complement cascade including complement component 3 (C3).[36]

A powerful predictor of AMD is found on chromosome *10q26* at LOC 387715. An insertion/deletion polymorphism at this site reduces expression of the *ARMS2* gene though destabilization of its mRNA through deletion of the polyadenylation signal.[37] ARMS2 protein may localize to the mitochondria and participate in energy metabolism, though much remains to be discovered about its function.

Other gene markers of progression risk includes tissue inhibitor of metalloproteinase 3 (TIMP3), suggesting a role for intracellular matrix metabolism in AMD progression.[38] Variations in cholesterol metabolising genes such as the hepatic lipase, cholesterol ester transferase, lipoprotein lipase and the ABC-binding cassette A1 correlate with disease progression. The early stigmata of disease, drusen, are rich in cholesterol, offering face validity to the results of genome-wide association studies.[39]

## Stages [edit]

In AMD there is a progressive accumulation of characteristic yellow deposits, called drusen (buildup of extracellular proteins and lipids), in the macula (a part of the retina), between the retinal pigment epithelium and the underlying choroid which is believed to damage the retina over time. Amyloid beta, which builds up in Alzheimer's disease brains, is one the proteins accumulating in AMD, which is one of the reasons AMD is sometimes called "Alzheimer's of the eye" or "Alzheimer's of the retina".[40] AMD can be divided into 3 stages: early, intermediate, and late, based partially on the extent (size and number) of drusen.[1]

AMD-like pathology begins with small yellow deposits (drusen) in the macula, between the retinal pigment epithelium and the underlying choroid. Most people with these early changes (referred to as age-related maculopathy) still have good vision. People with drusen may or may not develop AMD, in fact the majority of people over age 60 have drusen with no negative effects. The risk of developing symptoms is higher when the drusen are large and numerous and associated with disturbance in the pigmented cell layer under the macula. Large and soft drusen are thought to be related to elevated cholesterol deposits.

## Early AMD [edit]

Early AMD is diagnosed based on the presence of medium-sized drusen, about the width of an average human hair. Early AMD is usually asymptomatic.[1]

## Intermediate AMD [edit]

Intermediate AMD is diagnosed by large drusen, irreversible retinal damage (atrophy) caused by cell death, or both. Intermediate AMD may cause some vision loss, however, like Early AMD, it is usually asymptomatic.[1]

## Late AMD [edit]

In late AMD, enough retinal damage occurs that people have symptomatic central vision loss in addition to drusen. The damage can ether be worsening of atrophy from Intermediate AMD or the onset of Neovascular disease. Late AMD is further divided into two subtypes based on the types of damage: Dry AMD, and Wet AMD (also called Neovascular AMD).[1]

### Dry AMD [edit]

In dry AMD (also called atrophic AMD), patients have symptomatic central vision loss due to retinal atrophy. This form is the most common type of clinical AMD, accounting for 80–90% of cases and progresses slowly. In 10–20% of people, it progresses to the wet type.

### Wet AMD [edit]

Neovascular or exudative AMD, the "wet" form of advanced AMD, causes vision loss due to abnormal blood vessel growth (choroidal neovascularization) in the choriocapillaris, through Bruch's membrane. It is usually, but not always, preceded by the dry form of AMD. The proliferation of abnormal blood vessels in the retina is stimulated by vascular endothelial growth factor (VEGF). Unfortunately, because these blood vessels are abnormal, these new vessels are fragile, ultimately leading to blood and protein leakage below the macula. Bleeding, leaking, and scarring from these blood vessels eventually cause irreversible damage to the photoreceptors and rapid vision loss if left untreated.

## Oxidative stress [edit]

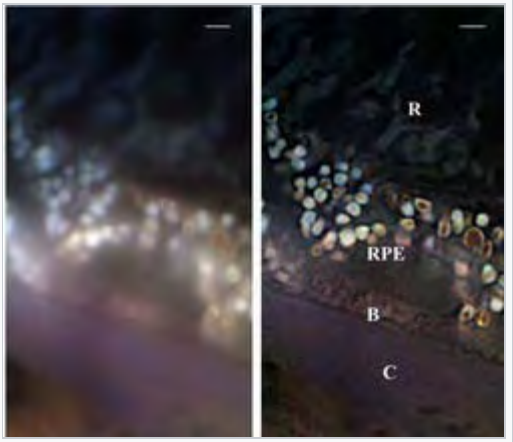
Age-related accumulation of low-molecular-weight, phototoxic, pro-oxidant melanin oligomers within lysosomes in the retinal pigment epithelium (RPE) may be partly responsible for decreasing the digestive rate of photoreceptor outer rod segments (POS) by the RPE – autophagy. A decrease in the digestive rate of POS has been shown to be associated with lipofuscin formation – a classic sign associated with AMD.[41][42]

The role of retinal oxidative stress in the etiology of AMD by causing further inflammation of the macula is suggested by the enhanced rate of disease in smokers and those exposed to UV irradiation.[43][44][45]

Mitochondrial dysfunction may play a role.[46]

## Diagnosis [edit]

Diagnosis of age-related macular degeneration rests on signs in the macula, irrespective of visual acuity. Diagnosis of AMD may include the following procedures and tests:



Super resolution microscopic investigation of human eye tissue affected by AMD

- There is a loss of contrast sensitivity, so that contours, shadows, and color vision are less vivid. The loss in contrast sensitivity can be quickly and easily measured by a contrast sensitivity test like Pelli Robson performed either at home or by an eye specialist.
- When viewing an Amsler grid, some straight lines appear wavy and some patches appear blank
- When viewing a Snellen chart, at least 2 lines decline
- Preferential hyperacuity perimetry changes (for wet AMD)[47][48]
- In dry macular degeneration, which occurs in 85–90 percent of AMD cases, drusen spots can be seen in Fundus photography
- In wet macular degeneration, angiography can visualize the leakage of bloodstream behind the macula. Fluorescein angiography allows for the identification and localization of abnormal vascular processes.
- Using an electroretinogram, points in the macula with a weak or absent response compared to a normal eye may be found
- Farnsworth-Munsell 100 hue test and Maximum Color Contrast Sensitivity test (MCCS) for assessing color acuity and color contrast sensitivity
- Optical coherence tomography is now used by most ophthalmologists in the diagnosis and the follow-up evaluation of the response to treatment with antiangiogenic drugs.

### Histology [edit]

- Pigmentary changes in the retina – In addition to the pigmented cells in the iris (the colored part of the eye), there are pigmented cells beneath the retina. As these cells break down and release their pigment, dark clumps of released pigment and later, areas that are less pigmented may appear
- Exudative changes: hemorrhages in the eye, hard exudates, subretinal/sub-RPE/intraretinal fluid
- Drusen, tiny accumulations of extracellular material that build up on the retina. While there is a tendency for drusen to be blamed for the progressive loss of vision, drusen deposits can be present in the retina without vision loss. Some patients with large deposits of drusen have normal visual acuity. If normal retinal reception and image transmission are sometimes possible in a retina when high concentrations of drusen are present, then, even if drusen can be implicated in the loss of visual function, there must be at least one other factor that accounts for the loss of vision.

## Prevention [edit]

A 2012 Cochrane review found the use of vitamin and mineral supplements, alone or in combination, by the general population had no effect on whether or not AMD started.[3]

## Management [edit]

Supplements that include lutein and zeaxanthin may slow down the worsening of AMD.[4][49] They have; however, not been shown to prevent the disease.[49] There is not enough evidence to determine if statins

have a role in preventing or slowing the progression of AMD.[50] Antiangiogenic steroids such as anecortave acetate and triamcinolone acetonide have shown no evidence in preventing visual loss in people with neovascular AMD.[51]

## Dry AMD [edit]

No medical or surgical treatment is available for this condition.

## Wet AMD [edit]

It can be treated with laser coagulation, and more commonly with medication that stops and sometimes reverses the growth of blood vessels.[52][53]

A randomized control trial found that bevacizumab and ranibizumab had similar efficacy, and reported no significant increase in adverse events with bevacizumab.[54] A 2014 Cochrane review found that the systemic safety of bevacizumab and ranibizumab are similar when used to treat neovascular AMD, except for gastrointestinal disorders.[55] Bevacizumab however is not FDA approved for treatment of macular degeneration. A controversy in the UK involved the off-label use of cheaper bevacizumab over the approved, but expensive, ranibizumab.[56] Ranibizumab is a smaller fragment, Fab fragment, of the parent bevacizumab molecule specifically designed for eye injections. Other approved antiangiogenic drugs for the treatment of neo-vascular AMD include pegaptanib[57] and aflibercept.[58]

The American Academy of Ophthalmology practice guidelines do not recommend laser coagulation therapy for macular degeneration, but state that it may be useful in people with new blood vessels in the choroid outside of the fovea who don't respond to drug treatment.[59][60] There is strong evidence that laser coagulation will result in the disappearance of drusen but does not affect choroidal neovascularisation.[61] A 2007 Cochrane review on found that laser photocoagulation of new blood vessels in the choroid outside of the fovea is effective and economical method, but that the benefits are limited for vessels next to or below the fovea.[62]

Photodynamic therapy has also been used to treat wet AMD.[63] The drug verteporfin is administered intravenously; light of a certain wavelength is then applied to the abnormal blood vessels. This activates the verteporfin destroying the vessels.

Cataract surgery could possibly improve visual outcomes for people with AMD, though there have been concerns of surgery increasing the progression of AMD. A randomized controlled trial found that people who underwent immediate cataract surgery (within 2 weeks) had improved visual acuity and better quality of life outcomes than those who underwent delayed cataract surgery (6 months).[64]

## Adaptive devices [edit]

Because peripheral vision is not affected, people with macular degeneration can learn to use their remaining vision to partially compensate.[65] Assistance and resources are available in many countries and every state in the U.S.[66] Classes for "independent living" are given and some technology can be obtained from a state department of rehabilitation.

Adaptive devices can help people read. These include magnifying glasses, special eyeglass lenses, computer screen readers, and TV systems that enlarge reading material.

Computer screen readers such as JAWS or Thunder work with standard Windows computers. Also Apple devices provide wide range of features (voice over,screen readers, Braille etc.,

Video cameras can be fed into standard or special-purpose computer monitors, and the image can be zoomed in and magnified. These

Josef Tal, an Israeli composer who was affected by macular degeneration, checks a manuscript using a CCTV desktop

systems often include a movable table to move the written material.

Accessible publishing provides larger fonts for printed books, patterns to make tracking easier, audiobooks and DAISY books with both text and audio.

unit.

## Epidemiology [edit]

Age-related macular degeneration accounts for more than 54% of all vision loss in the white population in the USA. An estimated 8 million Americans are affected with early age-related macular degeneration, of whom over 1 million will develop advanced age-related macular degeneration within the next 5 years. In the UK, age-related macular degeneration is the cause of blindness in almost 42% of those who go blind aged 65–74 years, almost two-thirds of those aged 75–84 years, and almost three-quarters of those aged 85 years or older.

Macular degeneration is more likely to be found in Caucasians than in people of African descent.[68][69]

## Research directions [edit]

### Association with other age-related diseases [edit]

Studies indicate drusen associated with AMD are similar in molecular composition to Beta-Amyloid (βA) plaques and deposits in other age-related diseases such as Alzheimer's disease and atherosclerosis. This suggests that similar pathways may be involved in the etiologies of AMD and other age-related diseases.[70]

### Genetic testing [edit]

A practical application of AMD-associated genetic markers is in the prediction of progression of AMD from early stages of the disease to neovascularization.[71][72]

### Stem cell transplant [edit]

*See also: Adeno associated virus and gene therapy of the human retina*

Cell based therapies using bone marrow stem cells as well as Retinal pigment epithelial transplantation are being studied.[73] Recent advancements within the field of stem cell research in the United States have led to the first human embryonic stem cell trial for dry AMD, which reports positive results.[74]

## Other types [edit]

There are a few other (rare) kinds of macular degeneration with similar symptoms but unrelated in etiology to Wet or Dry age-related macular degeneration. They are all genetic disorders that may occur in childhood or middle age.

- Best's disease
- Sorsby's fundus dystrophy is an autosomal dominant, retinal disease characterized by sudden acuity loss resulting from untreatable submacular neovascularisation
- Stargardt's disease (juvenile macular degeneration, STGD) is an autosomal recessive retinal disorder characterized by a juvenile-onset macular dystrophy, alterations of the peripheral retina, and subretinal

deposition of lipofuscin-like material.

Similar symptoms with a very different etiology and different treatment can be caused by epiretinal membrane or macular pucker or any other condition affecting the macula, such as central serous retinopathy.

## Notable cases [edit]

- Judi Dench[75]
- Joan Plowright[76]
- Peter Sallis,[77] notable of voices of Wallace from *Wallace and Gromit* until 2012
- Rosanne Barr[78]

## See also [edit]

- Cherry-red spot
- Fuchs spot
- Micropsia

# Refractive error

From Wikipedia, the free encyclopedia

**Refractive error**, also known as **refraction error**, is a problem with focusing of light on the retina due to the shape of the eye.[1] The most common types of refractive error are near-sightedness, far-sightedness, astigmatism, and presbyopia. Near-sightedness results in far objects being blurry, far-sightedness result in close objects being blurry, astigmatism causes objects to appear stretched out or blurry, and presbyopia results in a poor ability to focus on close objects. Other symptoms may include double vision, headaches, and eye strain.[1]

Near-sightedness is due to the length of the eyeball being too long, far-sightedness the eyeball too short, astigmatism the cornea being the wrong shape, and presbyopia aging of the lens of the eye such that it cannot change shape sufficiently. Some refractive errors are inherited from a person's parents. Diagnosis is by eye examination.[1]

Refractive errors are corrected with eyeglasses, contact lenses, or surgery. Eyeglasses are the easiest and safest method of correction. Contact lenses can provide a wider field of vision; however are associated with a risk of infection. Refractive surgery permanently changes the shape of the cornea.[1]

**Refraction error**

Glasses are a common treatment for refractive errors

[edit on Wikidata]

The number of people globally with refractive errors has been estimated at one to two billion. Rates vary between regions of the world with about 25% of Europeans and 80% of Asians affected.[2] Near-sightedness is the most common disorder.[3] Rates among adults are between 15-49% while rates among children are between 1.2-42%.[4] Far-sightedness more commonly affects young child and the elderly.[5][6] Presbyopia affects most people over the age of 35.[1] The number of people with refractive errors that have not been corrected was estimated at 660 million (10 per 100 people) in 2013.[7] Of these 9.5 million were blind due to the refractive error.[7] It is one of the most common causes of vision loss along with cataracts, macular degeneration, and vitamin A deficiency.[8]

Contents

## Classification [edit]

An eye that has no refractive error when viewing distant objects is said to have *emmetropia* or be *emmetropic* meaning the eye is in a state in which it can focus parallel rays of light (light from distant objects) on the retina, without using any accommodation. A distant object in this case is defined as an object 8 meters or further away from the eye.

An eye that has refractive error when viewing distant objects is said to have *ametropia* or be *ametropic*. This eye cannot focus parallel rays of light (light from distant objects) on the retina, or needs accommodation to do so.

The word "ametropia" can be used interchangeably with "refractive error". Types of ametropia include myopia, hyperopia and astigmatism. They are frequently categorized as spherical errors and cylindrical errors:

- Spherical errors occur when the optical power of the eye is either too large or too small to focus light on the retina. People with refractive error frequently have blurry vision.
  - **Nearsightedness**: When the optics are too powerful for the length of the eyeball one has myopia or nearsightedness. This can arise from a cornea or crystalline lens with too much curvature (refractive myopia) or an eyeball that is too long (axial myopia). Myopia can be corrected with a concave lens which causes the divergence of light rays before they reach the cornea.
  - **Farsightedness**: When the optics are too weak for the length of the eyeball, one has hyperopia or farsightedness. This can arise from a cornea or crystalline lens with not enough curvature (refractive hyperopia) or an eyeball that is too short (axial hyperopia). This can be corrected with convex lenses which cause light rays to converge prior to hitting the cornea.
  - **Presbyopia**: When the flexibility of the lens declines, typically due to age. The individual would experience difficulty in near vision, often relieved by reading glasses, bifocal, or progressive lenses.
- Cylindrical errors cause astigmatism, when the optical power of the eye is too powerful or too weak across one meridian, such as if the corneal curvature tends towards a cylindrical shape. The angle between that meridian and the horizontal is known as the axis of the cylinder.
  - **Astigmatism**: A person with astigmatic refractive error sees lines of a particular orientation less more clearly than lines at right angles to them. This defect can be corrected by refracting light more in one meridian than the other. Cylindrical lenses serve this purpose.

## Risk factors [edit]

### Genetics [edit]

Fundus of person with retinitis pigmentosa, early stage

The Online Mendelian Inheritance in Man (OMIM) database has listed 261 genetic disorders in which myopia is one of the symptoms.[9] Myopia may be present in heritable connective tissue disorders such as: Knobloch syndrome (OMIM 267750); Marfan syndrome (OMIM 154700); and Stickler syndrome (type 1, OMIM 108300; type 2, OMIM 604841).[10] Myopia is present in heritable connective tissue disorders such as: Knobloch syndrome (OMIM 267750); Marfan syndrome (OMIM 154700); and Stickler syndrome (type 1, OMIM 108300; type 2, OMIM 604841).[10] Myopia has also been reported in X-linked disorders caused by mutations in loci involved in retinal photoreceptor function (NYX, RP2, MYP1) such as: autosomal recessive congenital stationary night blindness (CSNB; OMIM 310500); retinitis pigmentosa 2 (RP2; OMIM 312600); Bornholm eye disease (OMIM 310460).[11] Many genes that have been associated with refractive error are clustered into common biological networks involved in connective tissue growth and extracellular matrix organization.[10] Although a large number of chromosomal localisations have been associated with myopia (MYP1-MYP17), few specific genes have been identified.[9]

## Environmental [edit]

In studies of the genetic predisposition of refractive error, there is a correlation between environmental factors and the risk of developing myopia.[12] Myopia has been observed in individuals with visually intensive occupations.[11] Reading has also been found to be a predictor of myopia in children. It has been reported that children with myopia spent significantly more time reading than non-myopic children who spent more time playing outdoors.[11] Socioeconomic status and higher levels of education have also been reported to be a risk factor for myopia.

# Diagnosis [edit]

Blurry vision may result from any number of conditions not necessarily related to refractive errors. The diagnosis of a refractive error is usually confirmed by an eye care professional during an eye examination using a large number of lenses of different optical powers, and often a retinoscope (a procedure entitled *retinoscopy*) to measure objectively in which the patient views a distant spot while the clinician changes the lenses held before the patient's eye and watches the pattern of reflection of a small light shone on the eye. Following that "objective refraction" the clinician typically shows the patient lenses of progressively higher or weaker powers in a process known as *subjective refraction*. Cycloplegic agents are frequently used to more accurately determine the amount of refractive error, particularly in children[13]

A doctor uses a trial frame and trial lenses to measure the patient's refractive error.

An automated refractor is an instrument that is sometimes used in place of retinoscopy to objectively estimate a person's refractive error.[14] Shack–Hartmann wavefront sensor and its inverse[15] can also be used to characterize eye aberrations in a higher level of resolution and accuracy.

Vision defects caused by refractive error can be distinguished from other problems using a pinhole occluder, which will improve vision only in the case of refractive error.

# Management [edit]

How refractive errors are treated or managed depends upon the amount and severity of the condition. Those who possess mild amounts of refractive error may elect to leave the condition uncorrected, particularly if the patient is asymptomatic. For those who are symptomatic, glasses, contact lenses, refractive surgery, or a combination of the three are typically used.

In the case of myopia, however, some believe that such treatments may also have the long-term effect of exacerbating that refractive error — i.e., making the patient even more nearsighted. This would be due to the very same prescription that is tailored for use at a 12-to-20-foot distance also commonly being used for close-up work as well, thus artificially amplifying the focusing stress that would normally be presented to the accommodation mechanisms of the eye at that distance.[*citation needed*]

However, this exacerbating effect is not generally believed to exist in the general case, although in cases where the myopia is due to accommodative spasm, removing the corrective lenses for a time may lead to improvement.[*citation needed*]

# Epidemiology [edit]

The number of people globally with refractive errors that have not

been corrected was estimated at 660 million (10 per 100 people) in 2013.[7]

The number of people globally with refractive errors has been estimated from 800 million to 2.3 billion.

DALYs per 100,000 people due to refractive errors in 2004.[16]

# Trachoma

**Trachoma**, also called **granular conjunctivitis**, **Egyptian ophthalmia**,[1] and **blinding trachoma**, is an infectious disease caused by bacterium *Chlamydia trachomatis*. The infection causes a roughening of the inner surface of the eyelids. This roughening can lead to pain in the eyes, breakdown of the outer surface or cornea of the eyes, and eventual blindness. Untreated, repeated trachoma infections can result in a form of permanent blindness when the eyelids turn inward.[2]

The bacteria that cause the disease can be spread by both direct and indirect contact with an affected person's eyes or nose. Indirect contact includes through clothing or flies that have come in to contact with an affected person's eyes or nose. Children spread the disease more often than adults. Poor sanitation, crowded living conditions, and not enough clean water and toilets also increase spread.[2]

Efforts to prevent the disease include improving access to clean water and decreasing the number of people infected by treatment with antibiotics.[2] This may include treating, all at once, whole groups of people in whom the disease is known to be common.[3] Washing by itself is not enough to prevent disease but may be useful with other measures.[4] Treatment options include oral azithromycin and topical tetracycline.[3] Azithromycin is preferred because it can be used as a single oral dose.[5] After scarring of the eyelid has occurred, surgery may be required to correct the position of the eyelashes and prevent blindness.[2]

Globally, about 80 million people have an active infection.[6] In some areas infections may be present in as many as 60–90% of children and it more commonly affects women than men likely due to their closer contact with children.[2] The disease is the cause of decreased vision in 2.2 million people of whom 1.2 million are completely blind.[2] It commonly occurs in 53 countries of Africa, Asia, Central and South America with about 230 million people at risk.[2] It results in US$8 billion of economic losses a year.[2] It belongs to a group of diseases known as neglected tropical diseases.[6]

## Signs and symptoms [edit]

The bacterium has an incubation period of 5 to 12 days, after which the affected individual experiences symptoms of conjunctivitis, or irritation similar to "pink eye." Blinding endemic trachoma results from multiple episodes of reinfection that maintains the intense inflammation in the conjunctiva. Without reinfection, the inflammation will gradually subside.[7]

The conjunctival inflammation is called "active trachoma" and usually is seen in children, especially pre-school children. It is characterized by white lumps in the undersurface of the upper eyelid (conjunctival follicles or lymphoid germinal centres) and by non-specific inflammation and thickening often associated with papillae. Follicles may also appear at the junction of the cornea and the sclera (limbal follicles). Active trachoma will often be irritating and have a watery discharge. Bacterial secondary infection may occur and cause a purulent discharge.

The later structural changes of trachoma are referred to as "cicatricial trachoma". These include scarring in the eyelid (tarsal conjunctiva) that leads to distortion of the eyelid with buckling of the lid (tarsus) so the lashes rub on the eye (trichiasis). These lashes will lead to corneal opacities and scarring and then to blindness. Linear scar present in the Sulcus subtarsalis is called Arlt's line (named after Carl Ferdinand von Arlt). In addition, blood vessels and scar tissue can invade the upper cornea (pannus). Resolved limbal follicles may leave small gaps in pannus (Herbert's Pits).

Most commonly children with active trachoma will not present with any symptoms as the low-grade irritation and ocular discharge is just accepted as normal. However, further symptoms may include:

- Eye discharge
- Swollen eyelids
- Trichiasis (turned-in eyelashes)
- Swelling of lymph nodes in front of the ears
- Sensitivity to bright lights
- Increased heart rate
- Further ear, nose and throat complications.

The major complication or the most important one is corneal ulcer occurring due to rubbing by concentrations, or trichiasis with superimposed bacterial infection.

## Cause [edit]

Trachoma is caused by *Chlamydia trachomatis*, serotypes (serovars) A, B, and C.[8] It is spread by direct contact with eye, nose, and throat secretions from affected individuals, or contact with fomites[9]

(inanimate objects that carry infectious agents), such as towels and/or washcloths, that have had similar contact with these secretions. Flies can also be a route of mechanical transmission.[9] Untreated, repeated trachoma infections result in entropion—a painful form of permanent blindness when the eyelids turn inward, causing the eyelashes to scratch the cornea. Children are the most susceptible to infection due to their tendency to easily get dirty, but the blinding effects or more severe symptoms are often not felt until adulthood.

Blinding endemic trachoma occurs in areas with poor personal and family hygiene. Many factors are indirectly linked to the presence of trachoma including lack of water, absence of latrines or toilets, poverty in general, flies, close proximity to cattle, crowding, and so forth.[7][10] However, the final common pathway seems to be the presence of dirty faces in children that facilitates the frequent exchange of infected ocular discharge from one child's face to another. Most transmission of trachoma occurs within the family.[7]

## Diagnosis [edit]

### McCallan's classification [edit]

McCallan in 1908 divided the clinical course of trachoma into 4 stages

| Stage 1 (Incipient trachoma) | Stage 2 (Established trachoma) | Stage 3 (Cicatrising trachoma) | Stage 4 (Healed trachoma) |
|---|---|---|---|
| Hyperaemia of palpebral conjunctiva | Appearance of mature follicle & papillae | Scarring of palpebral conjunctiva | Disease is cured or is not markable |
| Immature follicle | Progressive corneal pannus | Scars are easily visible as white bands | Sequelae to cicatrisation cause symptoms |

### WHO classification [edit]

The World Health Organization recommends a simplified grading system for trachoma.[11] The Simplified WHO Grading System is summarized below:

Trachomatous inflammation, follicular (TF)—Five or more follicles of >0.5 mm on the upper tarsal conjunctiva

Trachomatous inflammation, intense (TI)—Papillary hypertrophy and inflammatory thickening of the upper tarsal conjunctiva obscuring more than half the deep tarsal vessels

Trachomatous scarring (TS)—Presence of scarring in tarsal conjunctiva.

Trachomatous trichiasis (TT)—At least one ingrown eyelash touching the globe, or evidence of epilation (eyelash removal)

Corneal opacity (CO)—Corneal opacity blurring part of the pupil margin

## Prevention [edit]

Although trachoma was eliminated from much of the developed world in the 20th century, this disease persists in many parts of the developing world, particularly in communities without adequate access to water and sanitation.[12]

### Environmental measures [edit]

Environmental improvement: Modifications in water use, fly control, latrine use, health education, and proximity to domesticated animals have all been proposed to reduce transmission of *C. trachomatis*. These

changes pose numerous challenges for implementation. It seems likely that these environmental changes ultimately impact on the transmission of ocular infection by means of lack of facial cleanliness.[7] Particular attention is required for environmental factors that limit clean faces.

A systematic review examining the effectiveness of environmental sanitary measures on the prevalence of active trachoma in endemic areas showed that usage of insecticide spray resulted in significant reductions of trachoma and fly density in some studies.[13] Health education also resulted in reductions of active trachoma when implemented.[13] Improved water supply did not result in a reduction of trachoma incidence.[13]

### Antibiotics [edit]

Antibiotic therapy: WHO Guidelines recommend that a region should receive community-based, mass antibiotic treatment when the prevalence of active trachoma among one- to nine-year-old children is greater than 10 percent.[14] Subsequent annual treatment should be administered for three years, at which time the prevalence should be reassessed. Annual treatment should continue until the prevalence drops below five percent. At lower prevalences, antibiotic treatment should be family-based.

## Management [edit]

### Antibiotics [edit]

Antibiotic selection: Azithromycin (single oral dose of 20 mg/kg) or topical tetracycline (one percent eye ointment twice a day for six weeks). Azithromycin is preferred because it is used as a single oral dose. Although it is expensive, it is generally used as part of the international donation program organized by Pfizer through the International Trachoma Initiative.[5] Azithromycin can be used in children from the age of six months and in pregnancy.[7] As a community-based antibiotic treatment, some evidence suggests that oral azithromycin was more effective than topical tetracycline; however, there was no consistent evidence that supported oral or topical antibiotics as being more effective.[3] Antibiotic treatment reduces the risk of active trachoma in individuals infected with chlamydia trachomatis.[3]

### Surgery [edit]

Surgery: For individuals with trichiasis, a bilamellar tarsal rotation procedure is warranted to direct the lashes away from the globe.[15] Evidence suggests that usage of a lid clamp and absorbable sutures would result in reduced lid contour abnormalities and granuloma formulation post-surgery.[16] Early intervention is beneficial as the rate of recurrence is higher in more advanced disease.[17]

### Lifestyle measures [edit]

Facial cleanliness: Children with grossly visible nasal discharge, ocular discharge, or flies on their faces are at least twice as likely to have active trachoma as children with clean faces.[7] Intensive community-based health education programs to promote face-washing can significantly reduce the prevalence of active trachoma, especially intense trachoma (TI). If an individual is already infected washing one's face is strongly encouraged, especially a child, in order to prevent re-infection.[18] Some evidence exists that washing the face combined with topical tetracycline might be more effective in reducing severe trachoma compared to topical tetracycline alone.[4] The same trial found no statistically significant benefit of eye washing alone or in combination with tetracycline eye drops in reducing follicular trachoma amongst children.[4]

National governments in collaboration with numerous non-profit organizations implement trachoma control programs using the WHO-recommended SAFE strategy, which includes:

- Surgery to correct advanced stages of the disease;

Antibiotics to treat active infection, using azithromycin
- Facial cleanliness to reduce disease transmission;
- Environmental change to increase access to clean water and improved sanitation.

## Prognosis [edit]

If not treated properly with oral antibiotics, the symptoms may escalate and cause blindness, which is the result of ulceration and consequent scarring of the cornea. Surgery may also be necessary to fix eyelid deformities.

Without intervention, trachoma keeps families shackled within a cycle of poverty, as the disease and its long-term effects are passed from one generation to the next.

## Epidemiology [edit]

As of 2008, between 40–80 million people are infected,[6] and between 1.3 million and 8 million have permanent blindness due to trachoma.[19][20] It is common in more than 50 countries worldwide.[19] In many of these communities, women are three times more likely than men to be blinded by the disease, due to their roles as caregivers in the family.[21] About 110 million people live in endemic areas and need treatment. An additional 210 million live where trachoma is suspected endemic.

Disability-adjusted life year for trachoma per 100,000 inhabitants in 2004

| 80–100 | |

Ghana, Mexico, Saudi Arabia, Iran, Morocco and Oman report that the disease nationally eliminated.[22] Australia is the only developed country to still have endemic blinding trachoma.[23] In 2008, trachoma was found in half of Australia's very remote communities at endemic levels.[23]

The WHO has set a target to eliminate trachoma as a public health problem by 2020.[24] The International Coalition for Trachoma Control (ICTC) has produced a strategic plan called 2020 INSight that lays out actions and milestones to achieve global elimination of blinding trachoma by the year 2020.[25] "We can make this disease history, and this document lays out a plan to do so," said Dr. Paul Emerson, program director of the International Trachoma Initiative (ITI) and former director of the Carter Center's Trachoma Control Program. "There is an urgent need for action to avoid additional suffering and unnecessary blindness for hundreds of thousands of people." The International Trachoma Initiative (ITI) coordinated the publication of 2020 INSight, which was produced with input from a diverse set of stakeholders.

The Trachoma Atlas is an open-access resource on the geographical distribution of trachoma. It features maps that show the prevalence of trachoma. The maps are free to use and download.[26]

## History [edit]

The disease is one of the earliest known eye afflictions, having been identified in Egypt as early as 15 B.C.[7]

Its presence was also recorded in ancient China and Mesopotamia. Trachoma became a problem as people moved into crowded settlements or towns where hygiene was poor. It became a particular problem in Europe in the 19th century. After the Egyptian Campaign (1798–1802) and the Napoleonic Wars (1798–1815), trachoma was rampant in the army barracks of Europe and spread to those living in towns as troops returned home. Stringent control measures were introduced and by the early 20th century, trachoma was

essentially controlled in Europe, although cases were reported up until the 1950s.[7] Today, most victims of trachoma live in underdeveloped and poverty-stricken countries in Africa, the Middle East, and Asia.

In the United States, the Centers for Disease Control says "No national or international surveillance [for trachoma] exists. Blindness due to trachoma has been eliminated from the United States. The last cases were found among Native American populations and in Appalachia, and those in the boxing, wrestling, and sawmill industries (prolonged exposure to combinations of sweat and sawdust often lead to the disease). In the late 19th century and early 20th century, trachoma was the main reason for an immigrant coming through Ellis Island to be deported."[27][28]

In 1913, President Woodrow Wilson signed an act designating funds for the eradication of the disease.[29][30] Immigrants who attempted to enter the U.S. through Ellis Island, New York had to be checked for trachoma.[27] During this time treatment for the disease was by topical application of copper sulfate. By the late 1930s, a number of ophthalmologists reported success in treating trachoma with sulfonamide antibiotics.[31] In 1948, Vincent Tabone (who was later to become the President of Malta) was entrusted with the supervision of a campaign in Malta to treat trachoma using sulfonamide tablets and drops.[32]

Thanks to improved sanitation and overall living conditions, trachoma virtually disappeared from the industrialized world by the 1950s. However, it continues to plague the developing world to this day. Epidemiological studies were conducted in 1956-63 by the Trachoma Control Pilot Project in India under the Indian Council for Medical Research.[33] This potentially blinding disease remains endemic in the poorest regions of Africa, Asia, and the Middle East and in some parts of Latin America and Australia. Currently, 8 million people are visually impaired as a result of trachoma, and 41 million suffer from active infection.

Of the 54 countries that WHO cited as still having blinding trachoma occurring, Australia is the only developed country - Australian Aboriginal people who live in remote communities with inadequate sanitation are still blinded by this infectious eye disease.[34]

## Etymology [edit]

The term is derived from New Latin *trāchōma*, from Greek τράχωμα *trākhōma*, from τραχύς *trākhus* "rough."[35]

## Variants

*"ADD" and "A.D.H.D." redirect here. For other uses, see ADD (disambiguation) and A.D.H.D. (disambiguation).*
*"Minimal brain dysfunction" redirects here. It is not to be confused with mild cognitive impairment.*

**Attention deficit hyperactivity disorder** (**ADHD**) is a mental disorder of the neurodevelopmental type.[1][2] It is characterized by problems paying attention, excessive activity, or difficulty controlling behavior which is not appropriate for a person's age.[3][4] These symptoms begin by age six to twelve, are present for more than six months, and cause problems in at least two settings (such as school, home, or recreational activities).[5][6] In children, problems paying attention may result in poor school performance.[3] Although it causes impairment, particularly in modern society, many children with ADHD have a good attention span for tasks they find interesting.[7]

Despite being the most commonly studied and diagnosed mental disorder in children and adolescents, the exact cause is unknown in the majority of cases.[8] It affects about 5–7% of children when diagnosed via the DSM-IV criteria[9][4] and 1–2% when diagnosed via the ICD-10 criteria.[10] The World Health Organization (WHO) estimated that it affected about 39 million people as of 2013.[11] Rates are similar between countries and depend mostly on how it is diagnosed.[12] ADHD is diagnosed approximately three times more often in boys than in girls, although the disorder is often overlooked in girls due to their symptoms differing from those of boys.[13][14][15] About 30–50% of people diagnosed in childhood continue to have symptoms into adulthood and between 2–5% of adults have the condition.[16][17][18] The condition can be difficult to tell apart from other disorders, as well as to distinguish from high levels of activity that are still within the normal-range.[6]

ADHD management recommendations vary by country and usually involve some combination of counseling, lifestyle changes, and medications.[3] The British guideline only recommends medications as a first-line treatment in children who have severe symptoms and for medication to be considered in those with moderate symptoms who either refuse or fail to improve with counseling, though for adults medications are a first-line treatment.[19] Canadian and American guidelines recommend that medications and behavioral therapy be used together as a first-line therapy, except in preschool-aged children.[20][21] Stimulant medication therapy is not recommended as a first-line therapy in preschool-aged children in either guideline.[19][21] Treatment with stimulants is effective for up to 14 months; however, its long term effectiveness is unclear.[19][22][23][24] Adolescents and adults tend to develop coping skills which make up for some or all of their impairments.[25]

The medical literature has described symptoms similar to ADHD since the 19th century.[26] ADHD, its diagnosis, and its treatment have been considered controversial since the 1970s.[27] The controversies have involved

clinicians, teachers, policymakers, parents, and the media. Topics include ADHD's causes and the use of stimulant medications in its treatment.[28] Most healthcare providers accept ADHD as a genuine disorder in children and adults, and the debate in the scientific community mainly centers on how it is diagnosed and treated.[29][30][31] The condition was officially known as **attention deficit disorder** (**ADD**) from 1980 to 1987 while before this it was known as **hyperkinetic reaction of childhood**.[32][33]

## Signs and symptoms [edit]

Inattention, hyperactivity (restlessness in adults), disruptive behavior, and impulsivity are common in ADHD.[34][35] Academic difficulties are frequent as are problems with relationships.[34] The symptoms can be difficult to define as it is hard to draw a line at where normal levels of inattention, hyperactivity, and impulsivity end and significant levels requiring interventions begin.[36]

Play media

Video explaining ADHD

According to the DSM-5, symptoms must be present for six months or more to a degree that is much greater than others of the same age[4] and they must cause significant problems functioning in at least two settings (e.g., social, school/work, or home).[4] The full criteria must have been met prior to age 12 in order to receive a diagnosis of ADHD.[4]

ADHD is divided into three subtypes: predominantly inattentive (ADHD-PI or ADHD-I), predominantly hyperactive-impulsive (ADHD-PH), and combined type (ADHD-C).[4][36]

A child with ADHD inattentive type has most or all of following symptoms, excluding situations where these symptoms are better explained by another psychiatric or medical condition:[4][37]

- Be easily distracted, miss details, forget things, and frequently switch from one activity to another
- Have difficulty maintaining focus on one task
- Become bored with a task after only a few minutes, unless doing something enjoyable
- Have difficulty focusing attention on organizing and completing a task or learning something new

- Have trouble completing or turning in homework assignments, often losing things (e.g., pencils, toys, assignments) needed to complete tasks or activities
- Seem to not be listening when spoken to
- Daydream, become easily confused, and move slowly
- Have difficulty processing information as quickly and accurately as others
- Struggle to follow instructions
- Have trouble understanding minute details

A child with ADHD hyperactive/impulsive type has most or all of the following symptoms, excluding situations where these symptoms are better explained by another psychiatric or medical condition:[4][37]

- Fidget and squirm in their seats
- Talk nonstop
- Dash around, touching or playing with anything and everything in sight
- Have trouble sitting still during dinner, school, doing homework, and story time
- Be constantly in motion
- Have difficulty doing quiet tasks or activities
- Be very impatient
- Blurt out inappropriate comments, show their emotions without restraint, and act without regard for consequences
- Have difficulty waiting for things they want or waiting their turns in games
- Often interrupt conversations or others' activities

Symptoms of hyperactivity tend to go away with age and turn into "inner restlessness" in teens and adults with ADHD.[16]

People with ADHD of all ages are more likely to have problems with social skills, such as social interaction and forming and maintaining friendships. This is true for all subtypes. About half of children and adolescents with ADHD experience social rejection by their peers compared to 10–15% of non-ADHD children and adolescents. People with attention deficits are prone to having difficulty processing verbal and nonverbal language which can negatively affect social interaction. They also may drift off during conversations, and miss social cues.[38]

Difficulties managing anger are more common in children with ADHD[39] as are poor handwriting[40] and delays in speech, language and motor development.[41][42] Although it causes significant impairment, particularly in modern society, many children with ADHD have a good attention span for tasks they find interesting.[7]

## Associated disorders [edit]

In children, ADHD occurs with other disorders about ⅔ of the time.[7] Some commonly associated conditions include:

- Learning disabilities have been found to occur in about 20–30% of children with ADHD. Learning disabilities can include developmental speech and language disorders and academic skills disorders.[43] ADHD, however, is not considered a learning disability, but it very frequently causes academic difficulties.[43]
- Tourette syndrome has been found to occur more commonly in the ADHD population.[3]
- Oppositional defiant disorder (ODD) and conduct disorder (CD), which occur with ADHD in about 50% and 20% of cases respectively.[44] They are characterized by antisocial behaviors such as stubbornness, aggression, frequent temper tantrums, deceitfulness, lying, and stealing.[45] About half of those with hyperactivity and ODD or CD develop antisocial personality disorder in adulthood.[46] Brain imaging supports that conduct disorder and ADHD are separate conditions.[47]
- Primary disorder of vigilance, which is characterized by poor attention and concentration, as well as difficulties staying awake. These children tend to fidget, yawn and stretch and appear to be hyperactive in order to remain alert and active.[45]
- Mood disorders (especially bipolar disorder and major depressive disorder). Boys diagnosed with the combined ADHD subtype are more likely to have a mood disorder.[48] Adults with ADHD sometimes also have bipolar disorder, which requires careful assessment to accurately diagnose and treat both conditions.[49]
- Anxiety disorders have been found to occur more commonly in the ADHD population.[48]
- Obsessive-compulsive disorder (OCD) can co-occur with ADHD and shares many of its characteristics.[45]
- Substance use disorders. Adolescents and adults with ADHD are at increased risk of substance abuse.[16] This is most commonly seen with alcohol or cannabis.[16] The reason for this may be an altered reward pathway in the brains of ADHD individuals.[16] This makes the evaluation and treatment of ADHD more difficult, with serious substance misuse problems usually treated first due to their greater risks.[19][50]

- Restless legs syndrome has been found to be more common in those with ADHD and is often due to iron deficiency anaemia.[51][52] However, restless legs can simply be a part of ADHD and requires careful assessment to differentiate between the two disorders.[53]
- Sleep disorders and ADHD commonly co-exist. They can also occur as a side effect of medications used to treat ADHD. In children with ADHD, insomnia is the most common sleep disorder with behavioral therapy the preferred treatment.[54][55] Problems with sleep initiation are common among individuals with ADHD but often they will be deep sleepers and have significant difficulty getting up in the morning.[56] Melatonin is sometimes used in children who have sleep onset insomnia.[57]
- People with ADHD have an increased risk of persistent bed wetting.[58]
- A 2016 systematic review found a well established association between ADHD and obesity, asthma and sleep disorders, and tentative evidence for association with celiac disease and migraine,[59] while another 2016 systematic review did not support a clear link between celiac disease and ADHD, and stated that routine screening for celiac disease in people with ADHD is discouraged.[60]

### Intelligence [edit]

Overall, studies have shown that people with ADHD tend to have lower scores on intelligence quotient (IQ) tests.[61] The significance of this is controversial due to the differences between people with ADHD and the difficulty determining the influence of symptoms, such as distractibility, on lower scores rather than intellectual capacity.[61] In studies of ADHD, higher IQs may be over represented because many studies exclude individuals who have lower IQs despite those with ADHD scoring on average 9 points lower on standardized intelligence measures.[62]

## Cause [edit]

The cause of most cases of ADHD is unknown; however, it is believed to involve interactions between genetic and environmental factors.[63][64] Certain cases are related to previous infection of or trauma to the brain.[63]

### Genetics [edit]

Twin studies indicate that the disorder is often inherited from one's parents with genetics determining about 75% of cases.[19][65][66] Siblings of children with ADHD are three to four times more likely to develop the disorder than siblings of children without the disorder.[67] Genetic factors are also believed to be involved in determining whether ADHD persists into adulthood.[68]

Typically, a number of genes are involved, many of which directly affect dopamine neurotransmission.[69][70] Those involved with dopamine include DAT, DRD4, DRD5, TAAR1, MAOA, COMT, and DBH.[70][71][72] Other genes associated with ADHD include SERT, HTR1B, SNAP25, GRIN2A, ADRA2A, TPH2, and BDNF.[69][70] A common variant of a gene called LPHN3 is estimated to be responsible for about 9% of cases and when this variant is present, people are particularly responsive to stimulant medication.[73] The 7 repeat variant of dopamine receptor D4 (DRD4–7R) causes increased inhibitory effects induced by dopamine and is associated with ADHD. The DRD4 receptor is a G protein-coupled receptor that inhibits adenylyl cyclase. The DRD4–7R mutation results in a wide range of behavioral phenotypes, including ADHD symptoms reflecting split attention.[74]

Evolution may have played a role in the high rates of ADHD, particularly hyperactive and impulsive traits in males.[75] Some have hypothesized that some women may be more attracted to males who are risk takers, increasing the frequency of genes that predispose to hyperactivity and impulsivity in the gene pool.[76] Others have claimed that these traits may be an adaptation that helped males face stressful or dangerous environment with, for example, increased impulsivity and exploratory behavior.[75][76] In certain situations, ADHD traits may have been beneficial to society as a whole even while being harmful to the individual.[75][76][77] The high rates and heterogeneity of ADHD may have increased reproductive fitness and benefited society by adding diversity to the gene pool despite being detrimental to the individual.[77] In certain environments, some ADHD traits may have offered personal advantages to individuals, such as quicker response to predators or superior hunting skills.[78]

People with Down syndrome are more likely to have ADHD.[79]

### Environment [edit]

*See also: Diet and attention deficit hyperactivity disorder*

In addition to genetics, some environmental factors might play a role.[80] Alcohol intake during pregnancy can

cause fetal alcohol spectrum disorders which can include ADHD or symptoms like it.[81] Children exposed to certain toxic substances, such as lead or polychlorinated biphenyls, may develop problems which resemble ADHD.[8][82] Exposure to the organophosphate insecticides chlorpyrifos and dialkyl phosphate is associated with an increased risk; however, the evidence is not conclusive.[83] Exposure to tobacco smoke during pregnancy can cause problems with central nervous system development and can increase the risk of ADHD.[8][84]

Extreme premature birth, very low birth weight, and extreme neglect, abuse, or social deprivation also increase the risk[8][85] as do certain infections during pregnancy, at birth, and in early childhood. These infections include, among others, various viruses (measles, varicella zoster encephalitis, rubella, enterovirus 71).[86] At least 30% of children with a traumatic brain injury later develop ADHD[87] and about 5% of cases are due to brain damage.[88]

Some studies suggest that in a minority of children, artificial food dyes or preservative may be associated with an increased prevalence of ADHD or ADHD-like symptoms[8][89] but the evidence is weak and may only apply to children with food sensitivities.[89][90][91] The United Kingdom and the European Union have put in place regulatory measures based on these concerns.[92] In a minority of children, intolerances or allergies to certain foods may worsen ADHD symptoms.[93]

Research does not support popular beliefs that ADHD is caused by eating too much refined sugar, watching too much television, parenting, poverty or family chaos; however, they might worsen ADHD symptoms in certain people.[35]

### Society [edit]

The diagnosis of ADHD can represent family dysfunction or a poor educational system rather than an individual problem.[94] Some cases may be explained by increasing academic expectations, with a diagnosis being a method for parents in some countries to get extra financial and educational support for their child.[88] The youngest children in a class have been found to be more likely to be diagnosed as having ADHD possibly due to their being developmentally behind their older classmates.[95][96] Behaviors typical of ADHD occur more commonly in children who have experienced violence and emotional abuse.[19]

The social construct theory of ADHD suggests that because the boundaries between "normal" and "abnormal" behavior are socially constructed, i.e. jointly created and validated by all members of society, and in particular by physicians, parents, and teachers, it then follows that subjective valuations and judgements determine which diagnostic criteria are used and, thus, the number of people affected.[97] This could lead to the situation where the DSM-IV arrives at levels of ADHD three to four times higher than those obtained with the ICD-10.[15] Thomas Szasz, a supporter of this theory, has argued that ADHD was "invented and not discovered."[98][99]

## Pathophysiology [edit]

Current models of ADHD suggest that it is associated with functional impairments in some of the brain's neurotransmitter systems, particularly those involving dopamine and norepinephrine.[100][101] The dopamine and norepinephrine pathways that originate in the ventral tegmental area and locus coeruleus project to diverse regions of the brain and govern a variety of cognitive processes.[100][102] The dopamine pathways and norepinephrine pathways which project to the prefrontal cortex and striatum are directly responsible for modulating executive function (cognitive control of behavior), motivation, reward perception, and motor function;[100][101][102] these pathways are known to play a central role in the pathophysiology of ADHD.[100][102][103][104] Larger models of ADHD with additional pathways have been proposed.[101][103][104]

### Brain structure [edit]

In children with ADHD, there is a general reduction of volume in certain brain structures, with a proportionally greater decrease in the volume in the left-sided prefrontal cortex.[101][105] The posterior parietal cortex also shows thinning in ADHD individuals compared to controls.[101] Other brain structures in the prefrontal-striatal-cerebellar and prefrontal-striatal-thalamic circuits have also been found to differ between people with and without ADHD.[101][103][104]

### Neurotransmitter pathways [edit]

Previously it was thought that the elevated number of dopamine transporters in people with ADHD was part of the pathophysiology but it appears that the elevated numbers are due to adaptation to exposure to stimulants.[106] Current models involve the mesocorticolimbic dopamine pathway and the locus coeruleus-noradrenergic

system.[100][101][102] ADHD psychostimulants possess treatment efficacy because they increase neurotransmitter activity in these systems.[101][102][107] There may additionally be abnormalities in serotoninergic, glutamatergic, or cholinergic pathways.[107][108][109]

### Executive function and motivation [edit]

The symptoms of ADHD arise from a deficiency in certain executive functions (e.g., attentional control, inhibitory control, and working memory).[56][101][102][110] Executive functions are a set of cognitive processes that are required to successfully select and monitor behaviors that facilitate the attainment of one's chosen goals.[56][102][110] The executive function impairments that occur in ADHD individuals result in problems with staying organized, time keeping, excessive procrastination, maintaining concentration, paying attention, ignoring distractions, regulating emotions, and remembering details.[56][101][102] People with ADHD appear to have unimpaired long-term memory, and deficits in long-term recall appear to be attributed to impairments in working memory.[56][111] The criteria for an executive function deficit are met in 30–50% of children and adolescents with ADHD.[112] One study found that 80% of individuals with ADHD were impaired in at least one executive function task, compared to 50% for individuals without ADHD.[113] Due to the rates of brain maturation and the increasing demands for executive control as a person gets older, ADHD impairments may not fully manifest themselves until adolescence or even early adulthood.[56]

ADHD has also been associated with motivational deficits in children.[114] Children with ADHD find it difficult to focus on long-term over short-term rewards, and exhibit impulsive behavior for short-term rewards.[114]

## Diagnosis [edit]

ADHD is diagnosed by an assessment of a person's childhood behavioral and mental development, including ruling out the effects of drugs, medications and other medical or psychiatric problems as explanations for the symptoms.[19] It often takes into account feedback from parents and teachers[6] with most diagnoses begun after a teacher raises concerns.[88] It may be viewed as the extreme end of one or more continuous human traits found in all people.[19] Whether someone responds to medications does not confirm or rule out the diagnosis. As imaging studies of the brain do not give consistent results between individuals, they are only used for research purposes and not diagnosis.[115]

In North America, DSM-5 criteria are used for diagnosis, while European countries usually use the ICD-10. With the DSM-IV criteria a diagnosis of ADHD is 3–4 times more likely than with the ICD-10 criteria.[15] It is classified as neurodevelopmental psychiatric disorder.[2][16] Additionally, it is classified as a disruptive behavior disorder along with oppositional defiant disorder, conduct disorder, and antisocial personality disorder.[116] A diagnosis does not imply a neurological disorder.[19]

Associated conditions that should be screened for include anxiety, depression, oppositional defiant disorder, conduct disorder, and learning and language disorders. Other conditions that should be considered are other neurodevelopmental disorders, tics, and sleep apnea.[117]

Diagnosis of ADHD using quantitative electroencephalography (QEEG) is an ongoing area of investigation, although the value of QEEG in ADHD is currently unclear.[118][119] In the United States, the Food and Drug Administration has approved the use of QEEG to evaluate the morbidity of ADHD.[120]

Self-rating scales, such as the ADHD rating scale and the Vanderbilt ADHD diagnostic rating scale are used in the screening and evaluation of ADHD.[121]

### Diagnostic and Statistical Manual [edit]

As with many other psychiatric disorders, formal diagnosis should be made by a qualified professional based on a set number of criteria. In the United States, these criteria are defined by the American Psychiatric Association in the DSM. Based on the DSM criteria, there are three sub-types of ADHD:[4]

1. ADHD predominantly inattentive type (ADHD-PI) presents with symptoms including being easily distracted, forgetful, daydreaming, disorganization, poor concentration, and difficulty completing tasks.[5][4]
2. ADHD, predominantly hyperactive-impulsive type presents with excessive fidgetiness and restlessness, hyperactivity, difficulty waiting and remaining seated, immature behavior; destructive behaviors may also be present.[5][4]
3. ADHD, combined type is a combination of the first two subtypes.[5][4]

This subdivision is based on presence of at least six out of nine long-term (lasting at least six months) symptoms of inattention, hyperactivity–impulsivity, or both.[122] To be considered, the symptoms must have appeared by the age of six to twelve and occur in more than one environment (e.g. at home and at school or work).[5] The symptoms must be not appropriate for a child of that age[5][123] and there must be evidence that it is causing social, school or work related problems.[122]

## International Classification of Diseases [edit]

In the ICD-10, the symptoms of "hyperkinetic disorder" are analogous to ADHD in the DSM-5. When a conduct disorder (as defined by ICD-10)[41] is present, the condition is referred to as *hyperkinetic conduct disorder*. Otherwise, the disorder is classified as *disturbance of activity and attention*, *other hyperkinetic disorders* or *hyperkinetic disorders, unspecified*. The latter is sometimes referred to as *hyperkinetic syndrome*.[41]

In the preliminary draft for ICD-11 (planned for 2018), ADHD is classified under 6A42 *(Attention deficit hyperactivity disorder)* and everything seems to be fully identical now to DSM-5.[124]

## Adults [edit]

*Main article: Adult attention deficit hyperactivity disorder*

Adults with ADHD are diagnosed under the same criteria, including that their signs must have been present by the age of six to twelve. Questioning parents or guardians as to how the person behaved and developed as a child may form part of the assessment; a family history of ADHD also adds weight to a diagnosis.[16] While the core symptoms of ADHD are similar in children and adults they often present differently in adults than in children, for example excessive physical activity seen in children may present as feelings of restlessness and constant mental activity in adults.[16]

It is estimated that between 2–5% of adults have ADHD.[16] Around 25-50% of children with ADHD continue to experience ADHD symptoms into adulthood, while the rest experiences fewer or no symptoms.[4][16] Currently, most adults remain untreated.[125] Many adults with ADHD without diagnosis and treatment have a disorganized life and some use non-prescribed drugs or alcohol as a coping mechanism.[25] Other problems may include relationship and job difficulties, and an increased risk of criminal activities.[16] Associated mental health problems include: depression, anxiety disorder, and learning disabilities.[25]

Some ADHD symptoms in adults differ from those seen in children. While children with ADHD may climb and run about excessively, adults may experience an inability to relax, or they talk excessively in social situations. Adults with ADHD may start relationships impulsively, display sensation-seeking behavior, and be short-tempered. Addictive behavior such as substance abuse and gambling are common. The DSM-V criteria do specifically deal with adults, unlike those in DSM-IV, which were criticized for not being appropriate for adults; those who presented differently may lead to the claim that they outgrew the diagnosis.[16]

## Differential diagnosis [edit]

Symptoms of ADHD such as low mood and poor self-image, mood swings, and irritability can be confused with dysthymia, cyclothymia or bipolar disorder as well as with borderline personality disorder.[16] Some symptoms that are due to anxiety disorders, antisocial personality disorder, developmental disabilities or mental retardation or the effects of substance abuse such as intoxication and

These disorders can also sometimes occur along with ADHD. Medical conditions which can cause ADHD type symptoms include: hyperthyroidism, seizure disorder, lead toxicity, hearing deficits, hepatic disease, sleep apnea, drug interactions, untreated celiac disease, and head injury.[25][60]

Primary sleep disorders may affect attention and behavior and the symptoms of ADHD may affect sleep.[127] It is thus recommended that children with ADHD be regularly assessed for sleep problems.[128] Sleepiness in children may result in symptoms ranging from the classic ones of yawning and rubbing the eyes, to hyperactivity and inattentiveness.[129] Obstructive sleep apnea can also cause ADHD type symptoms.[129]

### Biomarker research [edit]

Reviews of ADHD biomarkers have noted that platelet monoamine oxidase expression, urinary norepinephrine, urinary MHPG, and urinary phenethylamine levels consistently differ between ADHD individuals and healthy control.[130][131] These measurements could potentially serve as diagnostic biomarkers for ADHD, but more research is needed to establish their diagnostic utility.[131] Urinary and blood plasma phenethylamine concentrations are lower in ADHD individuals relative to controls and the two most commonly prescribed drugs for ADHD, amphetamine and methylphenidate, increase phenethylamine biosynthesis in treatment-responsive individuals with ADHD.[71][130][131] Lower urinary phenethylamine concentrations are also associated with symptoms of inattentiveness in ADHD individuals.[131]

## Management [edit]

*Main article: Attention deficit hyperactivity disorder management*

The management of ADHD typically involves counseling or medications either alone or in combination. While treatment may improve long-term outcomes, it does not get rid of negative outcomes entirely.[132] Medications used include stimulants, atomoxetine, alpha-2 adrenergic receptor agonists, and sometimes antidepressants.[48][107] In those who have trouble focussing on long-term rewards, a large amount of positive reinforcement improves task performance.[114] ADHD stimulants also improve persistence and task performance in children with ADHD.[101][114]

### Behavioral therapies [edit]

There is good evidence for the use of behavioral therapies in ADHD and they are the recommended first line treatment in those who have mild symptoms or are preschool-aged.[133][134] Psychological therapies used include: psychoeducational input, behavior therapy, cognitive behavioral therapy (CBT), interpersonal psychotherapy, family therapy, school-based interventions, social skills training, behavioral peer intervention, organization training,[135] parent management training,[19] and neurofeedback.[136] Behavior modification and neurofeedback have the best support.[137]

Parent training and education have been found to have short-term benefits.[138][139] There is little high quality research on the effectiveness of family therapy for ADHD, but the evidence that exists shows that it is similar to community care and better than a placebo.[140] Several ADHD specific support groups exist as informational sources and may help families cope with ADHD.[141]

Training in social skills, behavioral modification and medication may have some limited beneficial effects. The most important factor in reducing later psychological problems, such as major depression, criminality, school failure, and substance use disorders is formation of friendships with people who are not involved in delinquent activities.[142]

Regular physical exercise, particularly aerobic exercise, is an effective add-on treatment for ADHD in children and adults, particularly when combined with stimulant medication, although the best intensity and type of aerobic exercise for improving symptoms are not currently known.[143][144][145] In particular, the long-term effects of regular aerobic exercise in ADHD individuals include better behavior and motor abilities, improved executive functions (including attention, inhibitory control, and planning, among other cognitive domains), faster information processing speed, and better memory.[143][144][145] Parent-teacher ratings of behavioral and socio-emotional outcomes in response to regular aerobic exercise include: better overall function, reduced ADHD symptoms, better self-esteem, reduced levels of anxiety and depression, fewer somatic complaints, better academic and classroom behavior, and improved social behavior.[143] Exercising while on stimulant medication augments the effect of [143]

stimulant medication on executive function. It is believed that these short-term effects of exercise are mediated by an increased abundance of synaptic dopamine and norepinephrine in the brain.[143]

## Medication [edit]

Stimulant medications are the pharmaceutical treatment of choice.[146][147] They have at least some effect on symptoms in the short term in about 80% of people.[24] Methylphenidate appears to improve symptoms as reported by teachers and parents.[148] Stimulants may also reduce the risk of injuries in children with ADHD.[149]

Methylphenidate (Ritalin) 10 mg tablets

There are a number of non-stimulant medications, such as atomoxetine, bupropion, guanfacine, and clonidine that may be used as alternatives, or added to stimulant therapy.[146][150] There are no good studies comparing the various medications; however, they appear more or less equal with respect to side effects.[151] Stimulants appear to improve academic performance while atomoxetine does not.[152] Atomoxetine, due to its lack of addiction liability, may be preferred in those who are at risk of recreational or compulsive stimulant use.[16] There is little evidence on the effects of medication on social behaviors.[151] As of June 2015, the long-term effects of ADHD medication have yet to be fully determined.[153][154] Magnetic resonance imaging studies suggest that long-term treatment with amphetamine or methylphenidate decreases abnormalities in brain structure and function found in subjects with ADHD.[155][156][157]

Guidelines on when to use medications vary by country, with the United Kingdom's National Institute for Health and Care Excellence recommending use for children only in severe cases, though for adults medication is a first-line treatment, while most United States guidelines recommend medications in most age groups.[20] Medications are not recommended for preschool children.[19][158] Underdosing of stimulants may occur and result in a lack of response or later loss of effectiveness.[159] This is particularly common in adolescents and adults as approved dosing is based on school-aged children, causing some practitioners to use weight based or benefit based off-label dosing instead.[160][161][162]

While stimulants and atomoxetine are usually safe, there are side-effects and contraindications to their use.[146] A large overdose on ADHD stimulants is commonly associated with symptoms such as stimulant psychosis and mania;[163] although very rare, at therapeutic doses these events appear to occur in approximately 0.1% of individuals within the first several weeks after starting amphetamine or methylphenidate therapy.[164][163][165] Administration of an antipsychotic medication has been found to effectively resolve the symptoms of acute amphetamine psychosis.[163] Regular monitoring has been recommended in those on long-term treatment.[166] Stimulant therapy should be stopped periodically to assess continuing need for medication, decrease possible growth delay, and reduce tolerance.[167][168] Long-term misuse of stimulant medications at doses above the therapeutic range for ADHD treatment is associated with addiction and dependence.[169][170] Untreated ADHD, however, is also associated with elevated risk of substance use disorders and conduct disorders.[169] The use of stimulants appears to either reduce this risk or have no effect on it.[16][153][169] The safety of these medications in pregnancy is unclear.[171]

## Diet [edit]

Dietary modifications may be of benefit to a small proportion of children with ADHD.[172] A 2013 meta-analysis found less than a third of children with ADHD see some improvement in symptoms with free fatty acid supplementation or decreased eating of artificial food coloring.[90] These benefits may be limited to children with food sensitivities or those who are simultaneously being treated with ADHD medications.[90] This review also found that evidence does not support removing other foods from the diet to treat ADHD.[90] A 2014 review found that an elimination diet results in a small overall benefit.[93] A 2016 review stated that the use of a gluten-free diet as standard ADHD treatment is discouraged.[60] Iron, magnesium and iodine may also have an effect on ADHD symptoms.[173] There is a small amount of evidence that lower tissue zinc levels may be associated with ADHD.[174] In the absence of a demonstrated zinc deficiency (which is rare outside of developing countries), zinc supplementation is not recommended as treatment for ADHD.[175] However, zinc supplementation may reduce the minimum effective dose of amphetamine when it is used with amphetamine for the treatment of ADHD.[176] There

is evidence of a modest benefit of omega 3 fatty acid supplementation, but it is not recommended in place of traditional medication.[177][178]

## Prognosis [edit]

An 8-year follow up of children diagnosed with ADHD (combined type) found that they often have difficulties in adolescence, regardless of treatment or lack thereof.[179] In the USA, fewer than 5% of individuals with ADHD get a college degree,[180] compared to 28% of the general population aged 25 years and older.[181] The proportion of children meeting criteria for ADHD drops by about half in the three years following the diagnosis and this occurs regardless of treatments used.[182][183] ADHD persists into adulthood in about 30–50% of cases.[17] Those affected are likely to develop coping mechanisms as they mature, thus compensating to some extent for their previous symptoms.[25]

## Epidemiology [edit]

*Main article: Epidemiology of attention deficit hyperactive disorder*

ADHD is estimated to affect about 6–7% of people aged 18 and under when diagnosed via the DSM-IV criteria.[9] When diagnosed via the ICD-10 criteria rates in this age group are estimated at 1–2%.[10] Children in North America appear to have a higher rate of ADHD than children in Africa and the Middle East; this is believed to be due to differing methods of diagnosis rather than a difference in underlying frequency.[184] If the same diagnostic methods are used, the rates are more or less the same between countries.[12] It is diagnosed approximately three times more often in boys than in girls.[14][15] This difference between sexes may reflect either a difference in susceptibility or that females with ADHD are less likely to be diagnosed than males.[185]

Rates of diagnosis and treatment have increased in both the United Kingdom and the United States since the 1970s.[186] This is believed to be primarily due to changes in how the condition is diagnosed[186] and how readily people are willing to treat it with medications rather than a true change in how common the condition is.[10] It is believed that changes to the diagnostic criteria in 2013 with the release of the DSM-5 will increase the percentage of people diagnosed with ADHD, especially among adults.[187]

## History [edit]

*Main article: History of attention deficit hyperactivity disorder*

Hyperactivity has long been part of the human condition. Sir Alexander Crichton describes "mental restlessness" in his book *An inquiry into the nature and origin of mental derangement* written in 1798.[188][189] ADHD was first clearly described by George Still in 1902.[186]

The terminology used to describe the condition has changed over time and has included: in the DSM-I (1952) "minimal brain dysfunction", in the DSM-II (1968) "hyperkinetic reaction of childhood", in the DSM-III (1980) "attention-deficit disorder (ADD) with or without hyperactivity".[186] In 1987 this was changed to ADHD in the DSM-III-R and the DSM-IV in 1994 split the diagnosis into three subtypes, ADHD inattentive type, ADHD hyperactive-impulsive type and ADHD combined type.[190] These terms were kept in the DSM-5 in 2013.[4] Other terms have included "minimal brain damage" used in the 1930s.[191]

The use of stimulants to treat ADHD was first described in 1937.[192] In 1934, Benzedrine became the first amphetamine medication approved for use in the United States.[193] Methylphenidate was introduced in the 1950s, and enantiopure dextroamphetamine in the 1970s.[186]

## Society and culture [edit]

### Controversies [edit]

*Main article: Attention deficit hyperactivity disorder controversies*

ADHD, its diagnosis, and its treatment have been controversial since the 1970s.[27][28][194] The controversies involve clinicians, teachers, policymakers, parents, and the media. Positions range from the view that ADHD is within the normal range of behavior[19][195] to the hypothesis that ADHD is a genetic condition.[196] Other areas

of controversy include the use of stimulant medications in children,[28][197] the method of diagnosis, and the possibility of overdiagnosis.[197] In 2012, the National Institute for Health and Care Excellence, while acknowledging the controversy, states that the current treatments and methods of diagnosis are based on the dominant view of the academic literature.[19] In 2014, Keith Conners, one of the early advocates for recognition of the disorder, spoke out against overdiagnosis in a *New York Times* article.[198] In contrast, a 2014 peer-reviewed medical literature review indicated that ADHD is underdiagnosed in adults.[18]

With widely differing rates of diagnosis across countries, states within countries, races, and ethnicities, some suspect factors other than the presence of the symptoms of ADHD are playing a role in diagnosis.[95] Some sociologists consider ADHD to be an example of the medicalization of deviant behavior, that is, the turning of the previously non-medical issue of school performance into a medical one.[27][88] Most healthcare providers accept ADHD as a genuine disorder, at least in the small number of people with severe symptoms.[88] Among healthcare providers the debate mainly centers on diagnosis and treatment in the much greater number of people with less severe symptoms.[30][31][88]

As of 2009, 8% of all United States Major League Baseball players had been diagnosed with ADHD, making the disorder common among this population. The increase coincided with the League's 2006 ban on stimulants, which has raised concern that some players are mimicking or falsifying the symptoms or history of ADHD to get around the ban on the use of stimulants in sport.[199]

## Media commentary [edit]

A number of public figures have given controversial statements regarding ADHD. Tom Cruise has described the medications Ritalin (methylphenidate) and Adderall (a mixed-salt amphetamine formulation) as "street drugs".[200] Ushma S. Neill criticized this view, stating that the doses of stimulants used in the treatment of ADHD do not cause addiction and that there is some evidence of a reduced risk of later substance addiction in children treated with stimulants.[201] In the UK, Susan Greenfield spoke out publicly in 2007 in the House of Lords about the need for a wide-ranging inquiry into the dramatic increase in the diagnosis of ADHD, and possible causes. Her comments followed a BBC *Panorama* program that highlighted research that suggested medications are no better than other forms of therapy in the long term.[202] In 2010, the BBC Trust criticized the 2007 *Panorama* program for summarizing the research as showing "no demonstrable improvement in children's behaviour after staying on ADHD medication for three years" when in actuality "the study found that medication did offer a significant improvement over time" although the long-term benefits of medication were found to be "no better than children who were treated with behavior therapy."[203]

PMID 18473983. "Although there is little direct evidence, changes in trace amines, in particular PE, have been identified as a possible factor for the onset of attention deficit/hyperactivity disorder (ADHD). … Further, amphetamines, which have clinical utility in ADHD, are good ligands at trace amine receptors. Of possible relevance in this aspect is modafanil, which has shown beneficial effects in ADHD patients and has been reported to enhance the activity of PE at TAAR1. Conversely, methylphenidate, …showed poor efficacy at the TAAR1 receptor. In this respect it is worth noting that the enhancement of functioning at TAAR1 seen with modafanil was not a result of a direct interaction with TAAR1."

"DA has multiple actions in the prefrontal cortex. It promotes the "cognitive control" of behavior: the selection and successful monitoring of behavior to facilitate attainment of chosen goals. Aspects of cognitive control in which DA plays a role include working memory, the ability to hold information "on line" in order to guide actions, suppression of prepotent behaviors that compete with goal-directed actions, and control of attention and thus the ability to overcome distractions. Cognitive control is impaired in several disorders, including attention deficit hyperactivity disorder. ... Noradrenergic projections from the LC thus interact with dopaminergic projections from the VTA to regulate cognitive control. ... it has not been shown that 5HT makes a therapeutic contribution to treatment of ADHD."
*NOTE: DA: dopamine, LC: locus coeruleus, VTA: ventral tegmental area, 5HT: serotonin (5-hydroxytryptamine)*

161. ^ Biederman, Joseph (2003). "New-Generation Long-Acting Stimulants for the Treatment of Attention-Deficit/Hyperactivity Disorder". *Medscape*. Retrieved 19 June 2016. "As most treatment guidelines and prescribing information for stimulant medications relate to experience in school-aged children, prescribed doses for older patients are lacking. Emerging evidence for both methylphenidate and Adderall indicate that when weight-corrected daily doses, equipotent with those used in the treatment of younger patients, are used to treat adults with ADHD, these patients show a very robust clinical response consistent with that observed in pediatric studies. These data suggest that older patients may require a more aggressive approach in terms of dosing, based on the same target dosage ranges that have already been established -- for methylphenidate, 1-1.5-2 mg/kg/day, and for D,L-amphetamine, 0.5-0.75-1 mg/kg/day....
In particular, adolescents and adults are vulnerable to underdosing, and are thus at potential risk of failing to receive adequate dosage levels. As with all therapeutic agents, the efficacy and safety of stimulant medications should always guide prescribing behavior: careful dosage titration of the selected stimulant product should help to ensure that each patient with ADHD receives an adequate dose, so that the clinical benefits of therapy can be fully attained."

Rev.* (1): CD003026. doi:10.1002/14651858.CD003026.pub3. PMID 19160215. "A minority of individuals who use amphetamines develop full-blown psychosis requiring care at emergency departments or psychiatric hospitals. In such cases, symptoms of amphetamine psychosis commonly include paranoid and persecutory delusions as well as auditory and visual hallucinations in the presence of extreme agitation. More common (about 18%) is for frequent amphetamine users to report psychotic symptoms that are sub-clinical and that do not require high-intensity intervention ... About 5–15% of the users who develop an amphetamine psychosis fail to recover completely (Hofmann 1983) ... Findings from one trial indicate use of antipsychotic medications effectively resolves symptoms of acute amphetamine psychosis."

# Alcoholism

From Wikipedia, the free encyclopedia

*"Alcoholic" redirects here. For alcoholic beverages, see alcoholic beverage. For the song by Starsailor, see Alcoholic (song).*

**Alcoholism**, also known as **alcohol use disorder** (**AUD**), is a broad term for any drinking of alcohol that results in problems.[1] It was previously divided into two types: alcohol abuse and alcohol dependence.[2][3] In a medical context, alcoholism is said to exist when two or more of the following conditions is present: a person drinks large amounts over a long time period, has difficulty cutting down, acquiring and drinking alcohol takes up a great deal of time, alcohol is strongly desired, usage results in not fulfilling responsibilities, usage results in social problems, usage results in health problems, usage results in risky situations, withdrawal occurs when stopping, and alcohol tolerance has occurred with use.[3] Risky situations include drinking and driving or having unsafe sex among others.[3] Alcohol use can affect all parts of the body but particularly affects the brain, heart, liver, pancreas, and immune system. This can result in mental illness, Wernicke–Korsakoff syndrome, an irregular heart beat, liver failure, and an increase in the risk of cancer, among other diseases.[4][5] Drinking during pregnancy can cause damage to the baby resulting in fetal alcohol spectrum disorders.[6] Generally women are more sensitive to alcohol's harmful physical and mental effects than men.[7]

Both environmental factors and genetics are associated with alcoholism with about half the risk attributed to each. A person with a parent or sibling with alcoholism is three to four times more likely to be alcoholic themselves.[4] Environmental factors include social, cultural, and behavioral influences.[8] High stress levels, anxiety, as well as inexpensive easily accessible alcohol increases risk.[4][9] People may continue to drink partly to prevent or improve symptoms of withdrawal. A low level of withdrawal may last for months following stopping.[9] Medically, alcoholism is considered both a physical and mental illness.[10][11] Both questionnaires and certain blood tests may detect people with possible alcoholism. Further information is then collected to confirm the diagnosis.[4]

Prevention of alcoholism is possible by regulating and limiting

the sale of alcohol, taxing alcohol to increase its cost, and providing inexpensive treatment.[12] Treatment may take several steps. Because of the medical problems that can occur during withdrawal, alcohol detoxification should be carefully controlled. One common method involves the use of benzodiazepine medications, such as diazepam. This can be either given while admitted to a health care institution or occasionally while a person remains in the community with close supervision.[13] Other addictions or mental illness may complicate treatment.[14] After detoxification support such as group therapy or support groups are used to help keep a person from returning to drinking.[15][16] One commonly used form of support is the group Alcoholics Anonymous.[17] The medications acamprosate, disulfiram, or naltrexone may also be used to help prevent further drinking.[18]

The World Health Organization estimates that as of 2010 there were 208 million people with alcoholism worldwide (4.1% of the population over 15 years of age).[7][19] In the United States about 17 million (7%) of adults and 0.7 million (2.8%) of those age 12 to 17 years of age are affected.[20] It is more common among males and young adults, becoming less common in middle and old age.[4] It is the least common in Africa at 1.1% and has the highest rates in Eastern Europe at 11%.[4] Alcoholism directly resulted in 139,000 deaths in 2013 up from 112,000 deaths in 1990.[21] A total of 3.3 million deaths (5.9% of all deaths) are believed to be due to alcohol.[20] It often reduces a person's life expectancy by around ten years.[22] In the United States it resulted in economic costs of $224 billion USD in 2006.[20] Many terms, some insulting and others informal, have been used to refer to people affected by alcoholism including: tippler, drunkard, dipsomaniac, and souse.[23] In 1979, the World Health Organization discouraged the use of "alcoholism" due to its inexact meaning, preferring "alcohol dependence syndrome".[24]

# Signs and symptoms

*See also: long-term effects of alcohol*

## Early signs

The risk of alcohol dependence begins at low levels of drinking and increases directly with both the volume of alcohol consumed and a pattern of drinking larger amounts on an occasion, to the point of intoxication, which is sometimes called "binge drinking". Young adults are particularly at risk of engaging in binge drinking.

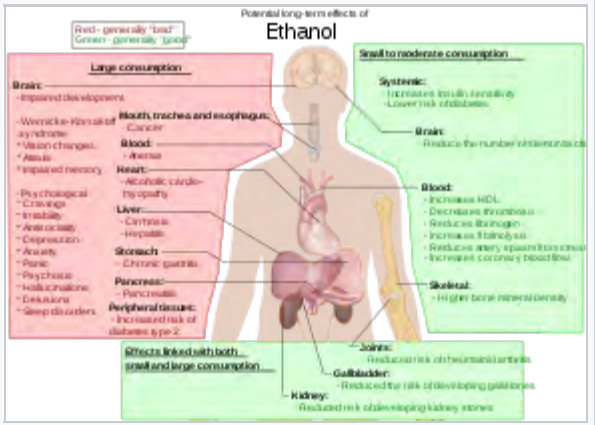
Effects of alcohol on the body

## Long-term misuse

Alcoholism is characterised by an increased tolerance to alcohol–which means that an individual can consume more alcohol–and physical dependence on alcohol, which makes it hard for an individual to control their consumption. The physical dependency caused by alcohol can lead to an affected individual having a very strong urge to drink alcohol. These characteristics play a role decreasing an alcoholic's ability to stop drinking.[25] Alcoholism can have adverse effects on mental health, causing psychiatric disorders and increasing the risk of suicide. A depressed mood is a common symptom of heavy alcohol drinkers.[26][27]



Some of the possible long-term effects of ethanol an individual may develop. Additionally, in pregnant women, alcohol can cause fetal alcohol syndrome.

## Warning signs

Warning signs of alcoholism include the consumption of increasing amounts of alcohol and frequent intoxication, preoccupation with drinking to the exclusion of other activities, promises to quit drinking and failure to keep them, the inability to remember what was said or done while drinking (colloquially known as "blackouts"), personality changes associated with drinking, denial or the making of excuses for drinking, the refusal to admit excessive drinking, dysfunction or other problems at work and/or school, the loss of interest in personal appearance or hygiene, marital and economic problems, and the complaint of poor health, with loss of appetite, respiratory infections, or increased anxiety.[28]

## Physical

### Short-term effects

*Main article: Short-term effects of alcohol*

Drinking enough to cause a blood alcohol concentration (BAC) of 0.03–0.12% typically causes an overall improvement in mood and possible euphoria (a "happy" feeling), increased self-confidence and sociability, decreased anxiety, a flushed, red appearance in the face and impaired judgment and fine muscle coordination. A BAC of 0.09% to 0.25% causes lethargy, sedation, balance problems and blurred vision. A BAC from 0.18% to 0.30% causes profound confusion, impaired speech (e.g., slurred speech), staggering, dizziness and vomiting. A BAC from 0.25% to 0.40% causes stupor, unconsciousness, anterograde amnesia,

vomiting (death may occur due to inhalation of vomit (pulmonary aspiration) while unconscious and respiratory depression (potentially life-threatening). A BAC from 0.35% to 0.80% causes a coma (unconsciousness), life-threatening respiratory depression and possibly fatal alcohol poisoning. With all alcoholic beverages, drinking while driving, operating an aircraft or heavy machinery increases the risk of an accident; many countries have penalties against drunk driving.

### Long-term effects

*See also: Long-term effects of alcohol consumption*

Drinking more than one drink a day for women or two drinks for men increases the risk of heart disease, high blood pressure, atrial fibrillation, and stroke.[29] Risk is greater in younger people due to binge drinking which may result in violence or accidents.[29] About 3.3 million deaths (5.9% of all deaths) are believed to be due to alcohol each year.[20] Alcoholism reduces a person's life expectancy by around ten years[22] and alcohol use is the third leading cause of early death in the United States.[29] No professional medical association recommends that people who are nondrinkers should start drinking wine.[29][30] Long-term alcohol abuse can cause a number of physical symptoms, including cirrhosis of the liver, pancreatitis, epilepsy, polyneuropathy, alcoholic dementia, heart disease, nutritional deficiencies, peptic ulcers[31] and sexual dysfunction, and can eventually be fatal. Other physical effects include an increased risk of developing cardiovascular disease, malabsorption, alcoholic liver disease, and cancer. Damage to the central nervous system and peripheral nervous system can occur from sustained alcohol consumption.[32][33] A wide range of immunologic defects can result and there may be a generalized skeletal fragility, in addition to a recognized tendency to accidental injury, resulting a propensity to bone fractures.[34]

Women develop long-term complications of alcohol dependence more rapidly than do men. Additionally, women have a higher mortality rate from alcoholism than men.[35] Examples of long-term complications include brain, heart, and liver damage[36] and an increased risk of breast cancer. Additionally, heavy drinking over time has been found to have a negative effect on reproductive functioning in women. This results in reproductive dysfunction such as anovulation, decreased ovarian mass, problems or irregularity of the menstrual cycle, and early menopause.[35] Alcoholic ketoacidosis can occur in individuals who chronically abuse alcohol and have a recent history of binge drinking.[37][38] The amount of alcohol that can be biologically processed and its effects differ between sexes. Equal dosages of alcohol consumed by men and women generally result in women having higher blood alcohol concentrations (BACs), since women generally have a higher percentage of body fat and therefore a lower volume of distribution for alcohol than men, and because the stomachs of men tend to metabolize alcohol more quickly.[39]

## Psychiatric

Long-term misuse of alcohol can cause a wide range of mental health problems. Severe cognitive problems are common; approximately 10 percent of all dementia cases are related to alcohol consumption, making it the second leading cause of dementia.[40] Excessive alcohol use causes damage to brain function, and psychological health can be increasingly affected over time.[41]Social skills are significantly impaired in people suffering from alcoholism due to the neurotoxic effects of alcohol on the brain, especially the prefrontal cortex area of the brain. The social skills that are impaired by alcohol abuse include impairments in perceiving facial emotions, prosody perception problems and theory of mind deficits; the ability to understand humour is also impaired in alcohol abusers.[42] Psychiatric disorders are common in alcoholics, with as many as 25 percent suffering severe psychiatric disturbances. The most prevalent psychiatric symptoms are anxiety and depression disorders. Psychiatric symptoms usually initially worsen during alcohol withdrawal, but typically improve or disappear with continued abstinence.[43] Psychosis, confusion, and organic brain syndrome may be caused by alcohol misuse, which can lead to a misdiagnosis such as schizophrenia.[44] Panic disorder can develop or worsen as a direct result of long-term alcohol misuse.[45][46]

The co-occurrence of major depressive disorder and alcoholism is well documented.[47][48][49] Among those

with comorbid occurrences, a distinction is commonly made between depressive episodes that remit with alcohol abstinence ("substance-induced"), and depressive episodes that are primary and do not remit with abstinence ("independent" episodes).[50][51][52] Additional use of other drugs may increase the risk of depression.[53] Psychiatric disorders differ depending on gender. Women who have alcohol-use disorders often have a co-occurring psychiatric diagnosis such as major depression, anxiety, panic disorder, bulimia, post-traumatic stress disorder (PTSD), or borderline personality disorder. Men with alcohol-use disorders more often have a co-occurring diagnosis of narcissistic or antisocial personality disorder, bipolar disorder, schizophrenia, impulse disorders or attention deficit/hyperactivity disorder (ADHD).[54] Women with alcoholism are more likely to experience physical or sexual assault, abuse and domestic violence than women in the general population,[54] which can lead to higher instances of psychiatric disorders and greater dependence on alcohol.

## Social effects

*See also: Drug-related crime*

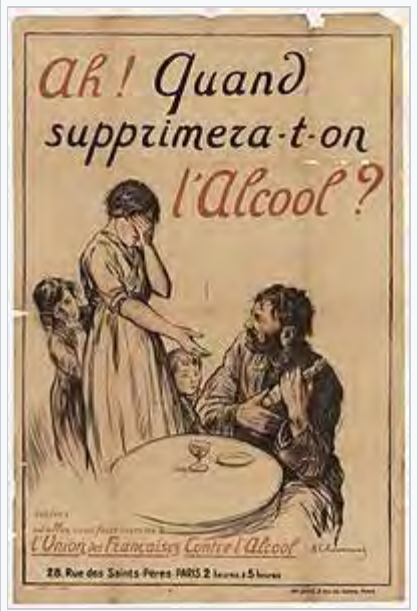
The social problems arising from alcoholism are serious, caused by the pathological changes in the brain and the intoxicating effects of alcohol.[40][55] Alcohol abuse is associated with an increased risk of committing criminal offences, including child abuse, domestic violence, rape, burglary and assault.[56] Alcoholism is associated with loss of employment,[57] which can lead to financial problems. Drinking at inappropriate times, and behavior caused by reduced judgment, can lead to legal consequences, such as criminal charges for drunk driving[58] or public disorder, or civil penalties for tortious behavior, and may lead to a criminal sentence. An alcoholic's behavior and mental impairment, while drunk, can profoundly affect those surrounding them and lead to isolation from family and friends. This isolation can lead to marital conflict and divorce, or contribute to domestic violence. Alcoholism can also lead to child neglect, with subsequent lasting damage to the emotional development of the alcoholic's children.[59] For this reason, children of alcoholic parents can develop a number of emotional problems. For example, they can become afraid of their parents, because of their unstable mood behaviors. In addition, they can develop considerable amount of shame over their inadequacy to liberate their parents from alcoholism. As a result of this failure, they develop wretched self-images, which can lead to depression.[60]

## Alcohol withdrawal

*Main article: Alcohol withdrawal syndrome*
*See also: Kindling (sedative-hypnotic withdrawal)*

As with similar substances with a sedative-hypnotic mechanism, such as barbiturates and benzodiazepines, withdrawal from alcohol dependence can be fatal if it is not properly managed.[55][61] Alcohol's primary effect is the increase in stimulation of the $GABA_A$ receptor, promoting central nervous system depression. With repeated heavy consumption of alcohol, these receptors are desensitized and reduced in number, resulting in tolerance and physical dependence. When alcohol consumption is stopped too abruptly, the person's nervous system suffers from uncontrolled synapse firing. This can result in symptoms that include anxiety, life-threatening seizures, delirium tremens, hallucinations, shakes and possible heart failure.[62][63] Other neurotransmitter systems are also involved, especially dopamine, NMDA and glutamate.[25][64]

Severe acute withdrawal symptoms such as delirium tremens and seizures rarely occur after 1-week post cessation of alcohol. The acute withdrawal phase can be defined as lasting between one and three weeks. In the period of 3 – 6 weeks following cessation increased anxiety, depression, as well as sleep disturbance, is common;[65] fatigue and tension can persist for up to 5 weeks as part of the post-acute withdrawal syndrome; about a quarter of alcoholics experience anxiety and depression for up to 2 years.



A French temperance poster

from the Union des Françaises contre l'Alcool (this translates as "Union of French People Against Alcohol"). The poster states "Ah! Quand supprimera-t'on l'alcool?", which translates as "Ah! When will we [the nation] abolish alcohol?"

These post-acute withdrawal symptoms have also been demonstrated in animal models of alcohol dependence and withdrawal.[66] A kindling effect also occurs in alcoholics whereby each subsequent withdrawal syndrome is more severe than the previous withdrawal episode; this is due to neuroadaptations which occur as a result of periods of abstinence followed by re-exposure to alcohol. Individuals who have had multiple withdrawal episodes are more likely to develop seizures and experience more severe anxiety during withdrawal from alcohol than alcohol-dependent individuals without a history of past alcohol withdrawal episodes. The kindling effect leads to persistent functional changes in brain neural circuits as well as to gene expression.[67] Kindling also results in the intensification of psychological symptoms of alcohol withdrawal.[65] There are decision tools and questionnaires which help guide physicians in evaluating alcohol withdrawal. For example, the CIWA-Ar objectifies alcohol withdrawal symptoms in order to guide therapy decisions which allows for an efficient interview while at the same time retaining clinical usefulness, validity, and reliability, ensuring proper care for withdrawal patients, who can be in danger of death.[68]

# Causes

William Hogarth's *Gin Lane*, 1751

A complex mixture of genetic and environmental factors influences the risk of the development of alcoholism.[69] Genes that influence the metabolism of alcohol also influence the risk of alcoholism, and may be indicated by a family history of alcoholism.[70] One paper has found that alcohol use at an early age may influence the expression of genes which increase the risk of alcohol dependence.[71] Individuals who have a genetic disposition to alcoholism are also more likely to begin drinking at an earlier age than average.[72] Also, a younger age of onset of drinking is associated with an increased risk of the development of alcoholism,[72] and about 40 percent of alcoholics will drink excessively by their late adolescence. It is not entirely clear whether this association is causal, and some researchers have been known to disagree with this view.[73]

Severe childhood trauma is also associated with a general increase in the risk of drug dependency.[69] Lack of peer and family support is associated with an increased risk of alcoholism developing.[69] Genetics and adolescence are associated with an increased sensitivity to the neurotoxic effects of chronic alcohol abuse. Cortical degeneration due to the neurotoxic effects increases impulsive behaviour, which may contribute to the development, persistence and severity of alcohol use disorders. There is evidence that with abstinence, there is a reversal of at least some of the alcohol induced central nervous system damage.[74] The use of cannabis was associated with later problems with alcohol use.[75] Alcohol use was associated with an increased probability of later use of tobacco, cannabis, and other illegal drugs.[76]

## Availability

Alcohol is the most available, widely consumed, and widely abused recreational drug. Beer alone is the world's most widely consumed[77] alcoholic beverage; it is the third-most popular drink overall, after water and tea.[78] It is thought by some to be the oldest fermented beverage.[79][80][81][82]

## Gender difference

Based on combined data from SAMHSA's 2004–2005 National Surveys on Drug Use & Health, the rate of past-year alcohol dependence or abuse among persons aged 12 or older varied by level of alcohol use: 44.7% of past month heavy drinkers, 18.5% binge drinkers, 3.8% past month non-binge drinkers, and

1.3% of those who did not drink alcohol in the past month met the criteria for alcohol dependence or abuse in the past year. Males had higher rates than females for all measures of drinking in the past month: any alcohol use (57.5% vs. 45%), binge drinking (30.8% vs. 15.1%), and heavy alcohol use (10.5% vs. 3.3%), and males were twice as likely as females to have met the criteria for alcohol dependence or abuse in the past year (10.5% vs. 5.1%).[83]

### Genetic variation

*See also: Human genetic variation*

Genetic differences exist between different racial groups which affect the risk of developing alcohol dependence. For example, there are differences between African, East Asian and Indo-racial groups in how they metabolize alcohol. These genetic factors are believed to, in part, explain the differing rates of alcohol dependence among racial groups.[84][85] The alcohol dehydrogenase allele ADH1 B*3 causes a more rapid metabolism of alcohol. The allele ADH1 B*3 is only found in those of African descent and certain Native American tribes. African Americans and Native Americans with this allele have a reduced risk of developing alcoholism.[86] Native Americans however, have a significantly higher rate of alcoholism than average; it is unclear why this is the case.[87] Other risk factors such as cultural environmental effects e.g. trauma have been proposed to explain the higher rates of alcoholism among Native Americans compared to alcoholism levels in caucasians.[88][89]

## Diagnosis

*See also: Addiction medicine*

### Definition

Misuse, problem use, abuse, and heavy use of alcohol refer to improper use of alcohol which may cause physical, social, or moral harm to the drinker.[90] Moderate use is defined by *The Dietary Guidelines for Americans* as no more than two alcoholic beverages a day for men and no more than one alcoholic beverage a day for women.[91] Some drinkers may drink more than 600 ml of alcohol per day during a heavy drinking period.[92] The National Institute on Alcohol Abuse and Alcoholism (NIAAA) defines binge drinking as the amount of alcohol leading to a blood alcohol content (BAC) of 0.08, which, for most adults, would be reached by consuming five drinks for men or four for women over a two-hour period. According to the NIAAA, men may be at risk for alcohol-related problems if their alcohol consumption exceeds 14 standard drinks per week or 4 drinks per day, and women may be at risk if they have more than 7 standard drinks per week or 3 drinks per day. It defines a standard drink as one 12-ounce bottle of beer, one 5-ounce glass of wine, or 1.5 ounces of distilled spirits.[93] Despite this risk, a 2014 report in the National Survey on Drug Use and Health found that only 10% of either "heavy drinkers" or "binge drinkers" defined according to the above criteria also met the criteria for alcohol dependence, while only 1.3% of non-binge drinkers met this criteria. An inference drawn from this study is that evidence-based policy strategies and clinical preventive services may effectively reduce binge drinking without requiring addiction treatment in most cases.[94]

A picture of a man drinking from a bottle of alcohol while sitting on a boardwalk, ca. 1905-1914. Picture by Austrian photographer Emil Mayer.

### Alcoholism

The term *alcoholism* is commonly used amongst laypeople, but it is poorly defined. The WHO calls *alcoholism* "a term of long-standing use and variable meaning", and use of the term was disfavored by a 1979 WHO expert committee. *The Big Book* (from Alcoholics Anonymous) states that once a person is an

alcoholic, they are always an alcoholic, but does not define what is meant by the term *alcoholic* in this context. In 1960, Bill W., co-founder of Alcoholics Anonymous (AA), said:

> We have never called alcoholism a disease because, technically speaking, it is not a disease entity. For example, there is no such thing as heart disease. Instead there are many separate heart ailments, or combinations of them. It is something like that with alcoholism. Therefore we did not wish to get in wrong with the medical profession by pronouncing alcoholism a disease entity. Therefore we always called it an illness, or a malady—a far safer term for us to use.[95] In professional and research contexts, the term "alcoholism" sometimes encompasses both alcohol abuse and alcohol dependence,[96] and sometimes is considered equivalent to alcohol dependence. Talbot (1989) observes that alcoholism in the classical disease model follows a progressive course: if a person continues to drink, their condition will worsen. This will lead to harmful consequences in their life, physically, mentally, emotionally and socially.[97]

## Johnson's typologies

Johnson (1980) explores the emotional progression of the addict's response to alcohol. He looks at this in four phases. The first two are considered "normal" drinking and the last two are viewed as "typical" alcoholic drinking.[98][99] Johnson's four phases consist of:

1. Learning the mood swing. A person is introduced to alcohol (in some cultures this can happen at a relatively young age), and the person enjoys the happy feeling it produces. At this stage there is no emotional cost.
2. Seeking the mood swing. A person will drink to regain that feeling of euphoria experienced in phase 1; the drinking will increase as more intoxication is required to achieve the same effect. Again at this stage, there are no significant consequences.
3. At the third stage there are physical and social consequences, i.e., hangovers, family problems, work problems, etc. A person will continue to drink excessively, disregarding the problems.
4. The fourth stage can be detrimental, as Johnson cites it as a risk for premature death. As a person now drinks to feel normal, they block out the feelings of overwhelming guilt, remorse, anxiety, and shame they experience when sober.[100]

## Milam & Ketcham's physical deterioration stages

Other theorists such as Milam & Ketcham (1983) focus on the physical deterioration that alcohol consumption causes. They describe the process in three stages:

1. Adaptive stage – The person will not experience any negative symptoms, and they believe they have capacity for drinking alcohol without problems. Physiological changes are happening with the increase in tolerance, but this will not be noticeable to the drinker or others.
2. Dependent stage – At this stage, symptoms build up gradually. Hangover symptoms from excessive drinking may be confused with withdrawal symptoms. Many addicts will maintain their drinking to avoid withdrawal sickness, drinking small amounts frequently. They will try to hide their drinking problem from others, and will avoid gross intoxication.
3. Deterioration stage – Various organs are damaged due to long-term drinking. Medical treatment in a rehabilitation center will be required; otherwise the pathological changes will cause death.

## DSM and ICD

In psychology and psychiatry, the DSM is the most common global standard, while in medicine, the standard is ICD. The terms they recommend are similar but not identical.

| Organization | Preferred term(s) | Definition |
|---|---|---|
| | "alcohol | ▪ alcohol abuse = repeated use despite recurrent adverse consequences.[101]<br>▪ alcohol dependence = *alcohol abuse* combined with tolerance, |

| | | |
|---|---|---|
| APA's DSM-IV | abuse" and "alcohol dependence" | withdrawal, and an uncontrollable drive to drink.[101] The term "alcoholism" was split into "alcohol abuse" and "alcohol dependence" in 1980's DSM-III, and in 1987's DSM-III-R behavioral symptoms were moved from "abuse" to "dependence".[102] It has been suggested that DSM-V merge alcohol abuse and alcohol dependence into a single new entry,[103] named "alcohol-use disorder".[104] |
| WHO's ICD-10 | "alcohol harmful use" and "alcohol dependence syndrome" | Definitions are similar to that of the DSM-IV. The World Health Organisation uses the term "alcohol dependence syndrome" rather than alcoholism.[24] The concept of "harmful use" (as opposed to "abuse") was introduced in 1992's ICD-10 to minimize underreporting of damage in the absence of dependence.[102] The term "alcoholism" was removed from ICD between ICD-8/ICDA-8 and ICD-9.[105] |

The DSM-IV diagnosis of alcohol dependence represents one approach to the definition of alcoholism. In part, this is to assist in the development of research protocols in which findings can be compared to one another. According to the DSM-IV, an alcohol dependence diagnosis is: "maladaptive alcohol use with clinically significant impairment as manifested by at least three of the following within any one-year period: tolerance; withdrawal; taken in greater amounts or over longer time course than intended; desire or unsuccessful attempts to cut down or control use; great deal of time spent obtaining, using, or recovering from use; social, occupational, or recreational activities given up or reduced; continued use despite knowledge of physical or psychological sequelae."[106] Despite the imprecision inherent in the term, there have been attempts to define how the word *alcoholism* should be interpreted when encountered. In 1992, it was defined by the National Council on Alcoholism and Drug Dependence (NCADD) and ASAM as "a primary, chronic disease characterized by impaired control over drinking, preoccupation with the drug alcohol, use of alcohol despite adverse consequences, and distortions in thinking."[107] MeSH has had an entry for "alcoholism" since 1999, and references the 1992 definition.[108]

AA describes alcoholism as an illness that involves a physical allergy[109]:28 (where "allergy" has a different meaning than that used in modern medicine.[110]) and a mental obsession.[109]:23[111] The doctor and addiction specialist Dr. William D. Silkworth M.D. writes on behalf of AA that "Alcoholics suffer from a "(physical) craving beyond mental control".[109]:XXVI A 1960 study by E. Morton Jellinek is considered the foundation of the modern disease theory of alcoholism.[112] Jellinek's definition restricted the use of the word *alcoholism* to those showing a particular natural history. The modern medical definition of *alcoholism* has been revised numerous times since then. The American Medical Association uses the word alcoholism to refer to a particular chronic primary disease.[113]

## Social barriers

Attitudes and social stereotypes can create barriers to the detection and treatment of alcohol abuse. This is more of a barrier for women than men. Fear of stigmatization may lead women to deny that they are suffering from a medical condition, to hide their drinking, and to drink alone. This pattern, in turn, leads family, physicians, and others to be less likely to suspect that a woman they know is an alcoholic.[35] In contrast, reduced fear of stigma may lead men to admit that they are suffering from a medical condition, to display their drinking publicly, and to drink in groups. This pattern, in turn, leads family, physicians, and others to be more likely to suspect that a man they know is an alcoholic.[54]

## Screening

Several tools may be used to detect a loss of control of alcohol use. These tools are mostly self-reports in questionnaire form. Another common theme is a score or tally that sums up the general severity of alcohol use.[114]

The CAGE questionnaire, named for its four questions, is one such example that may be used to screen patients quickly in a doctor's office.

Two "yes" responses indicate that the respondent should be investigated further.

The questionnaire asks the following questions:

1. Have you ever felt you needed to **C**ut down on your drinking?
2. Have people **A**nnoyed you by criticizing your drinking?
3. Have you ever felt **G**uilty about drinking?
4. Have you ever felt you needed a drink first thing in the morning (**E**ye-opener) to steady your nerves or to get rid of a hangover?[115][116]

The CAGE questionnaire has demonstrated a high effectiveness in detecting alcohol-related problems; however, it has limitations in people with less severe alcohol-related problems, white women and college students.[117]

Other tests are sometimes used for the detection of alcohol dependence, such as the Alcohol Dependence Data Questionnaire, which is a more sensitive diagnostic test than the CAGE questionnaire. It helps distinguish a diagnosis of alcohol dependence from one of heavy alcohol use.[118] The Michigan Alcohol Screening Test (MAST) is a screening tool for alcoholism widely used by courts to determine the appropriate sentencing for people convicted of alcohol-related offenses,[119] driving under the influence being the most common. The Alcohol Use Disorders Identification Test (AUDIT), a screening questionnaire developed by the World Health Organization, is unique in that it has been validated in six countries and is used internationally. Like the CAGE questionnaire, it uses a simple set of questions – a high score earning a deeper investigation.[120] The Paddington Alcohol Test (PAT) was designed to screen for alcohol-related problems amongst those attending Accident and Emergency departments. It concords well with the AUDIT questionnaire but is administered in a fifth of the time.[121] Certain blood tests may also indicate possible alcoholism.[4]

## Genetic predisposition testing

Psychiatric geneticists John I. Nurnberger, Jr., and Laura Jean Bierut suggest that alcoholism does not have a single cause—including genetic—but that genes do play an important role "by affecting processes in the body and brain that interact with one another and with an individual's life experiences to produce protection or susceptibility". They also report that fewer than a dozen alcoholism-related genes have been identified, but that more likely await discovery.[122] At least one genetic test exists for an allele that is correlated to alcoholism and opiate addiction.[123] Human dopamine receptor genes have a detectable variation referred to as the DRD2 TaqI polymorphism. Those who possess the A1 allele (variation) of this polymorphism have a small but significant tendency towards addiction to opiates and endorphin-releasing drugs like alcohol.[124] Although this allele is slightly more common in alcoholics and opiate addicts, it is not by itself an adequate predictor of alcoholism, and some researchers argue that evidence for DRD2 is contradictory.[122]

## Urine and blood tests

There are reliable tests for the actual use of alcohol, one common test being that of blood alcohol content (BAC).[125] These tests do not differentiate alcoholics from non-alcoholics; however, long-term heavy drinking does have a few recognizable effects on the body, including:[126]

- Macrocytosis (enlarged MCV)
- Elevated GGT
- Moderate elevation of AST and ALT and an AST: ALT ratio of 2:1
- High carbohydrate deficient transferrin (CDT)

With regard to alcoholism, BAC is useful to judge alcohol tolerance, which in turn is sign of alcoholism.[4]

However, none of these blood tests for biological markers is as sensitive as screening questionnaires.

# Prevention

The World Health Organization, the European Union and other regional bodies, national governments and parliaments have formed alcohol policies in order to reduce the harm of alcoholism.[127][128] Targeting adolescents and young adults is regarded as an important step to reduce the harm of alcohol abuse. Increasing the age at which licit drugs of abuse such as alcohol can be purchased, the banning or restricting advertising of alcohol has been recommended as additional ways of reducing the harm of alcohol dependence and abuse. Credible, evidence based educational campaigns in the mass media about the consequences of alcohol abuse have been recommended. Guidelines for parents to prevent alcohol abuse amongst adolescents, and for helping young people with mental health problems have also been suggested.[129]

# Management

Treatments are varied because there are multiple perspectives of alcoholism. Those who approach alcoholism as a medical condition or disease recommend differing treatments from, for instance, those who approach the condition as one of social choice. Most treatments focus on helping people discontinue their alcohol intake, followed up with life training and/or social support to help them resist a return to alcohol use. Since alcoholism involves multiple factors which encourage a person to continue drinking, they must all be addressed to successfully prevent a relapse. An example of this kind of treatment is detoxification followed by a combination of supportive therapy, attendance at self-help groups, and ongoing development of coping mechanisms. The treatment community for alcoholism typically supports an abstinence-based zero tolerance approach; however, some prefer a harm-reduction approach.[130]

## Detoxification

*Main article: Alcohol detoxification*

Alcohol detoxification or 'detox' for alcoholics is an abrupt stop of alcohol drinking coupled with the substitution of drugs, such as benzodiazepines, that have similar effects to prevent alcohol withdrawal. Individuals who are only at risk of mild to moderate withdrawal symptoms can be detoxified as outpatients. Individuals at risk of a severe withdrawal syndrome as well as those who have significant or acute comorbid conditions are generally treated as inpatients. Detoxification does not actually treat alcoholism, and it is necessary to follow up detoxification with an appropriate treatment program for alcohol dependence or abuse to reduce the risk of relapse.[13] Some symptoms of alcohol withdrawal such as depressed mood and anxiety typically take weeks or months to abate while other symptoms persist longer due to persisting neuroadaptations.[65] Alcoholism has serious adverse effects on brain function; on average it takes one year of abstinence to recover from the cognitive deficits incurred by chronic alcohol abuse.[131]

## Psychological

Various forms of group therapy or psychotherapy can be used to deal with underlying psychological issues that are related to alcohol addiction, as well as provide relapse prevention skills. The mutual-help group-counseling approach is one of the most common ways of helping alcoholics maintain sobriety.[15] Alcoholics Anonymous was one of the first organizations formed to provide mutual, nonprofessional counseling, and it is still the largest. Others include LifeRing Secular Recovery, SMART Recovery, Women For Sobriety, and Secular Organizations for Sobriety.[132] Rationing and moderation programs such as Moderation Management and DrinkWise do not mandate complete abstinence. While most alcoholics are unable to limit their drinking in this way, some return to moderate drinking. A 2002 US study by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) showed that 17.7 percent of

A regional service center for Alcoholics Anonymous.

individuals diagnosed as alcohol dependent more than one year prior returned to low-risk drinking. This group, however, showed fewer initial symptoms of dependency.[133] A follow-up study, using the same subjects that were judged to be in remission in 2001–2002, examined the rates of return to problem drinking in 2004–2005. The study found abstinence from alcohol was the most stable form of remission for recovering alcoholics.[134] A long-term (60 year) follow-up of two groups of alcoholic men concluded that "return to controlled drinking rarely persisted for much more than a decade without relapse or evolution into abstinence."[135]

## Medications

In the United States there are four currently approved medications for alcoholism: disulfiram, two forms of naltrexone, and acamprosate.[136] Several other drugs are also used and many are under investigation.

- Acamprosate (Campral) may stabilise the brain chemistry that is altered due to alcohol dependence via antagonising the actions of glutamate, a neurotransmitter which is hyperactive in the post-withdrawal phase.[137] By reducing excessive NMDA activity which occurs at the onset of alcohol withdrawal, acamprosate can reduce or prevent alcohol withdrawal related neurotoxicity.[138] Acamprosate reduces the risk of relapse amongst alcohol dependent persons.[139][140]
- Benzodiazepines, while useful in the management of acute alcohol withdrawal, if used long-term can cause a worse outcome in alcoholism. Alcoholics on chronic benzodiazepines have a lower rate of achieving abstinence from alcohol than those not taking benzodiazepines. This class of drugs is commonly prescribed to alcoholics for insomnia or anxiety management.[141] Initiating prescriptions of benzodiazepines or sedative-hypnotics in individuals in recovery has a high rate of relapse with one author reporting more than a quarter of people relapsed after being prescribed sedative-hypnotics. Those who are long-term users of benzodiazepines should not be withdrawn rapidly, as severe anxiety and panic may develop, which are known risk factors for relapse into alcohol abuse. Taper regimes of 6–12 months have been found to be the most successful, with reduced intensity of withdrawal.[142][143]
- Calcium carbimide (Temposil) works in the same way as disulfiram; it has an advantage in that the occasional adverse effects of disulfiram, hepatotoxicity and drowsiness, do not occur with calcium carbimide.[144]
- Disulfiram (Antabuse) prevents the elimination of acetaldehyde, a chemical the body produces when breaking down ethanol. Acetaldehyde itself is the cause of many hangover symptoms from alcohol use. The overall effect is severe discomfort when alcohol is ingested: an extremely fast-acting and long-lasting uncomfortable hangover. This discourages an alcoholic from drinking in significant amounts while they take the medicine.
- Naltrexone is a competitive antagonist for opioid receptors, effectively blocking the effects of endorphins and opiates. Naltrexone is used to decrease cravings for alcohol and encourage abstinence. Alcohol causes the body to release endorphins, which in turn release dopamine and activate the reward pathways; hence when naltrexone is in the body there is a reduction in the pleasurable effects from consuming alcohol.[145] Evidence supports a reduced risk of relapse among alcohol dependent persons and a decrease in excessive drinking.[140] Nalmefene also appears effective and works by a similar manner.[140]

The Sinclair method is a method of using opiate antagonists to treat alcoholism by having the person take the medication about an hour before they drink alcohol, and only then.[146][147] The opioid blocks the positive reinforcement effects of ethanol and hopefully allows the person to stop drinking or drink less.[147]

Evidence does not support the use of selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), antipsychotics, or gabapentin.[140]

## Dual addictions and dependences

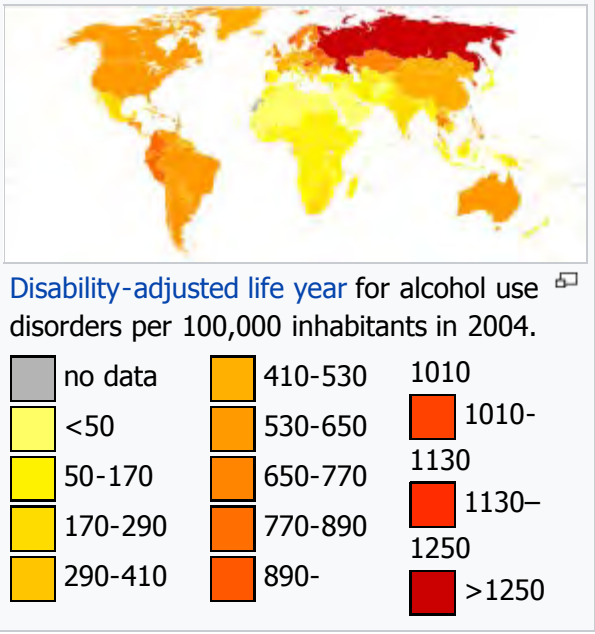
Alcoholics may also require treatment for other psychotropic drug addictions and drug dependences. The most common dual dependence syndrome with alcohol dependence is benzodiazepine dependence, with studies showing 10–20 percent of alcohol-dependent individuals had problems of dependence and/or

misuse problems of benzodiazepine drugs such as valium or clonazopam. These drugs are, like alcohol, depressants. Benzodiazepines may be used legally, if they are prescribed by doctors for anxiety problems or other mood disorders, or they may be purchased as illegal drugs "on the street" through illicit channels. Benzodiazepine use increases cravings for alcohol and the volume of alcohol consumed by problem drinkers.[148] Benzodiazepine dependency requires careful reduction in dosage to avoid benzodiazepine withdrawal syndrome and other health consequences. Dependence on other sedative-hypnotics such as zolpidem and zopiclone as well as opiates and illegal drugs is common in alcoholics. Alcohol itself is a sedative-hypnotic and is cross-tolerant with other sedative-hypnotics such as barbiturates, benzodiazepines and nonbenzodiazepines. Dependence upon and withdrawal from sedative-hypnotics can be medically severe and, as with alcohol withdrawal, there is a risk of psychosis or seizures if not managed properly.[149]

# Epidemiology

The World Health Organization estimates that as of 2010 there are 208 million people with alcoholism worldwide (4.1% of the population over 15 years of age).[7][19] Substance use disorders are a major public health problem facing many countries. "The most common substance of abuse/dependence in patients presenting for treatment is alcohol."[130] In the United Kingdom, the number of 'dependent drinkers' was calculated as over 2.8 million in 2001.[151] About 12% of American adults have had an alcohol dependence problem at some time in their life.[152] In the United States and Western Europe, 10 to 20 percent of men and 5 to 10 percent of women at some point in their lives will meet criteria for alcoholism.[153]

Within the medical and scientific communities, there is a broad consensus regarding alcoholism as a disease state. For example, the American Medical Association considers alcohol a drug and states that "drug addiction is a chronic, relapsing brain disease characterized by compulsive drug seeking and use despite often devastating consequences. It results from a complex interplay of biological vulnerability, environmental exposure, and developmental factors (e.g., stage of brain maturity)."[113] Alcoholism has a higher prevalence among men, though, in recent decades, the proportion of female alcoholics has increased.[36] Current evidence indicates that in both men and women, alcoholism is 50–60 percent genetically determined, leaving 40–50 percent for environmental influences.[154] Most alcoholics develop alcoholism during adolescence or young adulthood.[69] 31 percent of college students show signs of alcohol abuse, while six percent are dependent on alcohol. Under the DSM's new definition of alcoholics, that means about 37 percent of college students may meet the criteria.[155]

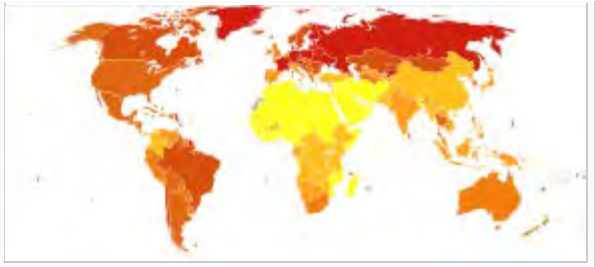


Disability-adjusted life year for alcohol use disorders per 100,000 inhabitants in 2004.

Total recorded yearly alcohol per capita consumption (15+), in litres of pure alcohol[150]

# Prognosis

Alcoholism often reduces a person's life expectancy by around ten years.[22] The most common cause of death in alcoholics is from cardiovascular complications.[156] There is a high rate of suicide in chronic alcoholics, which increases the longer a



Alcohol use disorders deaths per million persons in 2012

| 4-6 | 21-37 | |

person drinks. Approximately 3–15 percent of alcoholics commit suicide,[157] and research has found that over 50 percent of all suicides are associated with alcohol or drug dependence. This is believed to be due to alcohol causing physiological distortion of brain chemistry, as well as social isolation. Suicide is also very common in adolescent alcohol abusers, with 25 percent of suicides in adolescents being related to alcohol abuse.[158] Among those with alcohol dependence after one year, some met the criteria for low-risk drinking, even though only 25.5 percent of the group received any treatment, with the breakdown as follows: 25 percent were found to be still dependent, 27.3 percent were in partial remission (some symptoms persist), 11.8 percent asymptomatic drinkers (consumption increases chances of relapse) and 35.9 percent were fully recovered — made up of 17.7 percent low-risk drinkers plus 18.2 percent abstainers.[159] In contrast, however, the results of a long-term (60-year) follow-up of two groups of alcoholic men indicated that "return to controlled drinking rarely persisted for much more than a decade without relapse or evolution into abstinence."[160] There was also "return-to-controlled drinking, as reported in short-term studies, is often a mirage."

## History

Adriaen Brouwer, *Inn with Drunken Peasants*, 1620s

Historically the name "dipsomania" was coined by German physician C. W. Hufeland in 1819 before it was superseded by "alcoholism".[161][162] That term now has a more specific meaning.[163] The term "alcoholism" was first used in 1849 by the Swedish physician Magnus Huss to describe the systematic adverse effects of alcohol.[164] Alcohol has a long history of use and misuse throughout recorded history. Biblical, Egyptian and Babylonian sources record the history of abuse and dependence on alcohol. In some ancient cultures alcohol was worshiped and in others, its abuse was condemned. Excessive alcohol misuse and drunkenness were recognized as causing social problems even thousands of years ago. However, the defining of habitual drunkenness as it was then known as and its adverse consequences were not well established medically until the 18th century. In 1647 a Greek monk named Agapios was the first to document that chronic alcohol misuse was associated with toxicity to the nervous system and body which resulted in a range of medical disorders such as seizures, paralysis, and internal bleeding. In 1920 the effects of alcohol abuse and chronic drunkenness led to the failed prohibition of alcohol being considered and eventually enforced briefly in America. In 2005 the cost of alcohol dependence and abuse was estimated to cost the US economy approximately 220 billion dollars per year, more than cancer and obesity.[165]

## Society and culture

The various health problems associated with long-term alcohol consumption are generally perceived as detrimental to society, for example, money due to lost labor-hours, medical costs due to injuries due to drunkenness and organ damage from long-term use, and secondary treatment costs, such as the costs of

1904 advertisement describing alcoholism as a disease.

rehabilitation facilities and detoxification centers. Alcohol use is a major contributing factor for head injuries, motor vehicle accidents (due to drunk driving), domestic violence, and assaults. Beyond the financial costs that alcohol consumption imposes, there are also significant social costs to both the alcoholic and their family and friends.[55] For instance, alcohol consumption by a pregnant woman can lead to fetal alcohol syndrome,[166] an incurable and damaging condition.[167] Estimates of the economic costs of alcohol abuse, collected by the World Health Organization, vary from one to six percent of a country's GDP.[168] One Australian estimate pegged alcohol's social costs at 24% of all drug abuse costs; a similar Canadian study concluded alcohol's share was 41%.[169] One study quantified the cost to the UK of *all* forms of alcohol misuse in 2001 as £18.5–20 billion.[151][170] All economic costs in the United States in 2006 have been estimated at $223.5 billion.[171]

Stereotypes of alcoholics are often found in fiction and popular culture. The "town drunk" is a stock character in Western popular culture. Stereotypes of drunkenness may be based on racism or xenophobia, as in the fictional depiction of the Irish as heavy drinkers.[172] Studies by social psychologists Stivers and Greeley attempt to document the perceived prevalence of high alcohol consumption amongst the Irish in America.[173] Alcohol consumption is relatively similar between many European cultures, the United States, and Australia. In Asian countries that have a high gross domestic product, there is heightened drinking compared to other Asian countries, but it is nowhere near as high as it is in other countries like the United States. It is also inversely seen, with countries that have very low gross domestic product showing high alcohol consumption.[174] In a study done on Korean immigrants in Canada, they reported alcohol was even an integral part of their meal, and is the only time solo drinking should occur. They also believe alcohol is necessary at any social event as it helps conversations start.[175]

Caucasians have a much lower abstinence rate (11.8%) and much higher tolerance to symptoms (3.4±2.45 drinks) of alcohol than Chinese (33.4% and 2.2±1.78 drinks respectively). Also, the more acculturation there is between cultures, the more influenced the culture is to adopt Caucasians drinking practices.[176] Peyote, a psychoactive agent, has even shown promise in treating alcoholism. Alcohol had actually replaced peyote as Native Americans' psychoactive agent of choice in rituals when peyote was outlawed.[177]

# Research

## Topiramate

Topiramate, a derivative of the naturally occurring sugar monosaccharide D-fructose, has been found effective in helping alcoholics quit or cut back on the amount they drink. Evidence suggests that topiramate antagonizes excitatory glutamate receptors, inhibits dopamine release, and enhances inhibitory gamma-aminobutyric acid function. A 2008 review of the effectiveness of topiramate concluded that the results of

published trials are promising, however as of 2008, data was insufficient to support using topiramate in conjunction with brief weekly compliance counseling as a first-line agent for alcohol dependence.[178] A 2010 review found that topiramate may be superior to existing alcohol pharmacotherapeutic options. Topiramate effectively reduces craving and alcohol withdrawal severity as well as improving quality-of-life-ratings.[179]

### Baclofen

Baclofen, a GABAB receptor agonist, is under study for the treatment of alcoholism.[180] A 2015 systematic review concluded that there is insufficient evidence for the use of baclofen for withdrawal symptoms in alcoholism.[181] There is tentative data supporting baclofen in alcohol dependence however further trials are needed as of 2013.[182]

### Ondansetron

Ondansetron, a 5HT3 antagonist, appears to have promise as a treatment.[183]

# Anorexia nervosa

From Wikipedia, the free encyclopedia

*"Anorexia" and "Anorectic" redirect here. For the medication, see Anorectic. For other uses, see Anorexia (disambiguation).*

## Variants

**Anorexia nervosa**, often referred to simply as **anorexia**,[1] is an eating disorder characterized by a low weight, fear of gaining weight, a strong desire to be thin, and food restriction.[2] Many people with anorexia see themselves as overweight even though they are in fact underweight.[2][3] If asked they usually deny they have a problem with low weight.[4] Often they weigh themselves frequently, eat only small amounts, and only eat certain foods. Some will exercise excessively, force themselves to vomit, or use laxatives to produce weight loss. Complications may include osteoporosis, infertility and heart damage, among others.[2] Women will often stop having menstrual periods.[4]

The cause is not known. There appear to be some genetic components with identical twins more often affected than non-identical twins.[3] Cultural factors also appear to play a role with societies that value thinness having higher rates of disease.[4] Additionally, it occurs more commonly among those involved in activities that value thinness such as high-level athletics, modelling, and dancing.[4][5] Anorexia often begins following a major life change or stress-inducing event. The diagnosis requires a significantly low weight. The severity of disease is based on body mass index (BMI) in adults with mild disease having a BMI of greater than 17, moderate a BMI of 16 to 17, severe a BMI of 15 to 16, and extreme a BMI less than 15. In children a BMI for age percentile of less than the 5th percentile is often used.[4]

Treatment of anorexia involves restoring a healthy weight, treating the underlying psychological problems, and addressing behaviors that promote the problem. While medications do not help with weight gain, they may be used to help with associated anxiety or depression.[2] A number of types of therapy may be useful including an approach where parents assume responsibility for feeding their child, known as Maudsley family therapy and cognitive behavioral therapy.[2][6] Sometimes people require admission to hospital to restore weight.[7] Evidence for benefit from nasogastric tube feeding; however, is unclear.[8] Some people will just have a single episode and recover while others may have many episodes over years.[7] Many complications improve or

resolve with regaining of weight.[7]

Globally, anorexia is estimated to affect two million people as of 2013.[9] It is estimated to occur in 0.9% to 4.3% of women and 0.2% to 0.3% of men in Western countries at some point in their life.[10] About 0.4% of young females are affected in a given year and it is estimated to occur ten times less commonly in males.[4][10] Rates in most of the developing world are unclear.[4] Often it begins during the teen years or young adulthood.[2] While anorexia became more commonly diagnosed during the 20th century it is unclear if this was due to an increase in its frequency or simply better diagnosis.[3] In 2013 it directly resulted in about 600 deaths globally up from 400 deaths in 1990.[11] Eating disorders also increase a person's risk of death from a wide range of other causes including suicide.[2][10] About 5% of people with anorexia die from complications over a ten-year period, a nearly 6 times increased risk.[4][12] The term anorexia nervosa was first used in 1873 by William Gull to describe this condition.[13]

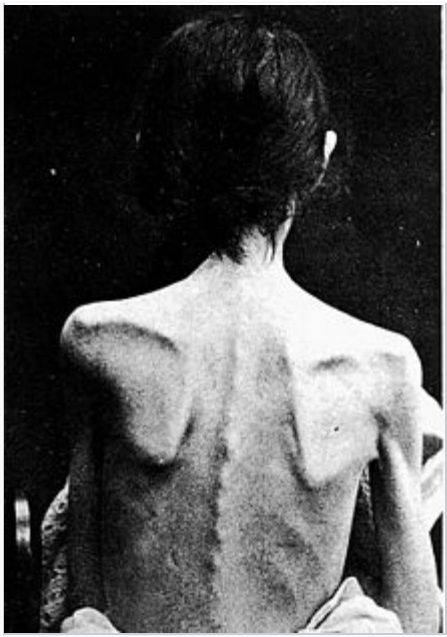
Video explanation

## Signs and symptoms [edit]

Anorexia nervosa is an eating disorder characterized by attempts to lose weight, to the point of starvation. A person with anorexia nervosa may exhibit a number of signs and symptoms, the type and severity of which may vary and may be present but not readily apparent.[14]



The back of a person with anorexia

Anorexia nervosa, and the associated malnutrition that results from self-imposed starvation, can cause complications in every major organ system in the body.[15] Hypokalaemia, a drop in the level of potassium in the blood, is a sign of anorexia nervosa.[16][17] A significant drop in potassium can cause abnormal heart rhythms, constipation, fatigue, muscle damage and paralysis.[18] Some individuals may lack awareness that they are ill.

Symptoms may include:

- A low body mass index for ones age, height and weight.
- Amenorrhea, a symptom that occurs after prolonged weight loss; causes menses to stop, hair becomes brittle, and skin becomes yellow and unhealthy.
- Fear of even the slightest weight gain; taking all precautionary measures to avoid weight gain or becoming "overweight".[19]
- Rapid, continuous weight loss.[20]
- Lanugo: soft, fine hair growing over the face and body.[17]
- An Obsession with counting calories and monitoring fat contents of food.
- Preoccupation with food, recipes, or cooking; may cook elaborate dinners for others, but not eat the food themselves or consume a very small portion.
- Food restrictions despite being underweight or at a healthy weight.
- Food rituals, such as cutting food into tiny pieces, refusing to eat around others and hiding or discarding of food.
- Purging: May use laxatives, diet pills, ipecac syrup, or water pills to flush food out of their system after eating or may engage in self-induced vomiting though this is a more common symptom of bulimia.
- Excessive exercise[21] including micro-exercising, for example making small persistent movements of fingers or toes.[22]
- Perception of self as overweight, even though they might not be.
- Intolerance to cold and frequent complaints of being cold; body temperature may lower (hypothermia) in an effort to conserve energy due to malnutrition.[23]
- Hypotension or orthostatic hypotension.
- Bradycardia or tachycardia.
- Depression, anxiety disorders and insomnia.
- Solitude: may avoid friends and family and become more withdrawn and secretive.
- Abdominal distension.
- Halitosis (from vomiting or starvation-induced ketosis).
- Dry hair and skin, as well as hair thinning.
- Chronic fatigue.[19]
- Rapid mood swings.
- Being protective of ones social media accounts due to eating disorder content.
- Having feet discoloration causing an orange appearance.
- Having severe muscle tension + aches and pains.
- Seeming on edge more often than usual.
- Having teary eyes and suicidal tendencies.
- Evidence/habits of self harming or self-loathing.
- Admiration of thinner people.

## Associated problems [edit]

Other psychological issues may factor into anorexia nervosa; some fulfill the criteria for a separate Axis I diagnosis or a personality disorder which is coded Axis II and thus are considered comorbid to the diagnosed eating disorder. Some people have a previous disorder which may increase their vulnerability to developing an eating disorder and some develop them afterwards.[*medical citation needed*] The presence of Axis I or Axis II psychiatric comorbidity has been shown to affect the severity and type of anorexia nervosa symptoms in both adolescents and adults.[*medical citation needed*]

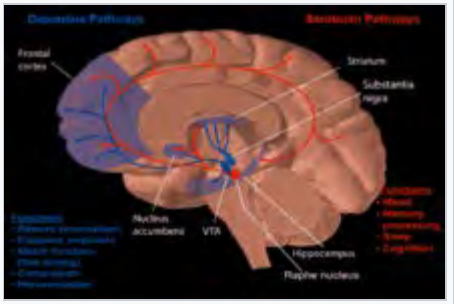
Obsessive-compulsive disorder (OCD) and obsessive-compulsive personality disorder (OCPD) are highly comorbid with AN, particularly the restrictive subtype.[24] Obsessive-compulsive personality disorder is linked with more severe symptomatology and worse prognosis.[25] The causality between personality disorders and eating disorders has yet to be fully established.[*medical citation needed*] Other comorbid conditions include depression,[26] alcoholism,[27] borderline and other personality disorders,[28][29] anxiety disorders,[30] attention deficit hyperactivity disorder,[31] and body dysmorphic disorder (BDD).[32] Depression and anxiety are the most common comorbidities,[33] and depression is associated with a worse outcome.[33]

Autism spectrum disorders occur more commonly among people with eating disorders than in the general population.[34] Zucker *et al.* (2007) proposed that conditions on the autism spectrum make up the cognitive endophenotype underlying anorexia nervosa and appealed for increased interdisciplinary collaboration.[35]

## Causes [edit]

There is evidence for biological, psychological, developmental, and sociocultural risk factors, but the exact cause of eating disorders is unknown.[36]

### Biological [edit]



Dysregulation of the serotonin pathways has been implicated in the etiology, pathogenesis and pathophysiology of anorexia nervosa.[36]

- Genetics: anorexia nervosa is highly heritable.[36] Twin studies have shown a heritability rate of between 28 and 58%.[37] Association studies have been performed, studying 128 different polymorphisms related to 43 genes including genes involved in regulation of eating behavior, motivation and reward mechanics, personality traits and emotion. Consistent associations have been identified for polymorphisms associated with agouti-related peptide, brain derived neurotrophic factor, catechol-o-methyl transferase, SK3 and opioid receptor delta-1.[38] Epigenetic modifications, such as DNA methylation, may contribute to the development or maintenance of anorexia nervosa, though clinical research in this area is in its infancy.[39]
- Obstetric complications: prenatal and perinatal complications may factor into the development of anorexia nervosa, such as maternal anemia, diabetes mellitus, preeclampsia, placental infarction, and neonatal cardiac abnormalities. Neonatal complications may also have an influence on harm avoidance, one of the personality traits associated with the development of AN.[*medical citation needed*]
- Neuroendocrine dysregulation: altered signalling of peptides that facilitate communication between the gut, brain and adipose tissue, such as ghrelin, leptin, neuropeptide Y and orexin, may contribute to the pathogenesis of anorexia nervosa by disrupting regulation of hunger and satiety.[40][41]
- Gastrointestinal diseases: people with gastrointestinal disorders may be more risk of developing disorders eating practices than the general population, principally restrictive eating disturbances.[42] An association of anorexia nervosa with celiac disease has been found.[43] The role that gastrointestinal symptoms play in the development of eating disorders seems rather complex. Some authors report that unresolved symptoms prior to gastrointestinal disease diagnosis may create a food aversion in these

persons, causing alterations to their eating patterns. Other authors report that greater symptoms throughout their diagnosis led to greater risk. It has been documented that some people with celiac disease, irritable bowel syndrome or inflammatory bowel disease who are not conscious about the importance of strictly following their diet, choose to consume their trigger foods to promote weight loss. On the other hand, individuals with good dietary management may develop anxiety, food aversion and eating disorders because of concerns around cross contamination of their foods.[42] Some authors suggest that medical professionals should evaluate the presence of an unrecognized celiac disease in all people with eating disorder, especially if they present any gastrointestinal symptom (such as decreased appetite, abdominal pain, bloating, distension, vomiting, diarrhea or constipation), weight loss, or growth failure; and also routinely ask celiac patients about weight or body shape concerns, dieting or vomiting for weight control, to evaluate the possible presence of eating disorders,[43] specially in women.[44]

Studies have hypothesized the continuance of disordered eating patterns may be epiphenomena of starvation. The results of the Minnesota Starvation Experiment showed normal controls exhibit many of the behavioral patterns of anorexia nervosa (AN) when subjected to starvation. This may be due to the numerous changes in the neuroendocrine system, which results in a self-perpetuating cycle.[45][46][47]

Another hypothesis is that anorexia nervosa is more likely to occur in populations in which obesity is more prevalent, and results from a sexually selected evolutionary drive to appear youthful in populations in which size becomes the primary indicator of age.[48]

Anorexia nervosa is more likely to occur in a person's pubertal years. Some explanatory hypotheses for the rising prevalence of eating disorders in adolescence are "increase of adipose tissue in girls, hormonal changes of puberty, societal expectations of increased independence and autonomy that are particularly difficult for anorexic adolescents to meet; [and] increased influence of the peer group and its values." [49]

## Psychological [edit]

Early theories of the cause of anorexia linked it to childhood sexual abuse or dysfunctional families;[50][51] evidence is conflicting, and well-designed research is needed.[36] The fear of food is known as *sitiophobia*,[52] *cibophobia*,[53] or *sitophobia* and is part of the differential diagnosis.[54][55] Other psychological causes of Anorexia includes low self-esteem, feeling like there is lack of control, depression, anxiety, and loneliness.[56] Peer pressure and constant pressure media and others around can lead to low self-esteem and other psychological symptoms and causes eating disorders like Anorexia.[57]

## Sociological [edit]

Anorexia nervosa has been increasingly diagnosed since 1950;[58] the increase has been linked to vulnerability and internalization of body ideals.[49] People in professions where there is a particular social pressure to be thin (such as models and dancers) were more likely to develop anorexia,[*medical citation needed*] and those with anorexia have much higher contact with cultural sources that promote weight loss.[*medical citation needed*] This trend can also be observed for people who partake in certain sports, such as jockeys and wrestlers.[59] There is a higher incidence and prevalence of anorexia nervosa in sports with an emphasis on aesthetics, where low body fat is advantageous, and sports in which one has to make weight for competition.[60] Family dynamics can play big part in the cause of anorexia.[61] When there is a constant pressure from people to be thin, teasing, bullying can cause low self-esteem and other psychological symptoms.[56]

## Media effects [edit]

Constant exposure to media that presents body ideals may constitute a risk factor for body dissatisfaction and anorexia nervosa. The cultural ideal for body shape for men versus women continues to favor slender women and athletic, V-shaped muscular men. A 2002 review found that, of the magazines most popular among people aged 18 to 24 years, those read by men, unlike those read by women, were more likely to [*unreliable medical source?*][62]

feature ads and articles on shape than on diet. Body dissatisfaction and internalization of body ideals are risk factors for anorexia nervosa that threaten the health of both male and female populations.[*medical citation needed*]

Websites that stress the importance of attainment of body ideals extol and promote anorexia nervosa through the use of religious metaphors, lifestyle descriptions, "thinspiration" or "fitspiration" (inspirational photo galleries and quotes that aim to serve as motivators for attainment of body ideals).[63] Pro-anorexia websites reinforce internalization of body ideals and the importance of their attainment.[63]

The media gives men and women a false view of what people truly look like. In magazines, movies and even on billboards most of the actors/models are photoshopped in multiple ways. People then strive to look like these "perfect" role models when in reality they aren't any where near perfection themselves.[64]

## Mechanisms [edit]

- Serotonin dysregulation: brain imaging studies implicate alterations of 5-HT1A and 5-HT2A receptors and the 5-HT transporter.[36] Alterations of these circuits may affect mood and impulse control as well as the motivating and hedonic aspects of feeding behavior.[65] Starvation has been hypothesized to be a response to these effects, as it is known to lower tryptophan and steroid hormone metabolism, which might reduce serotonin levels at these critical sites and ward off anxiety.[65]
- Addiction to the chemicals released in the brain during starving and physical activity:[66][67] people affected with anorexia often report getting some sort of high from not eating. The effect of food restriction and intense activity causes symptoms similar to anorexia in female rats,[66] though it is not explained why this addiction affects only females.
- Resting state fMRI has identified the insular cortex and corticolimbic circuitry as likely brain areas responsible for the symptomology of anorexia nervosa.[68]

## Diagnosis [edit]

A diagnostic assessment includes the person's current circumstances, biographical history, current symptoms, and family history. The assessment also includes a mental state examination, which is an assessment of the person's current mood and thought content, focusing on views on weight and patterns of eating.

### DSM-5 [edit]

Anorexia nervosa is classified under the Feeding and Eating Disorders in the latest revision of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM 5).

Relative to the previous version of the DSM (DSM-IV-TR), the 2013 revision (DSM5) reflects changes in the criteria for anorexia nervosa, most notably that of the amenorrhea criterion being removed.[7][69] Amenorrhea was removed for several reasons: it does not apply to males, it is not applicable for females before or after the age of menstruation or taking birth control pills, and some women who meet the other criteria for AN still report some menstrual activity.[7]

### Subtypes [edit]

There are two subtypes of AN:[15][70]

- Binge-eating/purging type: the individual utilizes binge eating or displays purging behavior as a means for losing weight.[70] It is different from bulimia nervosa in terms of the individual's weight. An individual with binge-eating/purging type anorexia does not maintain a healthy or normal weight but is significantly underweight. People with bulimia nervosa on the other hand can sometimes be overweight.[19]
- Restricting type: the individual uses restricting food intake, fasting, diet pills, or exercise as a means for

losing weight;[15] they may exercise excessively to keep off weight or prevent weight gain, and some individuals eat only enough to stay alive.[15][19]

## Levels of severity [edit]

Body mass index (BMI) is used by the DSM-5 as an indicator of the level of severity of anorexia nervosa. The DSM-5 states these as follows:[71]

- Mild: BMI of greater than 17
- Moderate: BMI of 16–16.99
- Severe: BMI of 15–15.99
- Extreme: BMI of less than 15

## Investigations [edit]

Medical tests to check for signs of physical deterioration in anorexia nervosa may be performed by a general physician or psychiatrist, including:

- Complete Blood Count (CBC): a test of the white blood cells, red blood cells and platelets used to assess the presence of various disorders such as leukocytosis, leukopenia, thrombocytosis and anemia which may result from malnutrition.[72]
- Urinalysis: a variety of tests performed on the urine used in the diagnosis of medical disorders, to test for substance abuse, and as an indicator of overall health[73]
- Chem-20: Chem-20 also known as SMA-20 a group of twenty separate chemical tests performed on blood serum. Tests include cholesterol, protein and electrolytes such as potassium, chlorine and sodium and tests specific to liver and kidney function.[74]
- Glucose tolerance test: Oral glucose tolerance test (OGTT) used to assess the body's ability to metabolize glucose. Can be useful in detecting various disorders such as diabetes, an insulinoma, Cushing's Syndrome, hypoglycemia and polycystic ovary syndrome.[75]
- Serum cholinesterase test: a test of liver enzymes (acetylcholinesterase and pseudocholinesterase) useful as a test of liver function and to assess the effects of malnutrition.[76]
- Liver Function Test: A series of tests used to assess liver function some of the tests are also used in the assessment of malnutrition, protein deficiency, kidney function, bleeding disorders, and Crohn's Disease.[77]
- Lh response to GnRH: Luteinizing hormone (Lh) response to gonadotropin-releasing hormone (GnRH): Tests the pituitary glands' response to GnRh a hormone produced in the hypothalamus. Hypogonadism is often seen in anorexia nervosa cases.[16]
- Creatine Kinase Test (CK-Test): measures the circulating blood levels of creatine kinase an enzyme found in the heart (CK-MB), brain (CK-BB) and skeletal muscle (CK-MM).[78]
- Blood urea nitrogen (BUN) test: urea nitrogen is the byproduct of protein metabolism first formed in the liver then removed from the body by the kidneys. The BUN test is primarily used to test kidney function. A low BUN level may indicate the effects of malnutrition.[79]
- BUN-to-creatinine ratio: A BUN to creatinine ratio is used to predict various conditions. A high BUN/creatinine ratio can occur in severe hydration, acute kidney failure, congestive heart failure, and intestinal bleeding. A low BUN/creatinine ratio can indicate a low protein diet, celiac disease, rhabdomyolysis, or cirrhosis of the liver.[80][81]
- Electrocardiogram (EKG or ECG): measures electrical activity of the heart. It can be used to detect various disorders such as hyperkalemia[82]
- Electroencephalogram (EEG): measures the electrical activity of the brain. It can be used to detect abnormalities such as those associated with pituitary tumors.[83]
- Thyroid Screen TSH, t4, t3 :test used to assess thyroid functioning by checking levels of thyroid-stimulating hormone (TSH), thyroxine (T4), and triiodothyronine (T3)[84]

## Differential diagnoses [edit]

*Main article: Anorexia nervosa (differential diagnoses)*

A variety of medical and psychological conditions have been misdiagnosed as anorexia nervosa; in some cases the correct diagnosis was not made for more than ten years.

The distinction between the diagnoses of anorexia nervosa, bulimia nervosa and eating disorder not otherwise specified (EDNOS) is often difficult to make as there is considerable overlap between people diagnosed with these conditions. Seemingly minor changes in a people's overall behavior or attitude can change a diagnosis from anorexia: binge-eating type to bulimia nervosa. A main factor differentiating binge-purge anorexia from bulimia is the gap in physical weight. Someone with bulimia nervosa is ordinarily at a healthy weight, or slightly overweight. Someone with binge-purge anorexia is commonly underweight.[85] People with the binge-purging subtype of AN may be significantly underweight and typically do not binge-eat large amounts of food, yet they purge the small amount of food they eat.[85] In contrast, those with bulimia nervosa tend to be at normal weight or overweight and binge large amounts of food.[85] It is not unusual for a person with an eating disorder to "move through" various diagnoses as their behavior and beliefs change over time.[35]

## Treatment [edit]

There is no conclusive evidence that any particular treatment for anorexia nervosa works better than others; however, there is enough evidence to suggest that early intervention and treatment are more effective.[86] Treatment for anorexia nervosa tries to address three main areas.

- Restoring the person to a healthy weight;
- Treating the psychological disorders related to the illness;
- Reducing or eliminating behaviours or thoughts that originally led to the disordered eating.[87]

Although restoring the person's weight is the primary task at hand, optimal treatment also includes and monitors behavioral change in the individual as well.[88] There is some evidence that hospitalisation might adversely affect long term outcome.[89]

Psychotherapy for individuals with AN is challenging as they may value being thin and may seek to maintain control and resist change.[90] Some studies demonstrate that family based therapy in adolescents with AN is superior to individual therapy.[91]

Treatment of people with AN is difficult because they are afraid of gaining weight. Initially developing a desire to change may be important.[92]

### Diet [edit]

Diet is the most essential factor to work on in people with anorexia nervosa, and must be tailored to each person's needs. Food variety is important when establishing meal plans as well as foods that are higher in energy density.[93] People must consume adequate calories, starting slowly, and increasing at a measured pace.[21] Evidence of a role for zinc supplementation during refeeding is unclear.[8]

### Therapy [edit]

Family-based treatment (FBT) has been shown to be more successful than individual therapy for adolescents with AN.[12][94] Various forms of family-based treatment have been proven to work in the treatment of adolescent AN including conjoint family therapy (CFT), in which the parents and child are seen together by the same therapist, and separated family therapy (SFT) in which the parents and child attend therapy separately with different therapists.[12] Proponents of Family therapy for adolescents with AN assert that it is important to include parents in the adolescent's treatment.[12]

A four- to five-year follow up study of the Maudsley family therapy, an evidence-based manualized model, showed full recovery at rates up to 90%.[95] Although this model is recommended by the NIMH,[96] critics claim that it has the potential to create power struggles in an intimate relationship and may disrupt equal

partnerships.[97]

Cognitive behavioral therapy (CBT) is useful in adolescents and adults with anorexia nervosa;[98] acceptance and commitment therapy is a type of CBT, which has shown promise in the treatment of AN.[99] Cognitive remediation therapy (CRT) is used in treating anorexia nervosa.[100]

### Medication [edit]

Pharmaceuticals have limited benefit for anorexia itself.[101]

### Admission to hospital [edit]

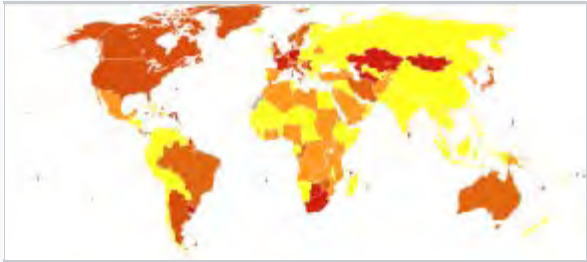
AN has a high mortality[102] and patients admitted in a severely ill state to medical units are at particularly high risk. Diagnosis can be challenging, risk assessment may not be performed accurately, consent and the need for compulsion may not be assessed appropriately, refeeding syndrome may be missed or poorly treated and the behavioural and family problems in AN may be missed or poorly managed.[103] The MARSIPAN guidelines recommend that medical and psychiatric experts work together in managing severely ill people with AN.[104]

### Nutrition [edit]

The rate of refeeding can be difficult to establish, because the fear of refeeding syndrome (RFS) can lead to underfeeding. It is thought that RFS, with falling phosphate and potassium levels, is more likely to occur when BMI is very low, and when medical comorbidities such as infection or cardiac failure, are present. In those circumstances, it is recommended to start refeeding slowly but to build up rapidly as long as RFS does not occur. Recommendations on energy requirements vary, from 5–10 kCal/Kg/day in the most medically compromised patients, who appear to have the highest risk of RFS to 1900 Kcal/day[105][106]

## Prognosis [edit]

AN has the highest mortality rate of any psychological disorder.[12] The mortality rate is 6 to 12 times higher than expected, and the suicide risk is 56 times higher; half of women with AN achieve a full recovery, while an additional 20–30% may partially recover.[12][16] Not all people with anorexia recover completely: about 20% develop anorexia nervosa as a chronic disorder.[86] If anorexia nervosa is not treated, serious complications such as heart conditions[14] and kidney failure can arise and eventually lead to death.[107] The average number of years from onset to remission of AN is seven for women and three for men. After ten to fifteen years, 70% of people no longer meet the diagnostic criteria, but many still continue to have eating-related problems.[108]



Alexithymia influences treatment outcome.[101] Recovery is also viewed on a spectrum rather than black and white. According to the Morgan-Russell criteria, individuals can have a good, intermediate, or poor outcome. Even when a person is classified as having a "good" outcome, weight only has to be within 15% of average, and normal menstruation must be present in females. The good outcome also excludes psychological health. Recovery for people with anorexia nervosa is undeniably positive, but recovery does not mean a return to normal.[*medical citation needed*]

### Complications [edit]

Anorexia nervosa can have serious implications if its duration and severity are significant and if onset occurs

before the completion of growth, pubertal maturation, or the attainment of peak bone mass.[*medical citation needed*] Complications specific to adolescents and children with anorexia nervosa can include the following: Growth retardation may occur, as height gain may slow and can stop completely with severe weight loss or chronic malnutrition. In such cases, provided that growth potential is preserved, height increase can resume and reach full potential after normal intake is resumed.[*medical citation needed*] Height potential is normally preserved if the duration and severity of illness are not significant or if the illness is accompanied with delayed bone age (especially prior to a bone age of approximately 15 years), as hypogonadism may negate the deleterious effects of undernutrition on stature by allowing for a longer duration of growth compared to controls.[*medical citation needed*] In such cases, appropriate early treatment can preserve height potential and may even help to increase it in some post-anorexic subjects due to the aforementioned reasons in addition to factors such as long-term reduced estrogen-producing adipose tissue levels compared to premorbid levels.[*medical citation needed*] In some cases, especially where onset is pre-pubertal, physical consequences such as stunted growth and pubertal delay are usually fully reversible.[109]

Anorexia nervosa causes alterations in the female reproductive system; significant weight loss, as well as psychological stress and intense exercise, typically results in a cessation of menstruation in women who are past puberty. In patients with anorexia nervosa, there is a reduction of the secretion of gonadotropin releasing hormone in the central nervous system, preventing ovulation.[110] Anorexia nervosa can also result in pubertal delay or arrest. Both height gain and pubertal development are dependent on the release of growth hormone and gonadotrophins (LH and FSH) from the pituitary gland. Suppression of gonadotrophins in people with anorexia nervosa has been documented.[111] Typically, growth hormone (GH) levels are high, but levels of IGF-1, the downstream hormone that should be released in response to GH are low; this indicates a state of "resistance" to GH due to chronic starvation.[112] IGF-1 is necessary for bone formation, and decreased levels in anorexia nervosa contribute to a loss of bone density and potentially contribute to osteopenia or osteoporosis.[112] Anorexia nervosa can also result in reduction of peak bone mass. Buildup of bone is greatest during adolescence, and if onset of anorexia nervosa occurs during this time and stalls puberty, low bone mass may be permanent.[113] Hepatic steatosis, or fatty infiltration of the liver, can also occur, and is an indicator of malnutrition in children.[114] Neurological disorders that may occur as complications include seizures and tremors. Wernicke encephalopathy, which results from vitamin B1 deficiency, has been reported in patients who are extremely malnourished; symptoms include confusion, oculomotor dysfunction, and abnormalities in walking gait.

The most common gastrointestinal complications of anorexia nervosa are delayed stomach emptying and constipation, but also include elevated liver function tests, diarrhea, acute pancreatitis, heartburn, difficulty swallowing, and, rarely, superior mesenteric artery syndrome.[115] Delayed stomach emptying, or gastroparesis, often develops following food restriction and weight loss; the most common symptom is bloating with gas and abdominal distension, and often occurs after eating. Other symptoms of gastroparesis include early satiety, fullness, nausea, and vomiting. The symptoms may inhibit efforts at eating and recovery, but can be managed by limiting high-fiber foods, using liquid nutritional supplements, or using metoclopramide to increase emptying of food from the stomach.[115] Gastroparesis generally resolves when weight is regained.

## Cardiac complications [edit]

Anorexia nervosa increases the risk of sudden cardiac death, though the precise cause is unknown. Cardiac complications include structural and functional changes to the heart.[116] Some of these cardiovascular changes are mild and are reversible with treatment, while others may be life-threatening. Cardiac complications can include arrhythmias, abnormally slow heart beat, low blood pressure, decreased size of the heart muscle, reduced heart volume, mitral valve prolapse, myocardial fibrosis, and pericardial effusion.[116]

Abnormalities in conduction and repolarization of the heart that can result from anorexia nervosa include QT prolongation, increased QT dispersion, conduction delays, and junctional escape rhythms.[116] Electrolyte abnormalities, particularly hypokalemia and hypomagnesemia can cause anomalies in the electrical activity of the heart, and result in life-threatening arrhythmias. Hypokalemia most commonly results in anorexic patients when restricting is accompanied by purging (induced vomiting or laxative use). Hypotension (low

blood pressure) is common, and symptoms include fatigue and weakness. Orthostatic hypotension, a marked decrease in blood pressure when standing from a supine position, may also occur. Symptoms include lightheadedness upon standing, weakness, and cognitive impairment, and may result in fainting or near-fainting.[116] Orthostasis in anorexia nervosa indicates worsening cardiac function and may indicate a need for hospitalization.[116] Hypotension and orthostasis generally resolve upon recovery to a normal weight. The weight loss in anorexia nervosa also causes atrophy of cardiac muscle. This leads to decreased ability to pump blood, a reduction in the ability to sustain exercise, a diminished ability to increase blood pressure in response to exercise, and a subjective feeling of fatigue.[117] Some individuals may also have a decrease in cardiac contractility. Cardiac complications can be life-threatening, but the heart muscle generally improves with weight gain, and the heart normalizes in size normalizes over weeks to months, with recovery.[117] Atrophy of the heart muscle is a marker of the severity of the disease, and while it is reversible with treatment and refeeding, it is possible that it may cause permanent, microscopic changes to the heart muscle that increase the risk of sudden cardiac death.[116] Individuals with anorexia nervosa may experience chest pain or palpitations; these can be a result of mitral valve prolapse. Mitral valve prolapse occurs because the size of the heart muscle decreases while the tissue of the mitral valve remains the same size. Studies have shown rates of mitral valve prolapse of around 20 percent in those with anorexia nervosa, while the rate in the general population is estimated at 2–4 percent.[118] It has been suggested that there is an association between mitral valve prolapse and sudden cardiac death, but it has not been proven to be causative, either in patients with anorexia nervosa or in the general population.[116]

### Relapse [edit]

Relapse occurs in approximately a third of people in hospital, and is greatest in the first six to eighteen months after release from an institution.[119]

## Epidemiology [edit]

Anorexia is estimated to occur in 0.9% to 4.3% of women and 0.2% to 0.3% of men in Western countries at some point in their life.[10] About 0.4% of young females are affected in a given year and it is estimated to occur three to ten times less commonly in males.[4][10][119] Rates in most of the developing world are unclear.[4] Often it begins during the teen years or young adulthood.[2]

The lifetime rate of atypical anorexia nervosa, a form of ED-NOS in which not all of the diagnostic criteria for AN are met, is much higher, at 5–12%.[120]

While anorexia become more commonly diagnosed during the 20th century it is unclear if this was due to an increase in its frequency or simply better diagnosis.[3] Most studies show that since at least 1970 the incidence of AN in adult women is fairly constant, while there is some indication that the incidence may have been increasing for girls aged between 14 and 20.[121]

### Underrepresentation [edit]

Eating disorders are less reported in preindustrial, non-westernized countries than in Western countries. In Africa, not including South Africa, the only data presenting information about eating disorders occurs in case reports and isolated studies, not studies investigating prevalence. Data shows in research that in westernized civilizations, ethnic minorities have very similar rates of eating disorders, contrary to the belief that eating disorders predominantly occur in Caucasian people.[*medical citation needed*]

Due to different standards of beauty for men and women, men are often not diagnosed as anorexic. Generally men who alter their bodies do so to be lean and muscular rather than thin. In addition, men who might otherwise be diagnosed with anorexia may not meet the DSM IV criteria for BMI since they have muscle weight, but have very little fat.[122] Men and women athletes are often overlooked as anorexic.[122] Research emphasizes the importance to take athletes' diet, weight and symptoms into account when diagnosing anorexia, instead of just looking at weight and BMI. For athletes, ritualized activities such as weigh-ins place emphasis on weight, which may promote the development of eating disorders among

them.[*citation needed*] While women use diet pills, which is an indicator of unhealthy behavior and an eating disorder, men use steroids, which contextualizes the beauty ideals for genders. This also shows men having a preoccupation with their body, which is an indicator of an eating disorder.[36] In a Canadian study, 4% of boys in grade nine used anabolic steroids.[36] Anorexic men are sometimes referred to as *manorexic*.[123]

## History [edit]

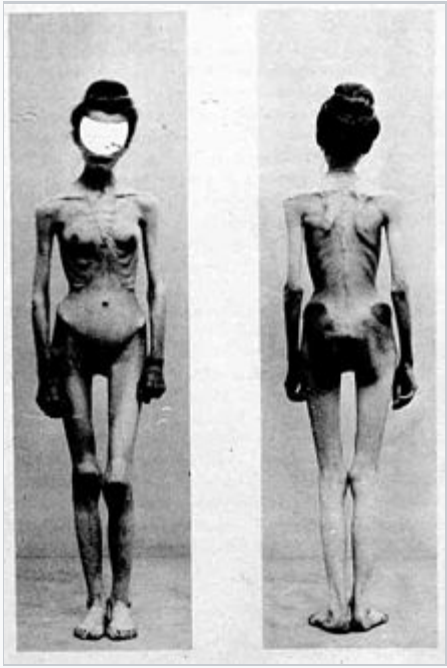
*Main article: History of anorexia nervosa*

The term *anorexia nervosa* was coined in 1873 by Sir William Gull, one of Queen Victoria's personal physicians.[124] The history of anorexia nervosa begins with descriptions of religious fasting dating from the Hellenistic era[125] and continuing into the medieval period. The medieval practice of self-starvation by women, including some young women, in the name of religious piety and purity also concerns anorexia nervosa; it is sometimes referred to as *anorexia mirabilis*.[126][127]

The earliest medical descriptions of anorexic illnesses are generally credited to English physician Richard Morton in 1689.[125] Case descriptions fitting anorexic illnesses continued throughout the 17th, 18th and 19th centuries.[128]

In the late 19th century anorexia nervosa became widely accepted by the medical profession as a recognized condition. In 1873, Sir William Gull, one of Queen Victoria's personal physicians, published a seminal paper which coined the term *anorexia nervosa* and provided a number of detailed case descriptions and treatments.[128] In the same year, French physician Ernest-Charles Lasègue similarly published details of a number of cases in a paper entitled *De l'Anorexie hystérique*.[129]

Awareness of the condition was largely limited to the medical profession until the latter part of the 20th century, when German-American psychoanalyst Hilde Bruch published *The Golden Cage: the Enigma of Anorexia Nervosa* in 1978. Despite major advances in neuroscience,[130] Bruch's theories tend to dominate popular thinking. A further important event was the death of the popular singer and drummer Karen Carpenter in 1983, which prompted widespread ongoing media coverage of eating disorders.[131]



Two images of an anorexic female person published in 1900 in "Nouvelle Iconographie de la Salpêtrière". The case was entitiled "Un cas d'anorexie hysterique" *(A case of hysteria anorexia).*

### Etymology [edit]

The term is of Greek origin: *an-* (ἀν-, prefix denoting negation) and *orexis* (ὄρεξις, "appetite"), translating literally to a nervous loss of appetite.[132]

# Anxiety disorder

From Wikipedia, the free encyclopedia

**Anxiety disorders** are a group of mental disorders characterized by feelings of anxiety and fear.[2] Anxiety is a worry about future events and fear is a reaction to current events. These feelings may cause physical symptoms, such as a fast heart rate and shakiness. There are a number of anxiety disorders: including generalized anxiety disorder, specific phobia, social anxiety disorder, separation anxiety disorder, agoraphobia, and panic disorder. The disorder differs by what results in the symptoms. People often have more than one anxiety disorder.[2]

The cause of anxiety disorders is a combination of genetic and environmental factors.[3] Risk factors include a history of child abuse, family history of mental disorders, and poverty. Anxiety disorders often occur with other mental disorders, particularly major depressive disorder, personality disorder, and substance use disorder.[4] To be diagnosed symptoms typically need to be present at least six months, be more than would be expected for the situation, and decrease functioning.[2][4] Other problems that may result in similar symptoms including hyperthyroidism, heart disease, caffeine, alcohol, or cannabis use, and withdrawal from certain drugs, among others.[4][5]

Without treatment, anxiety disorders tend to remain.[2][3] Treatment may include lifestyle changes, counselling, and medications. Counselling is typically with a type of cognitive behavioural therapy.[4] Medications, such as antidepressants or beta blockers, may improve symptoms.[3]

About 12% of people are affected by an anxiety disorder in a given year and between 5-30% are affected at some point in their life.[4][6] They occur about twice as often in females as males, and generally begin before the age of 25.[2][4] The most common are specific phobia which affects nearly 12% and social anxiety disorder which affects 10% at some point in their life. They affect those between the ages of 15 and 35 the most and become less common after the age of 55. Rates appear to be higher in the United States and Europe.[4]

## Classification [edit]

### Generalized [edit]

*Main article: Generalized anxiety disorder*

Facial expression of someone with chronic anxiety

Generalized anxiety disorder (GAD) is a common, chronic disorder characterized by long-lasting anxiety that is not focused on any one object or situation. Those suffering from generalized anxiety disorder experience non-specific persistent fear and worry, and become overly concerned with everyday matters. Generalized anxiety disorder is "characterized by chronic excessive worry accompanied by three or more of the following symptoms: restlessness, fatigue, concentration problems, irritability, muscle tension, and sleep disturbance".[7] Generalized anxiety disorder is the most common anxiety disorder to affect older adults.[8] Anxiety can be a symptom of a medical or substance abuse problem, and medical professionals must be aware of this. A diagnosis of GAD is made when a person has been excessively worried about an everyday problem for six months or more.[9] A person may find that they have problems making daily decisions and remembering commitments as a result of lack of concentration/preoccupation with worry.[10] Appearance looks strained, with increased sweating from the hands, feet, and axillae,[11] and they may be tearful, which can suggest depression.[12] Before a diagnosis of anxiety disorder is made, physicians must rule out drug-induced anxiety and other medical causes.[13]

In children GAD may be associated with headaches, restlessness, abdominal pain, and heart palpitations.[14]

Typically it begins around 8 to 9 years of age.[14]

## Phobias [edit]

*Main article: Phobia*

The single largest category of anxiety disorders is that of phobic disorders, which includes all cases in which fear and anxiety are triggered by a specific stimulus or situation. Between 5% and 12% of the population worldwide suffer from phobic disorders.[9] Sufferers typically anticipate terrifying consequences from encountering the object of their fear, which can be anything from an animal to a location to a bodily fluid to a particular situation. Sufferers understand that their fear is not proportional to the actual potential danger but still are overwhelmed by it.[15]

## Panic disorder [edit]

*Main article: Panic disorder*

With panic disorder, a person has brief attacks of intense terror and apprehension, often marked by trembling, shaking, confusion, dizziness, nausea, and/or difficulty breathing. These panic attacks, defined by the APA as fear or discomfort that abruptly arises and peaks in less than ten minutes, can last for several hours.[16] Attacks can be triggered by stress, fear, or even exercise; the specific cause is not always apparent.

In addition to recurrent unexpected panic attacks, a diagnosis of panic disorder requires that said attacks have chronic consequences: either worry over the attacks' potential implications, persistent fear of future attacks, or significant changes in behavior related to the attacks. As such, those suffering from panic disorder experience symptoms even outside specific panic episodes. Often, normal changes in heartbeat are noticed by a panic sufferer, leading them to think something is wrong with their heart or they are about to have another panic attack. In some cases, a heightened awareness (hypervigilance) of body functioning occurs during panic attacks, wherein any perceived physiological change is interpreted as a possible life-threatening illness (i.e., extreme hypochondriasis).

## Agoraphobia [edit]

*Main article: Agoraphobia*

Agoraphobia is the specific anxiety about being in a place or situation where escape is difficult or embarrassing or where help may be unavailable.[17] Agoraphobia is strongly linked with panic disorder and is often precipitated by the fear of having a panic attack. A common manifestation involves needing to be in constant view of a door or other escape route. In addition to the fears themselves, the term agoraphobia is often used to refer to avoidance behaviors that sufferers often develop.[18] For example, following a panic attack while driving, someone suffering from agoraphobia may develop anxiety over driving and will therefore avoid driving. These avoidance behaviors can often have serious consequences and often reinforce the fear they are caused by.

## Social anxiety disorder [edit]

*Main article: Social anxiety disorder*

Social anxiety disorder (SAD; also known as social phobia) describes an intense fear and avoidance of negative public scrutiny, public embarrassment, humiliation, or social interaction. This fear can be specific to particular social situations (such as public speaking) or, more typically, is experienced in most (or all) social interactions. Social anxiety often manifests specific physical symptoms, including blushing, sweating, and difficulty speaking. As with all phobic disorders, those suffering from social anxiety often will attempt to avoid the source of their anxiety; in the case of social anxiety this is particularly problematic, and in severe cases can lead to complete social isolation.

Social physique anxiety (SPA) is a subtype of social anxiety. It is concern over the evaluation of one's body by others.[19] SPA is common among adolescents, especially females.

## Post-traumatic stress disorder [edit]

*Main article: Post-traumatic stress disorder*

Post-traumatic stress disorder (PTSD) is an anxiety disorder that results from a traumatic experience. Post-traumatic stress can result from an extreme situation, such as combat, natural disaster, rape, hostage situations, child abuse, bullying, or even a serious accident. It can also result from long-term (chronic) exposure to a severe stressor,[20] for example soldiers who endure individual battles but cannot cope with continuous combat. Common symptoms include hypervigilance, flashbacks, avoidant behaviors, anxiety, anger and depression.[21] There are a number of treatments that form the basis of the care plan for those suffering with PTSD. Such treatments include cognitive behavioral therapy (CBT), psychotherapy and support from family and friends.[9]

Posttraumatic stress disorder (PTSD) research began with Vietnam veterans, as well as natural and non natural disaster victims. Studies have found the degree of exposure to a disaster has been found to be the best predictor of PTSD.[22]

## Separation anxiety [edit]

*Main article: Separation anxiety disorder*

Separation anxiety disorder (SepAD) is the feeling of excessive and inappropriate levels of anxiety over being separated from a person or place. Separation anxiety is a normal part of development in babies or children, and it is only when this feeling is excessive or inappropriate that it can be considered a disorder.[23] Separation anxiety disorder affects roughly 7% of adults and 4% of children, but the childhood cases tend to be more severe; in some instances, even a brief separation can produce panic.[24][25] Treating a child earlier may prevent problems. This may include training the parents and family on how to deal with it. Often, the parents will reinforce the anxiety because they do not know how to properly work through it with the child. In addition to parent training and family therapy, medication, such as SSRI's, can be used to treat separation anxiety.[26]

## Situational anxiety [edit]

Situational anxiety is caused by new situations or changing events. It can also be caused by various events that make that particular individual uncomfortable. Its occurrence is very common. Often, an individual will experience panic attacks or extreme anxiety in specific situations. A situation that causes one individual to experience anxiety may not affect another individual at all. For example, some people become uneasy in crowds or tight spaces, so standing in a tightly packed line, say at the bank or a store register, may cause them to experience extreme anxiety, possibly a panic attack.[27] Others, however, may experience anxiety when major changes in life occur, such as entering college, getting married, having children, etc.

## Obsessive–compulsive disorder [edit]

*Main article: Obsessive–compulsive disorder*

Obsessive–compulsive disorder (OCD) is not classified as an anxiety disorder by the DSM-5 but is by the ICD-10. It was previously classified as an anxiety disorder in the DSM-4. It is a condition where the person has obsessions (distressing, persistent, and intrusive thoughts or images) and/or compulsions (urges to repeatedly perform specific acts or rituals), that are not caused by drugs or physical order, and which cause distress or social dysfunction.[28][29] The compulsive rituals are personal rules followed to relieve the anxiety.[29] OCD affects roughly 1-2% of adults (somewhat more women than men), and under 3% of children and adolescents.[28][29]

A person with OCD knows that the symptoms are unreasonable and struggles against both the thoughts and the behavior.[28][30] Their symptoms could be related to external events they fear (such as their home burning down because they forget to turn off the stove) or worry that they will behave inappropriately.[30]

It is not certain why some people have OCD, but behavioral, cognitive, genetic, and neurobiological factors may be involved.[29] Risk factors include family history, being single (although that may result from the disorder), and higher socioeconomic class or not being in paid employment.[29] OCD is chronic; about 20% of people will overcome it, and symptoms will at least reduce over time for most people (a further 50%).[28]

## Causes [edit]

### Drugs [edit]

Anxiety and depression can be caused by alcohol abuse, which in most cases improves with prolonged abstinence. Even moderate, sustained alcohol use may increase anxiety levels in some individuals.[31] Caffeine, alcohol and benzodiazepine dependence can worsen or cause anxiety and panic attacks.[32] Anxiety commonly occurs during the acute withdrawal phase of alcohol and can persist for up to 2 years as part of a post-acute withdrawal syndrome, in about a quarter of people recovering from alcoholism.[33] In one study in 1988–1990, illness in approximately half of patients attending mental health services at one British hospital psychiatric clinic, for conditions including anxiety disorders such as panic disorder or social phobia, was determined to be the result of alcohol or benzodiazepine dependence. In these patients, an initial increase in anxiety occurred during the withdrawal period followed by a cessation of their anxiety symptoms.[34]

There is evidence that chronic exposure to organic solvents in the work environment can be associated with anxiety disorders. Painting, varnishing and carpet-laying are some of the jobs in which significant exposure to organic solvents may occur.[35]

Taking caffeine may cause or worsen anxiety disorders,[36][37] including panic disorder.[38][39][40] Those with anxiety disorders can have high caffeine sensitivity.[41][42] Caffeine-induced anxiety disorder is a subclass of the DSM-5 diagnosis of substance/medication-induced anxiety disorder. Substance/medication-induced anxiety disorder falls under the category of anxiety disorders, and not the category of substance-related and addictive disorders, even though the symptoms are due to the effects of a substance.[43]

Cannabis use is associated with anxiety disorders. However, the precise relationship between cannabis use and anxiety still needs to be established.[44][45]

### Medical conditions [edit]

Occasionally, an anxiety disorder may be a side-effect of an underlying endocrine disease that causes nervous system hyperactivity, such as pheochromocytoma[46][47] or hyperthyroidism.[48]

### Stress [edit]

Anxiety disorders can arise in response to life stresses such as financial worries or chronic physical illness. Anxiety among adolescents and young adults is common due to the stresses of social interaction, evaluation, and body image. Anxiety is also common among older people who have dementia. On the other hand, anxiety disorder is sometimes misdiagnosed among older adults when doctors misinterpret symptoms of a physical ailment (for instance, racing heartbeat due to cardiac arrhythmia) as signs of anxiety.[8]

### Genetics [edit]

GAD runs in families and is six times more common in the children of someone with the condition.[49]

While anxiety arose as an adaptation, in modern times it is almost always thought of negatively in the context of anxiety disorders. People with these disorders have highly sensitive systems; hence, their systems tend to overreact to seemingly harmless stimuli. Sometimes anxiety disorders occur in those who have had traumatic youths, demonstrating an increased prevalence of anxiety when it appears a child will have a difficult future.[50] In these cases, the disorder arises as a way to predict that the individual's

environment will continue to pose threats.

### Persistence of anxiety [edit]

At a low level, anxiety is not a bad thing. In fact, the hormonal response to anxiety has evolved as a benefit, as it helps humans react to dangers. Researchers in evolutionary medicine believe this adaptation allows humans to realize there is a potential threat and to act accordingly in order to ensure greatest possibility of protection. It has actually been shown that those with low levels of anxiety have a greater risk of death than those with average levels. This is because the absence of fear can lead to injury or death.[50] Additionally, patients with both anxiety and depression were found to have lower morbidity than those with depression alone.[51] The functional significance of the symptoms associated with anxiety includes: greater alertness, quicker preparation for action, and reduced probability of missing threats.[51] In the wild, vulnerable individuals, for example those who are hurt or pregnant, have a lower threshold for anxiety response, making them more alert.[51] This demonstrates a lengthy evolutionary history of the anxiety response.

### Evolutionary mismatch [edit]

It has been theorized that high rates of anxiety are a reaction to how the social environment has changed from the Paleolithic era. For example, in the Stone Age there was greater skin-to-skin contact and more handling of babies by their mothers, both of which are strategies that reduce anxiety.[50] Additionally, there is greater interaction with strangers in present times as opposed to interactions solely between close-knit tribes. Researchers posit that the lack of constant social interaction, especially in the formative years, is a driving cause of high rates of anxiety.

Many current cases are likely to have resulted from an evolutionary mismatch, which has been specifically termed a "psychopathogical mismatch." In evolutionary terms, a mismatch occurs when an individual possesses traits that were adapted for an environment that differs from the individual's current environment. For example, even though an anxiety reaction may have been evolved to help with life-threatening situations, for highly sensitized individuals in Westernized cultures simply hearing bad news can elicit a strong reaction.[52]

An evolutionary perspective may provide insight into alternatives to current clinical treatment methods for anxiety disorders. Simply knowing some anxiety is beneficial may alleviate some of the panic associated with mild conditions. Some researchers believe that, in theory, anxiety can be mediated by reducing a patient's feeling of vulnerability and then changing their appraisal of the situation.[52]

## Mechanisms [edit]

### Biological [edit]

Low levels of GABA, a neurotransmitter that reduces activity in the central nervous system, contribute to anxiety. A number of anxiolytics achieve their effect by modulating the GABA receptors.[53][54][55]

Selective serotonin reuptake inhibitors, the drugs most commonly used to treat depression, are frequently considered as a first line treatment for anxiety disorders.[56]

### Amygdala [edit]

The amygdala is central to the processing of fear and anxiety, and its function may be disrupted in anxiety disorders.[57] Sensory information enters the amygdala through the nuclei of the basolateral complex (consisting of lateral, basal, and accessory basal nuclei). The basolateral complex processes sensory-related fear memories and communicates their threat importance to memory and sensory processing elsewhere in the brain, such as the medial prefrontal cortex and sensory cortices.

Another important area is the adjacent central nucleus of the amygdala, which controls species-specific fear

responses, via connections to the brainstem, hypothalamus, and cerebellum areas. In those with general anxiety disorder, these connections functionally seem to be less distinct, with greater gray matter in the central nucleus. Another difference is that the amygdala areas have decreased connectivity with the insula and cingulate areas that control general stimulus salience, while having greater connectivity with the parietal cortex and prefrontal cortex circuits that underlie executive functions.[57]

The latter suggests a compensation strategy for dysfunctional amygdala processing of anxiety. Researchers have noted "Amygdalofrontoparietal coupling in generalized anxiety disorder patients may ... reflect the habitual engagement of a cognitive control system to regulate excessive anxiety."[57] This is consistent with cognitive theories that suggest the use in this disorder of attempts to reduce the involvement of emotions with compensatory cognitive strategies.

Clinical and animal studies suggest a correlation between anxiety disorders and difficulty in maintaining balance.[58][59][60][61] A possible mechanism is malfunction in the parabrachial area, a brain structure that, among other functions, coordinates signals from the amygdala with input concerning balance.[62]

Anxiety processing in the basolateral amygdala has been implicated with dendritic arborization of the amygdaloid neurons. SK2 potassium channels mediate inhibitory influence on action potentials and reduce arborization. By overexpressing SK2 in the basolateral amygdala, anxiety in experimental animals can be reduced together with general levels of stress-induced corticosterone secretion.[63]

## Prevention [edit]

Focus is increasing on prevention of anxiety disorders.[64] There is tentative evidence to support the use of cognitive behavior therapy[64] and mindfulness therapy.[65][66] As of 2013, there are no effective measures to prevent GAD in adults.[67]

## Diagnosis [edit]

Anxiety disorders are often severe chronic conditions, which can be present from an early age or begin suddenly after a triggering event. They are prone to flare up at times of high stress and are frequently accompanied by physiological symptoms such as headache, sweating, muscle spasms, tachycardia, palpitations, and hypertension, which in some cases lead to fatigue.

In casual discourse the words "anxiety" and "fear" are often used interchangeably; in clinical usage, they have distinct meanings: "anxiety" is defined as an unpleasant emotional state for which the cause is either not readily identified or perceived to be uncontrollable or unavoidable, whereas "fear" is an emotional and physiological response to a recognized external threat.[68] The term "anxiety disorder" includes fears (phobias) as well as anxieties.[*medical citation needed*]

The diagnosis of anxiety disorders is difficult because there are no objective biomarkers, it is based on symptoms,[69] which typically need to be present at least six months, be more than would be expected for the situation, and decrease functioning.[2][4] Several generic anxiety questionnaires can be used to detect anxiety symptoms, such as the State-Trait Anxiety Inventory (STAI), the Generalized Anxiety Disorder 7 (GAD-7), the Beck Anxiety Inventory (BAI), the Zung Self-Rating Anxiety Scale, and the Taylor Manifest Anxiety Scale.[70] Other questionnaires combine anxiety and depression measurement, such as the Hamilton Anxiety Rating Scale, the Hospital Anxiety and Depression Scale (HADS), the Patient Health Questionnaire (PHQ), and the Patient-Reported Outcomes Measurement Information System (PROMIS).[70] Examples of specific anxiety questionnaires include the Liebowitz Social Anxiety Scale (LSAS), the Social Interaction Anxiety Scale (SIAS), the Social Phobia Inventory (SPIN), the Social Phobia Scale (SPS), and the Social Anxiety Questionnaire (SAQ-A30).[71]

Anxiety disorders often occur along with other mental disorders, in particular depression, which may occur in as many as 60% of people with anxiety disorders. The fact that there is considerable overlap between symptoms of anxiety and depression, and that the same environmental triggers can provoke symptoms in [72]

either condition, may help to explain this high rate of comorbidity.

Studies have also indicated that anxiety disorders are more likely among those with family history of anxiety disorders, especially certain types.[73]

Sexual dysfunction often accompanies anxiety disorders, although it is difficult to determine whether anxiety causes the sexual dysfunction or whether they arise from a common cause. The most common manifestations in individuals with anxiety disorder are avoidance of intercourse, premature ejaculation or erectile dysfunction among men and pain during intercourse among women. Sexual dysfunction is particularly common among people affected by panic disorder (who may fear that a panic attack will occur during sexual arousal) and posttraumatic stress disorder.[74]

### Differential diagnosis [edit]

The diagnosis of an anxiety disorder requires first ruling out an underlying medical cause.[5][68] Diseases that may present similar to an anxiety disorder, including certain endocrine diseases (hypo- and hyperthyroidism, hyperprolactinemia),[4][5][68][75] metabolic disorders (diabetes),[5][76] deficiency states (low levels of vitamin D, B2, B12, folic acid),[5] gastrointestinal diseases (celiac disease, non-celiac gluten sensitivity, inflammatory bowel disease),[77][78][79] heart diseases,[4][5] blood diseases (anemia),[5] and brain degenerative diseases (Parkinson's disease, dementia, multiple sclerosis, Huntington's disease).[5][80][81][82]

Also, several drugs can cause or worsen anxiety, whether in intoxication, withdrawal, or from chronic use. These include alcohol, tobacco, cannabis, sedatives (including prescription benzodiazepines), opioids (including prescription pain killers and illicit drugs like heroin), stimulants (such as caffeine, cocaine and amphetamines), hallucinogens, and inhalants.[4][83]

## Treatment [edit]

Treatment options include lifestyle changes, therapy, and medications. There is no good evidence as to whether therapy or medication is more effective; the choice of which is up to the person with the anxiety disorder and most choose therapy first.[84] The other may be offered in addition to the first choice or if the first choice fails to relieve symptoms.[84]

### Lifestyle changes [edit]

Lifestyle changes include exercise, for which there is moderate evidence for some improvement, regularizing sleep patterns, reduce caffeine intake, and stopping smoking.[84] Stopping smoking has benefits in anxiety as large as or larger than those of medications.[85]

### Therapy [edit]

Cognitive behavioral therapy (CBT) is effective for anxiety disorders and is a first line treatment.[84][86][87][88] CBT appears to be equally effective when carried out via the internet.[89] While evidence for mental health apps is promising it is preliminary.[90]

Self-help books can contribute to the treatment of people with anxiety disorders.[91]

Mindfulness based programs also appear to be effective for managing anxiety disorders.[92][93] It is unclear if meditation has an effect on anxiety and transcendental meditation appears to be no different than other types of meditation.[94]

### Medications [edit]

Medications include SSRIs or SNRIs are first line choices for generalized anxiety disorder; there is no good evidence for any member of the class being better than another, so cost often drives drug choice.[84]

Buspirone, quetiapine and pregabalin are second line treatments for people who do not respond to SSRIs or SNRIs; there is also evidence that benzodiazepines including diazepam and clonazepam are effective but these are not preferred due to the risk of dependence.[84]

Medications need to be used with care among older adults, who are more likely to have side effects because of coexisting physical disorders. Adherence problems are more likely among older people, who may have difficulty understanding, seeing, or remembering instructions.[8]

In general medications are not seen as helpful in specific phobia but a benzodiazepine is sometimes used to help resolve acute episodes; as 2007 data were sparse for efficacy of any drug.[95]

### Alternative medicine [edit]

Many other remedies have been used for anxiety disorder. These include kava, where the potential for benefit seems greater than that for harm with short-term use in those with mild to moderate anxiety.[96][97] The American Academy of Family Physicians (AAFP) recommends use of kava for those with mild to moderate anxiety disorders who are not using alcohol or taking other medicines metabolized by the liver, but who wish to use "natural" remedies.[98] Side effects of kava in the clinical trials were rare and mild.

Inositol has been found to have modest effects in people with panic disorder or obsessive-compulsive disorder.[99] There is insufficient evidence to support the use of St. John's wort, valerian or passionflower.[99]

Aromatherapy has shown some tentative benefits for anxiety reduction in people with cancer when done with massages, although it not clear whether it could just enhance the effect of massage itself.[100]

### Children [edit]

Several methods of treatment have been found to be effective in treating childhood anxiety disorders. Therapy is strongly preferred to medication.[101]

Cognitive behavioral therapy (CBT), a well-established treatment for anxiety related disorders in children and adolescents, is a good first therapy approach.[101] Studies have also gathered substantial evidence for treatments that are not CBT based as being effective forms of treament, expanding treatment options for those who do not respond to CBT.[101] Like adults, children may undergo psychotherapy, cognitive-behavioral therapy, or counseling. Family therapy is a form of treatment in which the child meets with a therapist together with the primary guardians and siblings. Each family member may attend individual therapy, but family therapy is typically a form of group therapy. Art and play therapy are also used. Art therapy is most commonly used when the child will not or cannot verbally communicate, due to trauma or a disability in which they are nonverbal. Participating in art activities allows the child to express what they otherwise may not be able to communicate to others.[102] In play therapy, the child is allowed to play however they please as a therapist observes them. The therapist may intercede from time to time with a question, comment, or suggestion. This is often most effective when the family of the child plays a significant role in the treatment.[103]

In children and adolescents, a medication option is warranted, antidepressants such as SSRIs, SNRIs as well as tricyclic antidepressants can be effective.[104]

## Prognosis [edit]

The prognosis varies on the severity of each case and utilization of treatment for each individual. [105]

If these children are left untreated, they face risks such as poor results at school, avoidance of important social activities, and substance abuse. Children who have an anxiety disorder are likely to have other disorders such as depression, eating disorders, attention deficit disorders both hyperactive and inattentive.

## Epidemiology [edit]

Globally as of 2010 approximately 273 million (4.5% of the population) had an anxiety disorder.[106] It is more common in females (5.2%) than males (2.8%).[106]

In Europe, Africa and Asia, lifetime rates of anxiety disorders are between 9 and 16%, and yearly rates are between 4 and 7%.[107] In the United States, the lifetime prevalence of anxiety disorders is about 29%[108] and between 11 and 18% of adults have the condition in a given year.[107] This difference is affected by the range of ways in which different cultures interpret anxiety symptoms and what they consider to be normative behavior.[109][110] In general, anxiety disorders represent the most prevalent psychiatric condition in the United States, outside of substance use disorder.[111]

## Children [edit]

Like adults, children can experience anxiety disorders; between 10 and 20 percent of all children will develop a full-fledged anxiety disorder prior to the age of 18,[112] making anxiety the most common mental health issue in young people. Anxiety disorders in children are often more challenging to identify than their adult counterparts owing to the difficulty many parents face in discerning them from normal childhood fears. Likewise, anxiety in children is sometimes misdiagnosed as an attention deficit disorder or, due to the tendency of children to interpret their emotions physically (as stomach aches, head aches, etc.), anxiety disorders may initially be confused with physical ailments.[113]

Anxiety in children has a variety of causes; sometimes anxiety is rooted in biology, and may be a product of another existing condition, such as Autism or Asperger's Disorder.[114] Gifted children are also often more prone to excessive anxiety than non-gifted children.[115] Other cases of anxiety arise from the child having experienced a traumatic event of some kind, and in some cases, the cause of the child's anxiety cannot be pinpointed.[116]

Anxiety in children tends to manifest along age-appropriate themes, such as fear of going to school (not related to bullying) or not performing well enough at school, fear of social rejection, fear of something happening to loved ones, etc. What separates disordered anxiety from normal childhood anxiety is the duration and intensity of the fears involved.[113]

A small child will usually experience separation anxiety, for example, but he or she will generally grow out of it by about the age of 6, whereas in an anxious child it may linger for years longer, hindering the child's development.[117] Similarly, most children will fear the dark or losing their parents at some point, but this fear will dissipate over time without interfering a great deal in that child's normal day-to-day activities. In a child with an anxiety disorder, fearing the dark or loss of loved ones may grow into a lasting obsession which the child tries to deal with in compulsive ways which erode his or her quality of life.[117] The presence of co- occurring depressive symptoms in anxiety disorders may mark the transition to a more severe and detrimental and impairing disorder in preschool and early school age.[118]

Children, similar to adults, may suffer from a range of different anxiety disorders, including:

Generalized anxiety disorder: The child experiences persistent anxiety regarding a wide variety of situations, and this anxiety may adapt to fit each new situation that arises or be based largely on imagined situations which have yet to occur. Reassurance often has little effect.[113][117]

Separation anxiety disorder: A child who is older than 6 or 7 who has an extremely difficult time being away from his or her parents may be experiencing Separation Anxiety Disorder. Children with this disorder often fear that they will lose their loved ones during times of absence. As such, they frequently refuse to attend school.[119]

Social anxiety disorder should not be confused with shyness or introversion; shyness is frequently normal, especially in very young children. Children with social anxiety disorder often wish to engage in social activity (unlike introverts) but find themselves held back by obsessive fears of being disliked. They often convince

themselves they have made a poor impression on others, regardless of evidence to the contrary. Over time, they may develop a phobia of social situations.[120] This disorder affects older children and preteens more often than younger children. Social phobia in children may also be caused by some traumatic event, such as not knowing an answer when called on in class.[121]

While uncommon in children, OCD can occur. Rates are between two and four percent.[122] Like adults, children rely on "magical thinking" in order to allay their anxiety, i.e., he or she must perform certain rituals (often based in counting, organizing, cleaning, etc.) in order to "prevent" the calamity he or she feels is imminent. Unlike normal children, who can leave their magical thinking-based activities behind when called upon to do so, children with OCD are literally unable to cease engaging in these activities, regardless of the consequences.[117][123]

Panic disorder is more common in older children, though younger children sometimes also suffer from it. Panic disorder is frequently mistaken for a physical illness by children suffering from it, likely due to its strongly physical symptoms (a racing heartbeat, sweating, dizziness, nausea, etc.) These symptoms are, however, usually accompanied by extreme fear, particularly the fear of dying. Like adults with Panic Disorder, children may attempt to avoid any situation they feel is a "trigger" for their attacks.[117]

# Asperger syndrome

From Wikipedia, the free encyclopedia

**Asperger syndrome** (**AS**), also known as **Asperger's**, is a developmental disorder characterized by significant difficulties in social interaction and nonverbal communication, along with restricted and repetitive patterns of behavior and interests.[1] As a milder autism spectrum disorder (ASD), it differs from other ASDs by relatively normal language and intelligence.[2] Although not required for diagnosis, physical clumsiness and unusual use of language are common.[3][4] Signs usually begin before two years old and typically last for a person's entire life.[1]

The exact cause of Asperger's is unknown.[1] While it is probably partly inherited, the underlying genetics have not been determined conclusively.[3][5] Environmental factors are also believed to play a role.[1] Brain imaging has not identified a common underlying problem.[3] The diagnosis of Asperger's was removed in the 2013 fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), and people with these symptoms are now included within the autism spectrum disorder along with autism and pervasive developmental disorder not otherwise specified.[1][6] It remains within the tenth edition of the *International Classification of Diseases* (ICD-10) as of 2015.[2]

There is no single treatment, and the effectiveness of particular interventions is supported by only limited data.[3] Treatment is aimed at improving poor communication skills, obsessive or repetitive routines, and physical clumsiness.[7] Interventions may include social skills training, cognitive behavioral therapy, physical therapy, speech therapy, parent training, and medications for associated problems such as mood or anxiety.[7] Most children improve as they grow up, but social and communication difficulties usually persist.[8] Some researchers and people on the autism spectrum have advocated a shift in attitudes toward the view that autism spectrum disorder is a difference, rather than a disease that must be treated or cured.[9][10]

In 2013, Asperger's was estimated to affect 31 million people globally.[11] The syndrome is named after the Austrian

**Asperger syndrome**

**Synonyms** Asperger's syndrome, Asperger disorder (AD), Asperger's

Restricted interests or repetitive behaviors, such as this boy's interest in playing with a toy model of molecules, may be features of Asperger's.

pediatrician Hans Asperger who, in 1944, described children in his practice who lacked nonverbal communication, had limited understanding of others' feelings, and were physically clumsy.[12] The modern conception of Asperger syndrome came into existence in 1981 and went through a period of popularization.[13][14][15] It became a standardized diagnosis in the early 1990s.[16] Many questions and controversies remain about aspects of the disorder.[8] There is doubt about whether it is distinct from high-functioning autism (HFA).[17] Partly because of this, the percentage of people affected is not firmly established.[3]

# Classification

Play media

Autism spectrum disorder video

The extent of the overlap between AS and high-functioning autism (HFA—autism unaccompanied by intellectual disability) is unclear.[17][18][19] The ASD classification is to some extent an artifact of how autism was discovered,[20] and may not reflect the true nature of the spectrum;[21] methodological problems have beset Asperger syndrome as a valid diagnosis from the outset.[22][23] In the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), published in May 2013,[24] AS, as a separate diagnosis, was eliminated and folded into autism spectrum disorder.[25] Like the diagnosis of Asperger syndrome,[26] the change was controversial[26][27] and AS was not removed from the WHO's ICD-10.

The World Health Organization (WHO) defines Asperger syndrome (AS) as one of the autism spectrum disorders (ASD) or pervasive developmental disorders (PDD), which are a spectrum of psychological conditions that are characterized by abnormalities of social interaction and communication that pervade the individual's functioning, and by restricted and repetitive interests and behavior. Like other psychological development disorders, ASD begins in infancy or childhood, has a steady course without remission or relapse, and has impairments that result from maturation-related changes in various systems of the brain.[28] ASD, in turn, is a subset of the broader autism phenotype,[29]

which describes individuals who may not have ASD but do have autistic-like traits, such as social deficits. Of the other four ASD forms, autism is the most similar to AS in signs and likely causes, but its diagnosis requires impaired communication and allows delay in cognitive development; Rett syndrome and childhood disintegrative disorder share several signs with autism but may have unrelated causes; and pervasive developmental disorder not otherwise specified (PDD-NOS) is diagnosed when the criteria for a more specific disorder are unmet.[30]

# Characteristics

As a pervasive developmental disorder, Asperger syndrome is distinguished by a pattern of symptoms rather than a single symptom. It is characterized by qualitative impairment in social interaction, by stereotyped and restricted patterns of behavior, activities and interests, and by no clinically significant delay in cognitive development or general delay in language.[31] Intense preoccupation with a narrow subject, one-sided verbosity, restricted prosody, and physical clumsiness are typical of the condition, but are not required for diagnosis.[17] Suicidal behavior appears to occur at rates similar to those without ASD.[32]

People with Asperger syndrome often display restricted or specialized interests, such as this boy's interest in stacking cans.

## Social interaction

*Further information: Asperger syndrome and interpersonal relationships*

A lack of demonstrated empathy affects aspects of communal living for persons with Asperger syndrome.[4] Individuals with AS experience difficulties in basic elements of social interaction, which may include a failure to develop friendships or to seek shared enjoyments or achievements with others (for example, showing others objects of interest), a lack of social or emotional reciprocity (social "games" give-and-take mechanic), and impaired nonverbal behaviors in areas such as eye contact, facial expression, posture, and gesture.[3]

People with AS may not be as withdrawn around others, compared with those with other, more debilitating forms of autism; they approach others, even if awkwardly. For example, a person with AS may engage in a one-sided, long-winded speech about a favorite topic, while misunderstanding or not recognizing the listener's feelings or reactions, such as a wish to change the topic of talk or end the interaction.[17] This social awkwardness has been called "active but odd".[3] This failure to react appropriately to social interaction may appear as disregard for other people's feelings, and may come across as insensitive.[17] However, not all individuals with AS will approach others. Some of them may even display selective mutism, speaking not at all to most people and excessively to specific people. Some may choose only to talk to people they like.[33]

The cognitive ability of children with AS often allows them to articulate social norms in a laboratory context,[3] where they may be able to show a theoretical understanding of other people's emotions; however, they typically have difficulty acting on this knowledge in fluid, real-life situations.[17] People with AS may analyze and distill their observations of social interaction into rigid behavioral guidelines, and apply these rules in awkward ways, such as forced eye contact, resulting in a demeanor that appears rigid or socially naive. Childhood desire for companionship can become numbed through a history of failed social encounters.[3]

The hypothesis that individuals with AS are predisposed to violent or criminal behavior has been investigated, but is not supported by data.[3][34] More evidence suggests children with AS are victims rather than victimizers.[35] A 2008 review found that an overwhelming number of reported violent criminals with AS had coexisting psychiatric disorders such as schizoaffective disorder.[36]

## Restricted and repetitive interests and behavior

People with Asperger syndrome can display behavior, interests, and activities that are restricted and repetitive and are sometimes abnormally intense or focused. They may stick to inflexible routines, move in stereotyped and repetitive ways, preoccupy themselves with parts of objects or compulsive behaviors like lining things up in patterns.[31]

Pursuit of specific and narrow areas of interest is one of the most striking possible features of AS.[3] Individuals with AS may collect volumes of detailed information on a relatively narrow topic such as weather data or star names, without necessarily having a genuine understanding of the broader topic.[3][17] For example, a child might memorize camera model numbers while caring little about photography.[3] This behavior is usually apparent by age 5 or 6.[3] Although these special interests may change from time to time, they typically become more unusual and narrowly focused, and often dominate social interaction so much that the entire family may become immersed. Because narrow topics often capture the interest of children, this symptom may go unrecognized.[17]

Stereotyped and repetitive motor behaviors are a core part of the diagnosis of AS and other ASDs.[37] They include hand movements such as flapping or twisting, and complex whole-body movements.[31] These are typically repeated in longer bursts and look more voluntary or ritualistic than tics, which are usually faster, less rhythmical and less often symmetrical.[38]

According to the Adult Asperger Assessment (AAA) diagnostic test, a lack of interest in fiction and a positive preference towards non-fiction is common among adults with AS.[39]

## Speech and language

Although individuals with Asperger syndrome acquire language skills without significant general delay and their speech typically lacks significant abnormalities, language acquisition and use is often atypical.[17] Abnormalities include verbosity, abrupt transitions, literal interpretations and miscomprehension of nuance, use of metaphor meaningful only to the speaker, auditory perception deficits, unusually pedantic, formal or idiosyncratic speech, and oddities in loudness, pitch, intonation, prosody, and rhythm.[3] Echolalia has also been observed in individuals with AS.[40]

Three aspects of communication patterns are of clinical interest: poor prosody, tangential and circumstantial speech, and marked verbosity. Although inflection and intonation may be less rigid or monotonic than in classic autism, people with AS often have a limited range of intonation: speech may be unusually fast, jerky or loud. Speech may convey a sense of incoherence; the conversational style often includes monologues about topics that bore the listener, fails to provide context for comments, or fails to suppress internal thoughts. Individuals with AS may fail to detect whether the listener is interested or engaged in the conversation. The speaker's conclusion or point may never be made, and attempts by the listener to elaborate on the speech's content or logic, or to shift to related topics, are often unsuccessful.[17]

Children with AS may have an unusually sophisticated vocabulary at a young age and have been colloquially called "little professors", but have difficulty understanding figurative language and tend to use language literally.[3] Children with AS appear to have particular weaknesses in areas of nonliteral language that include humor, irony, teasing, and sarcasm. Although individuals with AS usually understand the cognitive basis of humor, they seem to lack understanding of the intent of humor to share enjoyment with others.[18] Despite strong evidence of impaired humor appreciation, anecdotal reports of humor in individuals with AS seem to challenge some psychological theories of AS and autism.[41]

## Motor and sensory perception

Individuals with Asperger syndrome may have signs or symptoms that are independent of the diagnosis, but can affect the individual or the family.[42] These include differences in perception and problems with motor skills, sleep, and emotions.

Individuals with AS often have excellent auditory and visual perception.[43] Children with ASD often

demonstrate enhanced perception of small changes in patterns such as arrangements of objects or well-known images; typically this is domain-specific and involves processing of fine-grained features.[44] Conversely, compared with individuals with high-functioning autism, individuals with AS have deficits in some tasks involving visual-spatial perception, auditory perception, or visual memory.[3] Many accounts of individuals with AS and ASD report other unusual sensory and perceptual skills and experiences. They may be unusually sensitive or insensitive to sound, light, and other stimuli;[45] these sensory responses are found in other developmental disorders and are not specific to AS or to ASD. There is little support for increased fight-or-flight response or failure of habituation in autism; there is more evidence of decreased responsiveness to sensory stimuli, although several studies show no differences.[46]

Hans Asperger's initial accounts[3] and other diagnostic schemes[47] include descriptions of physical clumsiness. Children with AS may be delayed in acquiring skills requiring motor dexterity, such as riding a bicycle or opening a jar, and may seem to move awkwardly or feel "uncomfortable in their own skin". They may be poorly coordinated, or have an odd or bouncy gait or posture, poor handwriting, or problems with visual-motor integration.[3][17] They may show problems with proprioception (sensation of body position) on measures of developmental coordination disorder (motor planning disorder), balance, tandem gait, and finger-thumb apposition. There is no evidence that these motor skills problems differentiate AS from other high-functioning ASDs.[3]

Children with AS are more likely to have sleep problems, including difficulty in falling asleep, frequent nocturnal awakenings, and early morning awakenings.[48][49] AS is also associated with high levels of alexithymia, which is difficulty in identifying and describing one's emotions.[50] Although AS, lower sleep quality, and alexithymia are associated, their causal relationship is unclear.[49]

## Causes

*Further information: Causes of autism*

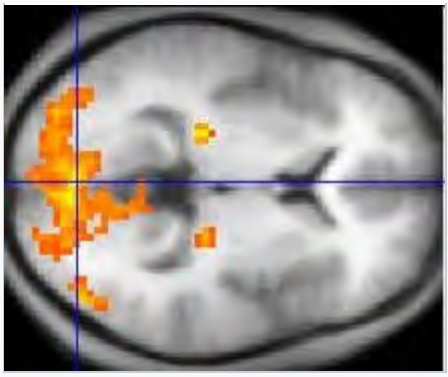
Hans Asperger described common symptoms among his patients' family members, especially fathers, and research supports this observation and suggests a genetic contribution to Asperger syndrome. Although no specific gene has yet been identified, multiple factors are believed to play a role in the expression of autism, given the phenotypic variability seen in children with AS.[3][51] Evidence for a genetic link is the tendency for AS to run in families and an observed higher incidence of family members who have behavioral symptoms similar to AS but in a more limited form (for example, slight difficulties with social interaction, language, or reading).[7] Most research suggests that all autism spectrum disorders have shared genetic mechanisms, but AS may have a stronger genetic component than autism.[3] There is probably a common group of genes where particular alleles render an individual vulnerable to developing AS; if this is the case, the particular combination of alleles would determine the severity and symptoms for each individual with AS.[7]

A few ASD cases have been linked to exposure to teratogens (agents that cause birth defects) during the first eight weeks from conception. Although this does not exclude the possibility that ASD can be initiated or affected later, it is strong evidence that it arises very early in development.[52] Many environmental factors have been hypothesized to act after birth, but none has been confirmed by scientific investigation.[53]

## Mechanism

*Further information: Autism § Mechanism*

Asperger syndrome appears to result from developmental factors that affect many or all functional brain systems, as opposed to localized effects.[56] Although the specific underpinnings of AS or factors that distinguish it from other ASDs are unknown, and no clear pathology [3]



Functional magnetic resonance imaging provides some evidence for both underconnectivity and mirror neuron theories.[54][55]

common to individuals with AS has emerged, it is still possible that AS's mechanism is separate from other ASDs.[57] Neuroanatomical studies and the associations with teratogens strongly suggest that the mechanism includes alteration of brain development soon after conception.[52] Abnormal migration of embryonic cells during fetal development may affect the final structure and connectivity of the brain, resulting in alterations in the neural circuits that control thought and behavior.[58] Several theories of mechanism are available; none are likely to provide a complete explanation.[59]

The underconnectivity theory hypothesizes underfunctioning high-level neural connections and synchronization, along with an excess of low-level processes.[54] It maps well to general-processing theories such as weak central coherence theory, which hypothesizes that a limited ability to see the big picture underlies the central disturbance in ASD.[60] A related theory—enhanced perceptual functioning—focuses more on the superiority of locally oriented and perceptual operations in autistic individuals.[61]

The mirror neuron system (MNS) theory hypothesizes that alterations to the development of the MNS interfere with imitation and lead to Asperger's core feature of social impairment.[55][62] For example, one study found that activation is delayed in the core circuit for imitation in individuals with AS.[63] This theory maps well to social cognition theories like the theory of mind, which hypothesizes that autistic behavior arises from impairments in ascribing mental states to oneself and others,[64] or hyper-systemizing, which hypothesizes that autistic individuals can systematize internal operation to handle internal events but are less effective at empathizing by handling events generated by other agents.[65]

## Diagnosis

*Main article: Diagnosis of Asperger syndrome*

Standard diagnostic criteria require impairment in social interaction and repetitive and stereotyped patterns of behavior, activities and interests, without significant delay in language or cognitive development. Unlike the international standard,[28] the DSM-IV-TR criteria also required significant impairment in day-to-day functioning;[31] DSM-5 eliminated AS as a separate diagnosis in 2013, and folded it into the umbrella of autism spectrum disorders.[25] Other sets of diagnostic criteria have been proposed by Szatmari *et al.*[66] and by Gillberg and Gillberg.[67]

Diagnosis is most commonly made between the ages of four and eleven.[3] A comprehensive assessment involves a multidisciplinary team[4][7][68] that observes across multiple settings,[3] and includes neurological and genetic assessment as well as tests for cognition, psychomotor function, verbal and nonverbal strengths and weaknesses, style of learning, and skills for independent living.[7] The "gold standard" in diagnosing ASDs combines clinical judgment with the Autism Diagnostic Interview-Revised (ADI-R)—a semistructured parent interview—and the Autism Diagnostic Observation Schedule (ADOS)—a conversation and play-based interview with the child.[8] Delayed or mistaken diagnosis can be traumatic for individuals and families; for example, misdiagnosis can lead to medications that worsen behavior.[68][69]

Underdiagnosis and overdiagnosis may be problems. The cost and difficulty of screening and assessment can delay diagnosis. Conversely, the increasing popularity of drug treatment options and the expansion of benefits has motivated providers to overdiagnose ASD.[70] There are indications AS has been diagnosed more frequently in recent years, partly as a residual diagnosis for children of normal intelligence who are not autistic but have social difficulties.[71]

There are questions about the external validity of the AS diagnosis. That is, it is unclear whether there is a practical benefit in distinguishing AS from HFA and from PDD-NOS;[71] the same child can receive different diagnoses depending on the screening tool.[7] The debate about distinguishing AS from HFA is partly due to a tautological dilemma where disorders are defined based on severity of impairment, so that studies that appear to confirm differences based on severity are to be expected.[72]

### Differential diagnosis

Many children with AS are initially misdiagnosed with attention deficit hyperactivity disorder (ADHD).[3] Diagnosing adults is more challenging, as standard diagnostic criteria are designed for children and the expression of AS changes with age.[73] Adult diagnosis requires painstaking clinical examination and thorough medical history gained from both the individual and other people who know the person, focusing on childhood behavior.[39] Conditions that must be considered in a differential diagnosis include other ASDs, the schizophrenia spectrum, ADHD, obsessive–compulsive disorder, major depressive disorder, semantic pragmatic disorder, nonverbal learning disorder,[68] Tourette syndrome,[38] stereotypic movement disorder, bipolar disorder,[51] and social-cognitive deficits due to brain damage from alcohol abuse.[74]

There are considerable similarities and overlap between Asperger's syndrome and obsessive–compulsive personality disorder (OCPD),[75] such as list-making, inflexible adherence to rules, and obsessive aspects of Asperger's syndrome, though the former may be distinguished from OCPD especially regarding affective behaviors, worse social skills, difficulties with theory of mind and intense intellectual interests, e.g. an ability to recall every aspect of a hobby.[76]

## Screening

Parents of children with Asperger syndrome can typically trace differences in their children's development to as early as 30 months of age.[51] Developmental screening during a routine check-up by a general practitioner or pediatrician may identify signs that warrant further investigation.[3][7] The United States Preventive Services Task Force in 2016 found it was unclear if screening was beneficial or harmful among children in whom there is no concerns.[77]

The diagnosis of AS is complicated by the use of several different screening instruments,[7][47] including the Asperger Syndrome Diagnostic Scale (ASDS), Autism Spectrum Screening Questionnaire (ASSQ), Childhood Autism Spectrum Test (CAST) (previously called the Childhood Asperger Syndrome Test),[78] Gilliam Asperger's disorder scale (GADS), Krug Asperger's Disorder Index (KADI),[79] and the Autism-spectrum quotient (AQ; with versions for children,[80] adolescents[81] and adults[82]). None have been shown to reliably differentiate between AS and other ASDs.[3]

## Management

*Further information: Autism therapies*

Asperger syndrome treatment attempts to manage distressing symptoms and to teach age-appropriate social, communication and vocational skills that are not naturally acquired during development,[3] with intervention tailored to the needs of the individual based on multidisciplinary assessment.[83] Although progress has been made, data supporting the efficacy of particular interventions are limited.[3][84]

### Therapies

The ideal treatment for AS coordinates therapies that address core symptoms of the disorder, including poor communication skills and obsessive or repetitive routines. While most professionals agree that the earlier the intervention, the better, there is no single best treatment package.[7] AS treatment resembles that of other high-functioning ASDs, except that it takes into account the linguistic capabilities, verbal strengths,

and nonverbal vulnerabilities of individuals with AS.[3] A typical program generally includes:[7]

- A positive behavior support procedure includes training and support of parents and school faculty in behavior management strategies to use in the home and school;
- An applied behavior analysis (ABA) technique called social skills training for more effective interpersonal interactions;[85]
- Cognitive behavioral therapy to improve stress management relating to anxiety or explosive emotions[86] and to cut back on obsessive interests and repetitive routines;
- Medication, for coexisting conditions such as major depressive disorder and anxiety disorder;[87]
- Occupational or physical therapy to assist with poor sensory processing and motor coordination;
- Social communication intervention, which is specialized speech therapy to help with the pragmatics of the give and take of normal conversation.[88]

Of the many studies on behavior-based early intervention programs, most are case reports of up to five participants and typically examine a few problem behaviors such as self-injury, aggression, noncompliance, stereotypies, or spontaneous language; unintended side effects are largely ignored.[89] Despite the popularity of social skills training, its effectiveness is not firmly established.[90] A randomized controlled study of a model for training parents in problem behaviors in their children with AS showed that parents attending a one-day workshop or six individual lessons reported fewer behavioral problems, while parents receiving the individual lessons reported less intense behavioral problems in their AS children.[91] Vocational training is important to teach job interview etiquette and workplace behavior to older children and adults with AS, and organization software and personal data assistants can improve the work and life management of people with AS.[3]

## Medications

No medications directly treat the core symptoms of AS.[87] Although research into the efficacy of pharmaceutical intervention for AS is limited,[3] it is essential to diagnose and treat comorbid conditions.[4] Deficits in self-identifying emotions or in observing effects of one's behavior on others can make it difficult for individuals with AS to see why medication may be appropriate.[87] Medication can be effective in combination with behavioral interventions and environmental accommodations in treating comorbid symptoms such as anxiety disorder, major depressive disorder, inattention and aggression.[3] The atypical antipsychotic medications risperidone and olanzapine have been shown to reduce the associated symptoms of AS;[3] risperidone can reduce repetitive and self-injurious behaviors, aggressive outbursts and impulsivity, and improve stereotypical patterns of behavior and social relatedness. The selective serotonin reuptake inhibitors (SSRIs) fluoxetine, fluvoxamine, and sertraline have been effective in treating restricted and repetitive interests and behaviors.[3][4][51]

Care must be taken with medications, as side effects may be more common and harder to evaluate in individuals with AS, and tests of drugs' effectiveness against comorbid conditions routinely exclude individuals from the autism spectrum.[87] Abnormalities in metabolism, cardiac conduction times, and an increased risk of type 2 diabetes have been raised as concerns with these medications,[92][93] along with serious long-term neurological side effects.[89] SSRIs can lead to manifestations of behavioral activation such as increased impulsivity, aggression, and sleep disturbance.[51] Weight gain and fatigue are commonly reported side effects of risperidone, which may also lead to increased risk for extrapyramidal symptoms such as restlessness and dystonia[51] and increased serum prolactin levels.[94] Sedation and weight gain are more common with olanzapine,[93] which has also been linked with diabetes.[92] Sedative side-effects in school-age children[95] have ramifications for classroom learning. Individuals with AS may be unable to identify and communicate their internal moods and emotions or to tolerate side effects that for most people would not be problematic.[96]

# Prognosis

There is some evidence that children with AS may see a lessening of symptoms; up to 20% of children may no longer meet the diagnostic criteria as adults, although social and communication difficulties may persist.[8] As of 2006, no studies addressing the long-term outcome of individuals with Asperger syndrome are available and there are no systematic long-term follow-up studies of children with AS.[17] Individuals with AS appear to have normal life expectancy, but have an increased prevalence of comorbid psychiatric conditions, such as major depressive disorder and anxiety disorder that may significantly affect prognosis.[3][8] Although social impairment may be lifelong, the outcome is generally more positive than with individuals with lower functioning autism spectrum disorders;[3] for example, ASD symptoms are more likely to diminish with time in children with AS or HFA.[97] Most students with AS/HFA have average mathematical ability and test slightly worse in mathematics than in general intelligence, but some are gifted in mathematics.[98] AS has potentially been linked to some accomplishments, such as Vernon L. Smith winning the Nobel Memorial Prize in Economic Sciences;[99] however, Smith is self-diagnosed.[100]

Although many attend regular education classes, some children with AS may utilize special education services because of their social and behavioral difficulties.[17] Adolescents with AS may exhibit ongoing difficulty with self care or organization, and disturbances in social and romantic relationships. Despite high cognitive potential, most young adults with AS remain at home, yet some do marry and work independently.[3] The "different-ness" adolescents experience can be traumatic.[101] Anxiety may stem from preoccupation over possible violations of routines and rituals, from being placed in a situation without a clear schedule or expectations, or from concern with failing in social encounters;[3] the resulting stress may manifest as inattention, withdrawal, reliance on obsessions, hyperactivity, or aggressive or oppositional behavior.[86] Depression is often the result of chronic frustration from repeated failure to engage others socially, and mood disorders requiring treatment may develop.[3] Clinical experience suggests the rate of suicide may be higher among those with AS, but this has not been confirmed by systematic empirical studies.[102]

Education of families is critical in developing strategies for understanding strengths and weaknesses;[4] helping the family to cope improves outcomes in children.[35] Prognosis may be improved by diagnosis at a younger age that allows for early interventions, while interventions in adulthood are valuable but less beneficial.[4] There are legal implications for individuals with AS as they run the risk of exploitation by others and may be unable to comprehend the societal implications of their actions.[4]

# Epidemiology

*Further information: Conditions comorbid to autism spectrum disorders*

Prevalence estimates vary enormously. A 2003 review of epidemiological studies of children found autism prevalence rates ranging from 0.03 to 4.84 per 1,000, with the ratio of autism to Asperger syndrome ranging from 1.5:1 to 16:1;[103] combining the geometric mean ratio of 5:1 with a conservative prevalence estimate for autism of 1.3 per 1,000 suggests indirectly that the prevalence of AS might be around 0.26 per 1,000.[104] Part of the variance in estimates arises from differences in diagnostic criteria. For example, a relatively small 2007 study of 5,484 eight-year-old children in Finland found 2.9 children per 1,000 met the ICD-10 criteria for an AS diagnosis, 2.7 per 1,000 for Gillberg and Gillberg criteria, 2.5 for DSM-IV, 1.6 for Szatmari *et al.*, and 4.3 per 1,000 for the union of the four criteria. Boys seem to be more likely to have AS than girls; estimates of the sex ratio range from 1.6:1 to 4:1, using the Gillberg and Gillberg criteria.[105] Females with autism spectrum disorders may be underdiagnosed.[106]

Anxiety disorder and major depressive disorder are the most common conditions seen at the same time; comorbidity of these in persons with AS is estimated at 65%.[3] Reports have associated AS with medical conditions such as aminoaciduria and ligamentous laxity, but these have been case reports or small studies and no factors have been associated with AS across studies.[3] One study of males with AS found an increased rate of epilepsy and a high rate (51%) of nonverbal learning disorder.[107] AS is associated with tics, Tourette syndrome, and bipolar disorder, and the repetitive behaviors of AS have many similarities with the symptoms of obsessive–compulsive disorder and obsessive–compulsive personality disorder.[108]

However many of these studies are based on clinical samples or lack standardized measures; nonetheless, comorbid conditions are relatively common.[8]

# History

*Main article: History of Asperger syndrome*

Named after the Austrian pediatrician Hans Asperger (1906–1980), Asperger syndrome is a relatively new diagnosis in the field of autism.[109] As a child, Asperger appears to have exhibited some features of the very condition named after him, such as remoteness and talent in language.[110][111] In 1944, Asperger described four children in his practice[4] who had difficulty in integrating themselves socially. The children lacked nonverbal communication skills, failed to demonstrate empathy with their peers, and were physically clumsy. Asperger called the condition "autistic psychopathy" and described it as primarily marked by social isolation.[7] Fifty years later, several standardizations of AS as a diagnosis were tentatively proposed, many of which diverge significantly from Asperger's original work.[112]

Unlike today's AS, autistic psychopathy could be found in people of all levels of intelligence, including those with intellectual disability.[113] Asperger defended the value of high-functioning autistic individuals, writing "We are convinced, then, that autistic people have their place in the organism of the social community. They fulfill their role well, perhaps better than anyone else could, and we are talking of people who as children had the greatest difficulties and caused untold worries to their care-givers."[12] Asperger also believed some would be capable of exceptional achievement and original thought later in life.[4] His paper was published during wartime and in German, so it was not widely read elsewhere.

Lorna Wing popularized the term *Asperger syndrome* in the English-speaking medical community in her 1981 publication[114] of a series of case studies of children showing similar symptoms,[109] and Uta Frith translated Asperger's paper to English in 1991.[12] Sets of diagnostic criteria were outlined by Gillberg and Gillberg in 1989 and by Szatmari *et al.* in the same year.[105] AS became a standard diagnosis in 1992, when it was included in the tenth edition of the World Health Organization's diagnostic manual, *International Classification of Diseases* (ICD-10); in 1994, it was added to the fourth edition of the American Psychiatric Association's diagnostic reference, *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV).[7]

Hundreds of books, articles and websites now describe AS, and prevalence estimates have increased dramatically for ASD, with AS recognized as an important subgroup.[109] Whether it should be seen as distinct from high-functioning autism is a fundamental issue requiring further study,[4] and there are questions about the empirical validation of the DSM-IV and ICD-10 criteria.[17] In 2013, DSM-5 eliminated AS as a separate diagnosis, folding it into the autism spectrum on a severity scale.[25]

# Society and culture

*See also: Sociological and cultural aspects of autism*

People identifying with Asperger syndrome may refer to themselves in casual conversation as *aspies* (a term first used in print by Liane Holliday Willey in 1999).[115] The word *neurotypical* (abbreviated *NT*) describes a person whose neurological development and state are typical, and is often used to refer to non-autistic people. The Internet has allowed individuals with AS to communicate with each other in a way that was not previously possible because of their rarity and geographic dispersal, forming a subculture composed of people with Asperger's. Internet sites like Wrong Planet have made it easier for individuals to connect.[9]

Students and families walk

Some autistic people have advocated a shift in perception of autism spectrum disorders as complex syndromes rather than diseases that must

to support Autism Awareness Month.

be cured. Proponents of this view reject the notion that there is an "ideal" brain configuration and that any deviation from the norm is pathological; they promote tolerance for what they call neurodiversity.[116] These views are the basis for the autistic rights and autistic pride movements.[117] There is a contrast between the attitude of adults with self-identified AS, who typically do not want to be cured and are proud of their identity, and parents of children with AS, who typically seek assistance and a cure for their children.[118]

Some researchers have argued that AS can be viewed as a different cognitive style, not a disorder,[9] and that it should be removed from the standard *Diagnostic and Statistical Manual*, much as homosexuality was removed.[119] In a 2002 paper, Simon Baron-Cohen wrote of those with AS, "In the social world, there is no great benefit to a precise eye for detail, but in the worlds of maths, computing, cataloging, music, linguistics, engineering, and science, such an eye for detail can lead to success rather than failure." Baron-Cohen cited two reasons why it might still be useful to consider AS to be a disability: to ensure provision for legally required special support, and to recognize emotional difficulties from reduced empathy.[10] Baron-Cohen argues that the genes for Asperger's combination of abilities have operated throughout recent human evolution and have made remarkable contributions to human history.[120]

By contrast, Pier Jaarsma and Welin wrote in 2011 that the "broad version of the neurodiversity claim, covering low-functioning as well as high-functioning autism, is problematic. Only a narrow conception of neurodiversity, referring exclusively to high-functioning autists, is reasonable."[121] They say that "higher functioning" individuals with autism may "not [be] benefited with such a psychiatric defect-based diagnosis ... some of them are being harmed by it, because of the disrespect the diagnosis displays for their natural way of being", but "think that it is still reasonable to include other categories of autism in the psychiatric diagnostics. The narrow conception of the neurodiversity claim should be accepted but the broader claim should not."[121] Jonathan Mitchell, an autistic author and blogger who advocates a cure for autism, has described autism as having "prevented me from making a living or ever having a girlfriend. It's given me bad fine motor coordination problems where I can hardly write. I have an impaired ability to relate to people. I can't concentrate or get things done."[122] He describes neurodiversity as a "tempting escape valve".[123]

# Autism

From Wikipedia, the free encyclopedia

## Variants

*This article is about the classic autistic disorder. For other conditions sometimes called "autism", see Autism spectrum.*

**Autism** is a neurodevelopmental disorder characterized by impaired social interaction, verbal and non-verbal communication, and restricted and repetitive behavior. Parents usually notice signs in the first two years of their child's life.[1] These signs often develop gradually, though some children with autism reach their developmental milestones at a normal pace and then regress.[2] The diagnostic criteria require that symptoms become apparent in early childhood, typically before age three.[3]

While autism is highly heritable, researchers suspect both environmental and genetic factors as causes.[4] Some cases are strongly associated with certain infections during pregnancy including rubella and use of alcohol or cocaine.[5] Controversies surround other proposed environmental causes;[6] for example, the vaccine hypotheses, which have since been disproven. Autism affects information processing in the brain by altering how nerve cells and their synapses connect and organize; how this occurs is not well understood.[7] In the DSM V it is included within the autism spectrum (ASDs), along with Asperger syndrome, which lacks delays in cognitive development and language, and pervasive developmental disorder, not otherwise specified (commonly abbreviated as PDD-NOS), which is diagnosed when the full set of criteria for autism or Asperger syndrome are not met.[8][3]

Early speech or behavioral interventions can help children with autism gain self-care, social, and communication skills.[1] Although there is no known cure,[1] there have been reported cases of children who recovered.[9] Not many children with autism live independently after reaching adulthood, though some become successful.[10] An autistic culture has developed, with some individuals seeking a cure and others believing autism should be accepted as a difference and not treated as a disorder.[11]

Globally, autism is estimated to affect 21.7 million people as of 2013.[12] As of 2010, the number of people affected is estimated at about 1–2 per 1,000 worldwide. It occurs four to five times more often in boys than girls. About 1.5% of children in the United States (one in 68) are diagnosed with ASD as of 2014, a 30% increase from one in 88 in 2012.[13][14][15] The rate of autism among adults aged 18 years and over in the United Kingdom is 1.1%.[16] The number of people diagnosed has been increasing dramatically since the 1980s, partly due to changes in diagnostic practice and government-subsidized financial incentives for named diagnoses;[15] the question of whether actual rates have increased is unresolved.[17]

# Characteristics

Autism is a highly variable neurodevelopmental disorder[18] that first appears during infancy or childhood, and generally follows a steady course without remission.[19] People with autism may be severely impaired in some respects but normal, or even superior, in others.[20] Overt symptoms gradually begin after the age of six months, become established by age two or three years,[21] and tend to continue through adulthood, although often in more muted form.[22] It is distinguished not by a single symptom, but by a characteristic triad of symptoms: impairments in social interaction; impairments in communication; and restricted interests and repetitive behavior. Other aspects, such as atypical eating, are also common but are not essential for diagnosis.[23] Autism's individual symptoms occur in the general population and appear not to associate highly, without a sharp line separating pathologically severe from common traits.[24]

## Social development

Social deficits distinguish autism and the related autism spectrum disorders (ASD; see Classification) from other developmental disorders.[22] People with autism have social impairments and often lack the intuition about others that many people take for granted. Noted autistic Temple Grandin described her inability to understand the social communication of neurotypicals, or people with normal neural development, as leaving her feeling "like an anthropologist on Mars".[25]

Unusual social development becomes apparent early in childhood. Autistic infants show less attention to social stimuli, smile and look at others less often, and respond less to their own name. Autistic toddlers differ more strikingly from social norms; for example, they have less eye contact and turn-taking, and do not have the ability to use simple movements to express themselves, such as pointing at things.[26] Three- to five-year-old children with autism are less likely to exhibit social understanding, approach others spontaneously, imitate and respond to emotions, communicate nonverbally, and take turns with others. However, they do form attachments to their primary caregivers.[27] Most children with autism display moderately less attachment security than neurotypical children, although this difference disappears in children with higher mental development or less severe ASD.[28] Older children and adults with ASD perform worse on tests of face and emotion recognition[29] although this may

be partly due to a lower ability to define a person's own emotions.[30]

Children with high-functioning autism suffer from more intense and frequent loneliness compared to non-autistic peers, despite the common belief that children with autism prefer to be alone. Making and maintaining friendships often proves to be difficult for those with autism. For them, the quality of friendships, not the number of friends, predicts how lonely they feel. Functional friendships, such as those resulting in invitations to parties, may affect the quality of life more deeply.[31]

There are many anecdotal reports, but few systematic studies, of aggression and violence in individuals with ASD. The limited data suggest that, in children with intellectual disability, autism is associated with aggression, destruction of property, and tantrums.[32]

## Communication

About a third to a half of individuals with autism do not develop enough natural speech to meet their daily communication needs.[33] Differences in communication may be present from the first year of life, and may include delayed onset of babbling, unusual gestures, diminished responsiveness, and vocal patterns that are not synchronized with the caregiver. In the second and third years, children with autism have less frequent and less diverse babbling, consonants, words, and word combinations; their gestures are less often integrated with words. Children with autism are less likely to make requests or share experiences, and are more likely to simply repeat others' words (echolalia)[34][35] or reverse pronouns.[36] Joint attention seems to be necessary for functional speech, and deficits in joint attention seem to distinguish infants with ASD:[8] for example, they may look at a pointing hand instead of the pointed-at object,[26][35] and they consistently fail to point at objects in order to comment on or share an experience.[8] Children with autism may have difficulty with imaginative play and with developing symbols into language.[34][35]

In a pair of studies, high-functioning children with autism aged 8–15 performed equally well as, and adults better than, individually matched controls at basic language tasks involving vocabulary and spelling. Both autistic groups performed worse than controls at complex language tasks such as figurative language, comprehension and inference. As people are often sized up initially from their basic language skills, these studies suggest that people speaking to autistic individuals are more likely to overestimate what their audience comprehends.[37]

## Repetitive behavior

Autistic individuals display many forms of repetitive or restricted behavior, which the Repetitive Behavior Scale-Revised (RBS-R) categorizes as follows.[38]

A young boy with autism who has arranged his toys in a row

- Stereotyped behaviors: Repetitive movements, such as hand flapping, head rolling, or body rocking.
- Compulsive behaviors: Time-consuming behaviors intended to reduce anxiety that an individual feels compelled to perform repeatedly or according to rigid rules, such as placing objects in a specific order, checking things, or hand washing.
- Sameness: Resistance to change; for example, insisting that the furniture not be moved or refusing to be interrupted.
- Ritualistic behavior: Unvarying pattern of daily activities, such as an unchanging menu or a dressing ritual. This is closely associated with sameness and an independent validation has suggested combining the two factors.[38]
- Restricted interests: Interests or fixations that are abnormal in theme or intensity of focus, such as preoccupation with a single television program, toy, or game.
- Self-injury: Behaviors such as eye-poking, skin-picking, hand-biting and head-banging.[8]

No single repetitive or self-injurious behavior seems to be specific to autism, but autism appears to have an elevated pattern of occurrence and severity of these behaviors.[39]

## Other symptoms

Autistic individuals may have symptoms that are independent of the diagnosis, but that can affect the individual or the family.[23] An estimated 0.5% to 10% of individuals with ASD show unusual abilities, ranging from splinter skills such as the memorization of trivia to the extraordinarily rare talents of prodigious autistic savants.[40] Many individuals with ASD show superior skills in perception and attention, relative to the general population.[41] Sensory abnormalities are found in over 90% of those with autism, and are considered core features by some,[42]

although there is no good evidence that sensory symptoms differentiate autism from other developmental disorders.[43] Differences are greater for under-responsivity (for example, walking into things) than for over-responsivity (for example, distress from loud noises) or for sensation seeking (for example, rhythmic movements).[44] An estimated 60%–80% of autistic people have motor signs that include poor muscle tone, poor motor planning, and toe walking;[42] deficits in motor coordination are pervasive across ASD and are greater in autism proper.[45]

Unusual eating behavior occurs in about three-quarters of children with ASD, to the extent that it was formerly a diagnostic indicator. Selectivity is the most common problem, although eating rituals and food refusal also occur;[46] this does not appear to result in malnutrition. Although some children with autism also have gastrointestinal symptoms, there is a lack of published rigorous data to support the theory that children with autism have more or different gastrointestinal symptoms than usual;[47] studies report conflicting results, and the relationship between gastrointestinal problems and ASD is unclear.[48]

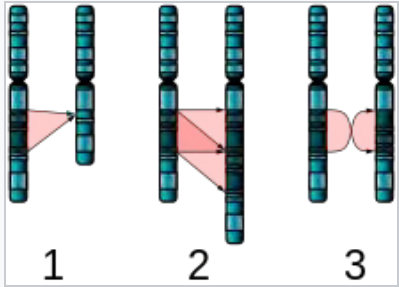
Parents of children with ASD have higher levels of stress.[26] Siblings of children with ASD report greater admiration of and less conflict with the affected sibling than siblings of unaffected children and were similar to siblings of children with Down syndrome in these aspects of the sibling relationship. However, they reported lower levels of closeness and intimacy than siblings of children with Down syndrome; siblings of individuals with ASD have greater risk of negative well-being and poorer sibling relationships as adults.[49]

## Causes

*Main article: Causes of autism*

It has long been presumed that there is a common cause at the genetic, cognitive, and neural levels for autism's characteristic triad of symptoms.[50] However, there is increasing suspicion that autism is instead a complex disorder whose core aspects have distinct causes that often co-occur.[50][51]

Autism has a strong genetic basis, although the genetics of autism are complex and it is unclear whether ASD is explained more by rare mutations with major effects, or by rare multigene interactions of common genetic variants.[53][54] Complexity arises due to interactions among multiple genes, the environment, and epigenetic factors which do not change DNA sequencing but are heritable and influence gene expression.[22] Many genes have been associated with autism through sequencing the genomes of affected individuals and their parents.[55]



Deletion (1), duplication (2) and inversion (3) are all chromosome abnormalities that have been implicated in autism.[52]

Studies of twins suggest that heritability is 0.7 for autism and as high as 0.9 for ASD, and siblings of those with autism are about 25 times more likely to be autistic than the general population.[42] However, most of the mutations that increase autism risk have not been identified. Typically, autism cannot be traced to a Mendelian (single-gene) mutation or to a single chromosome abnormality, and none of the genetic syndromes associated with ASDs have been shown to selectively cause ASD.[53] Numerous candidate genes have been located, with only small effects attributable to any particular gene.[53] Most loci individually explain less than 1% of cases of autism.[56] The large number of autistic individuals with unaffected family members may result from spontaneous structural variation — such as deletions, duplications or inversions in genetic material during meiosis.[57][58] Hence, a substantial fraction of autism cases may be traceable to genetic causes that are highly heritable but not inherited: that is, the mutation that causes the autism is not present in the parental genome.[52]

Several lines of evidence point to synaptic dysfunction as a cause of autism.[7] Some rare mutations may lead to autism by disrupting some synaptic pathways, such as those involved with cell adhesion.[59] Gene replacement studies in mice suggest that autistic symptoms are closely related to later developmental steps that depend on activity in synapses and on activity-dependent changes.[60] All known teratogens (agents that cause birth defects) related to the risk of autism appear to act during the first eight weeks from conception, and though this does not exclude the possibility that autism can be initiated or affected later, there is strong evidence that autism arises very early in development.[61]

Exposure to air pollution during pregnancy, especially heavy metals and particulates, may increase the risk of autism.[62] Environmental factors that have been claimed without evidence to contribute to or exacerbate autism include certain foods, infectious diseases, solvents, diesel exhaust, PCBs, phthalates and phenols used in plastic [17]

products, pesticides, brominated flame retardants, alcohol, smoking, illicit drugs, vaccines, and prenatal stress. No evidence has been found for these claims, and some such as the MMR vaccine have been completely disproven.[63]

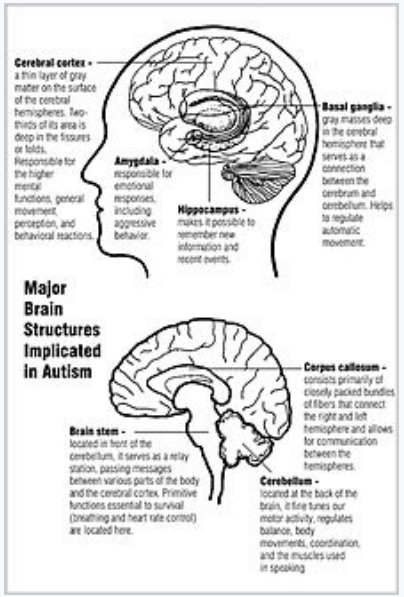
Parents may first become aware of autistic symptoms in their child around the time of a routine vaccination. This has led to unsupported theories blaming vaccine "overload", a vaccine preservative, or the MMR vaccine for causing autism.[64] The latter theory was supported by a litigation-funded study that has since been shown to have been "an elaborate fraud".[65] Although these theories lack convincing scientific evidence and are biologically implausible,[64] parental concern about a potential vaccine link with autism has led to lower rates of childhood immunizations, outbreaks of previously controlled childhood diseases in some countries, and the preventable deaths of several children.[66][67]

# Mechanism

Autism's symptoms result from maturation-related changes in various systems of the brain. How autism occurs is not well understood. Its mechanism can be divided into two areas: the pathophysiology of brain structures and processes associated with autism, and the neuropsychological linkages between brain structures and behaviors.[68] The behaviors appear to have multiple pathophysiologies.[24]

## Pathophysiology

Unlike many other brain disorders, such as Parkinson's, autism does not have a clear unifying mechanism at either the molecular, cellular, or systems level; it is not known whether autism is a few disorders caused by mutations converging on a few common molecular pathways, or is (like intellectual disability) a large set of disorders with diverse mechanisms.[18] Autism appears to result from developmental factors that affect many or all functional brain systems,[70] and to disturb the timing of brain development more than the final product.[69] Neuroanatomical studies and the associations with teratogens strongly suggest that autism's mechanism includes alteration of brain development soon after conception.[61] This anomaly appears to start a cascade of pathological events in the brain that are significantly influenced by environmental factors.[71] Just after birth, the brains of children with autism tend to grow faster than usual, followed by normal or relatively slower growth in childhood. It is not known whether early overgrowth occurs in all children with autism. It seems to be most prominent in brain areas underlying the development of higher cognitive specialization.[42] Hypotheses for the cellular and molecular bases of pathological early overgrowth include the following:



Autism affects the amygdala, cerebellum, and many other parts of the brain.[69]

- An excess of neurons that causes local overconnectivity in key brain regions.[72]
- Disturbed neuronal migration during early gestation.[73][74]
- Unbalanced excitatory–inhibitory networks.[74]
- Abnormal formation of synapses and dendritic spines,[74] for example, by modulation of the neurexin–neuroligin cell-adhesion system,[75] or by poorly regulated synthesis of synaptic proteins.[76][77] Disrupted synaptic development may also contribute to epilepsy, which may explain why the two conditions are associated.[78]

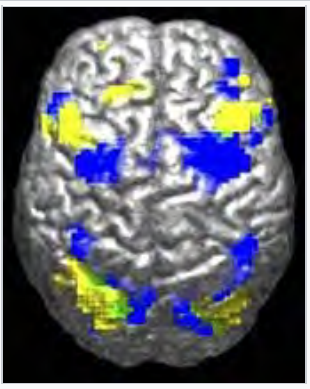
The immune system is thought to play an important role in autism. Children with autism have been found by researchers to have inflammation of both the peripheral and central immune systems as indicated by increased levels of pro-inflammatory cytokines and significant activation of microglia.[79][80][81] Biomarkers of abnormal immune function have also been associated with increased impairments in behaviors that are characteristic of the core features of autism such as deficits in social interactions and communication.[80] Interactions between the immune system and the nervous system begin early during the embryonic stage of life, and successful neurodevelopment depends on a balanced immune response. It is thought that activation of a pregnant mother's immune system such as from environmental toxicants or infection can contribute to causing autism through causing a disruption of brain development.[82][83][84] This is supported by recent studies that have found that infection during pregnancy is associated with an increased risk of autism.[85][86]

The relationship of neurochemicals to autism is not well understood; several have been investigated, with the most evidence for the role of serotonin and of genetic differences in its transport.[7] The role of group I metabotropic

glutamate receptors (mGluR) in the pathogenesis of fragile X syndrome, the most common identified genetic cause of autism, has led to interest in the possible implications for future autism research into this pathway.[87] Some data suggests neuronal overgrowth potentially related to an increase in several growth hormones[88] or to impaired regulation of growth factor receptors. Also, some inborn errors of metabolism are associated with autism, but probably account for less than 5% of cases.[89]

The mirror neuron system (MNS) theory of autism hypothesizes that distortion in the development of the MNS interferes with imitation and leads to autism's core features of social impairment and communication difficulties. The MNS operates when an animal performs an action or observes another animal perform the same action. The MNS may contribute to an individual's understanding of other people by enabling the modeling of their behavior via embodied simulation of their actions, intentions, and emotions.[90] Several studies have tested this hypothesis by demonstrating structural abnormalities in MNS regions of individuals with ASD, delay in the activation in the core circuit for imitation in individuals with Asperger syndrome, and a correlation between reduced MNS activity and severity of the syndrome in children with ASD.[91] However, individuals with autism also have abnormal brain activation in many circuits outside the MNS[92] and the MNS theory does not explain the normal performance of children with autism on imitation tasks that involve a goal or object.[93]

ASD-related patterns of low function and aberrant activation in the brain differ depending on whether the brain is doing social or nonsocial tasks.[95] In autism there is evidence for reduced functional connectivity of the default network, a large-scale brain network involved in social and emotional processing, with intact connectivity of the task-positive network, used in sustained attention and goal-directed thinking[*clarification needed*]. In people with autism the two networks are not negatively correlated in time, suggesting an imbalance in toggling between the two networks, possibly reflecting a disturbance of self-referential thought.[96]



Autistic individuals tend to use different areas of the brain (yellow) for a movement task compared to a control group (blue).[94]

The underconnectivity theory of autism hypothesizes that autism is marked by underfunctioning high-level neural connections and synchronization, along with an excess of low-level processes.[97] Evidence for this theory has been found in functional neuroimaging studies on autistic individuals[37] and by a brainwave study that suggested that adults with ASD have local overconnectivity in the cortex and weak functional connections between the frontal lobe and the rest of the cortex.[98] Other evidence suggests the underconnectivity is mainly within each hemisphere of the cortex and that autism is a disorder of the association cortex.[99]

From studies based on event-related potentials, transient changes to the brain's electrical activity in response to stimuli, there is considerable evidence for differences in autistic individuals with respect to attention, orientation to auditory and visual stimuli, novelty detection, language and face processing, and information storage; several studies have found a preference for nonsocial stimuli.[100] For example, magnetoencephalography studies have found evidence in children with autism of delayed responses in the brain's processing of auditory signals.[101]

In the genetic area, relations have been found between autism and schizophrenia based on duplications and deletions of chromosomes; research showed that schizophrenia and autism are significantly more common in combination with 1q21.1 deletion syndrome. Research on autism/schizophrenia relations for chromosome 15 (15q13.3), chromosome 16 (16p13.1) and chromosome 17 (17p12) are inconclusive.[102]

Functional connectivity studies have found both hypo- and hyper-connectivity in brains of people with autism. Hypo-connectivity seems to dominate, especially for interhemispheric and cortico-cortical functional connectivity.[103]

## Neuropsychology

Two major categories of cognitive theories have been proposed about the links between autistic brains and behavior.

The first category focuses on deficits in social cognition. Simon Baron-Cohen's empathizing–systemizing theory postulates that autistic individuals can systemize—that is, they can develop internal rules of operation to handle events inside the brain—but are less effective at empathizing by handling events generated by other agents. An extension, the extreme male brain theory, hypothesizes that autism is an extreme case of the male brain, defined psychometrically as individuals in whom systemizing is better than empathizing.[104] These theories are somewhat related to Baron-Cohen's earlier theory of mind approach, which hypothesizes that autistic behavior arises from an inability to ascribe mental states to oneself and others. The theory of mind hypothesis is supported by the atypical responses of children with autism to the Sally–Anne test for reasoning about others' motivations,[104] and the

mirror neuron system theory of autism described in *Pathophysiology* maps well to the hypothesis.[91] However, most studies have found no evidence of impairment in autistic individuals' ability to understand other people's basic intentions or goals; instead, data suggests that impairments are found in understanding more complex social emotions or in considering others' viewpoints.[105]

The second category focuses on nonsocial or general processing: the executive functions such as working memory, planning, inhibition. In his review, Kenworthy states that "the claim of executive dysfunction as a causal factor in autism is controversial", however, "it is clear that executive dysfunction plays a role in the social and cognitive deficits observed in individuals with autism".[106] Tests of core executive processes such as eye movement tasks indicate improvement from late childhood to adolescence, but performance never reaches typical adult levels.[107] A strength of the theory is predicting stereotyped behavior and narrow interests;[108] two weaknesses are that executive function is hard to measure[106] and that executive function deficits have not been found in young children with autism.[29]

Weak central coherence theory hypothesizes that a limited ability to see the big picture underlies the central disturbance in autism. One strength of this theory is predicting special talents and peaks in performance in autistic people.[109] A related theory—enhanced perceptual functioning—focuses more on the superiority of locally oriented and perceptual operations in autistic individuals.[110] These theories map well from the underconnectivity theory of autism.

Neither category is satisfactory on its own; social cognition theories poorly address autism's rigid and repetitive behaviors, while the nonsocial theories have difficulty explaining social impairment and communication difficulties.[51] A combined theory based on multiple deficits may prove to be more useful.[111]

## Diagnosis

Diagnosis is based on behavior, not cause or mechanism.[24][112] Under the DSM-5, autism is characterized by persistent deficits in social communication and interaction across multiple contexts, as well as restricted, repetitive patterns of behavior, interests, or activities. These deficits are present in early childhood, typically before age three, and lead to clinically significant functional impairment. Sample symptoms include lack of social or emotional reciprocity, stereotyped and repetitive use of language or idiosyncratic language, and persistent preoccupation with unusual objects. The disturbance must not be better accounted for by Rett syndrome, intellectual disability or global developmental delay.[3] ICD-10 uses essentially the same definition.[19]

Several diagnostic instruments are available. Two are commonly used in autism research: the Autism Diagnostic Interview-Revised (ADI-R) is a semistructured parent interview, and the Autism Diagnostic Observation Schedule (ADOS)[113] uses observation and interaction with the child. The Childhood Autism Rating Scale (CARS) is used widely in clinical environments to assess severity of autism based on observation of children.[26]

A pediatrician commonly performs a preliminary investigation by taking developmental history and physically examining the child. If warranted, diagnosis and evaluations are conducted with help from ASD specialists, observing and assessing cognitive, communication, family, and other factors using standardized tools, and taking into account any associated medical conditions.[114] A pediatric neuropsychologist is often asked to assess behavior and cognitive skills, both to aid diagnosis and to help recommend educational interventions.[115] A differential diagnosis for ASD at this stage might also consider intellectual disability, hearing impairment, and a specific language impairment[114] such as Landau–Kleffner syndrome.[116] The presence of autism can make it harder to diagnose coexisting psychiatric disorders such as depression.[117]

Clinical genetics evaluations are often done once ASD is diagnosed, particularly when other symptoms already suggest a genetic cause.[118] Although genetic technology allows clinical geneticists to link an estimated 40% of cases to genetic causes,[119] consensus guidelines in the US and UK are limited to high-resolution chromosome and fragile X testing.[118] A genotype-first model of diagnosis has been proposed, which would routinely assess the genome's copy number variations.[120] As new genetic tests are developed several ethical, legal, and social issues will emerge. Commercial availability of tests may precede adequate understanding of how to use test results, given the complexity of autism's genetics.[121] Metabolic and neuroimaging tests are sometimes helpful, but are not routine.[118]

ASD can sometimes be diagnosed by age 14 months, although diagnosis becomes increasingly stable over the first three years of life: for example, a one-year-old who meets diagnostic criteria for ASD is less likely than a three-year-old to continue to do so a few years later.[122] In the UK the National Autism Plan for Children recommends at most 30 weeks from first concern to completed diagnosis and assessment, though few cases are handled that quickly in practice.[114] Although the symptoms of autism and ASD begin early in childhood, they are sometimes

missed; years later, adults may seek diagnoses to help them or their friends and family understand themselves, to help their employers make adjustments, or in some locations to claim disability living allowances or other benefits.

Underdiagnosis and overdiagnosis are problems in marginal cases, and much of the recent increase in the number of reported ASD cases is likely due to changes in diagnostic practices. The increasing popularity of drug treatment options and the expansion of benefits has given providers incentives to diagnose ASD, resulting in some overdiagnosis of children with uncertain symptoms. Conversely, the cost of screening and diagnosis and the challenge of obtaining payment can inhibit or delay diagnosis.[123] It is particularly hard to diagnose autism among the visually impaired, partly because some of its diagnostic criteria depend on vision, and partly because autistic symptoms overlap with those of common blindness syndromes or blindisms.[124]

## Classification

Autism is one of the five pervasive developmental disorders (PDD), which are characterized by widespread abnormalities of social interactions and communication, and severely restricted interests and highly repetitive behavior.[19] These symptoms do not imply sickness, fragility, or emotional disturbance.[22]

Of the five PDD forms, Asperger syndrome is closest to autism in signs and likely causes; Rett syndrome and childhood disintegrative disorder share several signs with autism, but may have unrelated causes; PDD not otherwise specified (PDD-NOS; also called *atypical autism*) is diagnosed when the criteria are not met for a more specific disorder.[125] Unlike with autism, people with Asperger syndrome have no substantial delay in language development.[126] The terminology of autism can be bewildering, with autism, Asperger syndrome and PDD-NOS often called the *autism spectrum disorders* (ASD)[1] or sometimes the *autistic disorders*,[127] whereas autism itself is often called *autistic disorder*, *childhood autism*, or *infantile autism*. In this article, *autism* refers to the classic autistic disorder; in clinical practice, though, *autism*, *ASD*, and *PDD* are often used interchangeably.[118] ASD, in turn, is a subset of the broader autism phenotype, which describes individuals who may not have ASD but do have autistic-like traits, such as avoiding eye contact.[128]

The manifestations of autism cover a wide spectrum, ranging from individuals with severe impairments—who may be silent, developmentally disabled, and locked into hand flapping and rocking—to high functioning individuals who may have active but distinctly odd social approaches, narrowly focused interests, and verbose, pedantic communication.[129] Because the behavior spectrum is continuous, boundaries between diagnostic categories are necessarily somewhat arbitrary.[42] Sometimes the syndrome is divided into low-, medium- or high-functioning autism (LFA, MFA, and HFA), based on IQ thresholds,[130] or on how much support the individual requires in daily life; these subdivisions are not standardized and are controversial. Autism can also be divided into syndromal and non-syndromal autism; the syndromal autism is associated with severe or profound intellectual disability or a congenital syndrome with physical symptoms, such as tuberous sclerosis.[131] Although individuals with Asperger syndrome tend to perform better cognitively than those with autism, the extent of the overlap between Asperger syndrome, HFA, and non-syndromal autism is unclear.[132]

Some studies have reported diagnoses of autism in children due to a loss of language or social skills, as opposed to a failure to make progress, typically from 15 to 30 months of age. The validity of this distinction remains controversial; it is possible that regressive autism is a specific subtype,[2][34][122][133] or that there is a continuum of behaviors between autism with and without regression.[134]

Research into causes has been hampered by the inability to identify biologically meaningful subgroups within the autistic population[135] and by the traditional boundaries between the disciplines of psychiatry, psychology, neurology and pediatrics.[136] Newer technologies such as fMRI and diffusion tensor imaging can help identify biologically relevant phenotypes (observable traits) that can be viewed on brain scans, to help further neurogenetic studies of autism;[137] one example is lowered activity in the fusiform face area of the brain, which is associated with impaired perception of people versus objects.[7] It has been proposed to classify autism using genetics as well as behavior.[138]

# Screening

About half of parents of children with ASD notice their child's unusual behaviors by age 18 months, and about four-fifths notice by age 24 months.[122] According to an article failure to meet any of the following milestones "is an absolute indication to proceed with further evaluations. Delay in referral for such testing may delay early diagnosis and treatment and affect the long-term outcome".[23]

- No babbling by 12 months.
- No gesturing (pointing, waving, etc.) by 12 months.

No single words by 16 months.
- No two-word (spontaneous, not just echolalic) phrases by 24 months.
- Any loss of any language or social skills, at any age.

The United States Preventive Services Task Force in 2016 found it was unclear if screening was beneficial or harmful among children in whom there is no concerns.[139] The Japanese practice is to screen all children for ASD at 18 and 24 months, using autism-specific formal screening tests. In contrast, in the UK, children whose families or doctors recognize possible signs of autism are screened. It is not known which approach is more effective.[7] Screening tools include the Modified Checklist for Autism in Toddlers (M-CHAT), the Early Screening of Autistic Traits Questionnaire, and the First Year Inventory; initial data on M-CHAT and its predecessor, the Checklist for Autism in Toddlers (CHAT), on children aged 18–30 months suggests that it is best used in a clinical setting and that it has low sensitivity (many false-negatives) but good specificity (few false-positives).[122] It may be more accurate to precede these tests with a broadband screener that does not distinguish ASD from other developmental disorders.[140] Screening tools designed for one culture's norms for behaviors like eye contact may be inappropriate for a different culture.[141] Although genetic screening for autism is generally still impractical, it can be considered in some cases, such as children with neurological symptoms and dysmorphic features.[142]

## Prevention

Infection with rubella during pregnancy causes fewer than 1% of cases of autism;[143] vaccination against rubella can prevent many of those cases.[144]

## Management

*Main article: Autism therapies*

A three-year-old with autism points to fish in an aquarium, as part of an experiment on the effect of intensive shared-attention training on language development.[94]

The main goals when treating children with autism are to lessen associated deficits and family distress, and to increase quality of life and functional independence. In general, higher IQs are correlated with greater responsiveness to treatment and improved treatment outcomes.[145][146] No single treatment is best and treatment is typically tailored to the child's needs.[1] Families and the educational system are the main resources for treatment.[7] Studies of interventions have methodological problems that prevent definitive conclusions about efficacy,[147] however the development of evidence-based interventions has advanced in recent years.[145] Although many psychosocial interventions have some positive evidence, suggesting that some form of treatment is preferable to no treatment, the methodological quality of systematic reviews of these studies has generally been poor, their clinical results are mostly tentative, and there is little evidence for the relative effectiveness of treatment options.[148] Intensive, sustained special education programs and behavior therapy early in life can help children acquire self-care, social, and job skills,[1] and often improve functioning and decrease symptom severity and maladaptive behaviors;[149] claims that intervention by around age three years is crucial are not substantiated.[150] Available approaches include applied behavior analysis (ABA), developmental models, structured teaching, speech and language therapy, social skills therapy, and occupational therapy.[1] Among these approaches, interventions either treat autistic features comprehensively, or focalize treatment on a specific area of deficit.[145] There is some evidence that early intensive behavioral intervention (EIBI), an early intervention model based on ABA for 20 to 40 hours a week for multiple years, is an effective treatment for some children with ASD.[151] Two theoretical frameworks outlined for early childhood intervention include applied behavioral analysis (ABA) and developmental social pragmatic models (DSP).[145] One interventional strategy utilizes a parent training model, which teaches parents how to implement various ABA and DSP techniques, allowing for parents to disseminate interventions themselves.[145] Various DSP programs have been developed to explicitly deliver intervention systems through at-home parent implementation. Despite the recent development of parent training models, these interventions have demonstrated effectiveness in numerous studies, being evaluated as a probable efficacious mode of treatment.[145]

### Education

Educational interventions can be effective to varying degrees in most children: intensive ABA treatment has demonstrated effectiveness in enhancing global functioning in preschool children[152] and is well-established for improving intellectual performance of young children.[149] Similarly, teacher-implemented intervention that utilizes an ABA combined with a developmental social pragmatic approach has been found to be a well-established treatment in improving social-communication skills in young children, although there is less evidence in its treatment of global symptoms.[145] Neuropsychological reports are often poorly communicated to educators, resulting in a gap between what a report recommends and what education is provided.[115] It is not known whether treatment programs for children lead to significant improvements after the children grow up,[149] and the limited research on the effectiveness of adult residential programs shows mixed results.[153] The appropriateness of including children with varying severity of autism spectrum disorders in the general education population is a subject of current debate among educators and researchers.[154]

### Medication

Many medications are used to treat ASD symptoms that interfere with integrating a child into home or school when behavioral treatment fails.[22][155] More than half of US children diagnosed with ASD are prescribed psychoactive drugs or anticonvulsants, with the most common drug classes being antidepressants, stimulants, and antipsychotics.[156] Antipsychotics, such as risperidone and aripiprazole, have been found to be useful for treating irritability, repetitive behavior, and sleeplessness that often occurs with autism, however their side effects must be weighed against their potential benefits, and people with autism may respond atypically.[157] There is scant reliable research about the effectiveness or safety of drug treatments for adolescents and adults with ASD.[158] No known medication relieves autism's core symptoms of social and communication impairments.[159] Experiments in mice have reversed or reduced some symptoms related to autism by replacing or modulating gene function,[60][87] suggesting the possibility of targeting therapies to specific rare mutations known to cause autism.[59][160]

### Alternative medicine

Although many alternative therapies and interventions are available, few are supported by scientific studies.[29][161] Treatment approaches have little empirical support in quality-of-life contexts, and many programs focus on success measures that lack predictive validity and real-world relevance.[31] Scientific evidence appears to matter less to service providers than program marketing, training availability, and parent requests.[162] Some alternative treatments may place the child at risk. A 2008 study found that compared to their peers, autistic boys have significantly thinner bones if on casein-free diets;[163] in 2005, botched chelation therapy killed a five-year-old child with autism.[164] There has been early research looking at hyperbaric treatments in children with autism.[165]

Although popularly used as an alternative treatment for people with autism, there is no good evidence that a gluten-free diet is of benefit.[166][167][168] In the subset of people who have gluten sensitivity there is limited evidence that suggests that a gluten free diet may improve some autistic behaviors.[166][169][170][171]

### Cost

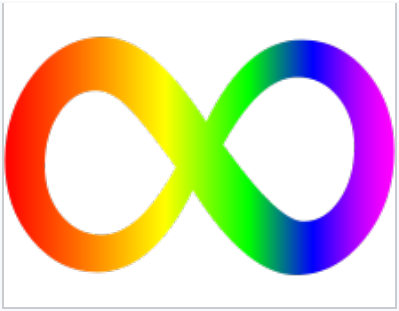
Treatment is expensive; indirect costs are more so. For someone born in 2000, a US study estimated an average lifetime cost of $4.11 million (net present value in 2017 dollars, inflation-adjusted from 2003 estimate),[172] with about 10% medical care, 30% extra education and other care, and 60% lost economic productivity.[173] Publicly supported programs are often inadequate or inappropriate for a given child, and unreimbursed out-of-pocket medical or therapy expenses are associated with likelihood of family financial problems;[174] one 2008 US study found a 14% average loss of annual income in families of children with ASD,[175] and a related study found that ASD is associated with higher probability that child care problems will greatly affect parental employment.[176] US states increasingly require private health insurance to cover autism services, shifting costs from publicly funded education programs to privately funded health insurance.[177] After childhood, key treatment issues include residential care, job training and placement, sexuality, social skills, and estate planning.[178]

## Society and culture

*Main article: Sociological and cultural aspects of autism*

The emergence of the autism rights movement has served as an attempt to encourage people to be more tolerant of those with autism.[179] Through this

movement, people hope to cause others to think of autism as a difference instead of a disease. Proponents of this movement wish to seek "acceptance, not cures."[180] There have also been many worldwide events promoting autism awareness such as World Autism Awareness Day, Light It Up Blue, Autism Sunday, Autistic Pride Day, Autreat, and others.[181][182][183][184][185] There have also been many organizations dedicated to increasing the awareness of autism and the effects that autism has on someone's life. These organizations include Autism Speaks, Autism National Committee, Autism Society of America, and many others.[186] Social-science scholars have had an increased focused on studying those with autism in hopes to learn more about "autism as a culture, transcultural comparisons… and research on social movements."[187] Media has had an influence on how the public perceives those with autism. *Rain Man*, a film that won 4 Oscars including Best Picture, depicts a character with autism who has incredible talents and abilities.[188] While many autistics don't have these special abilities, there are some autistic individuals who have been successful in their fields.[189][190][191]



The rainbow-colored infinity is often used as a symbol for the diversity of the autism spectrum as well as neurodiversity in general.

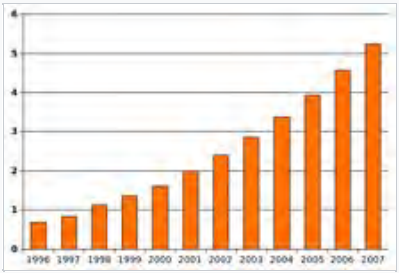
## Prognosis

There is no known cure.[1][7] Children recover occasionally, so that they lose their diagnosis of ASD;[9] this occurs sometimes after intensive treatment and sometimes not. It is not known how often recovery happens;[149] reported rates in unselected samples of children with ASD have ranged from 3% to 25%.[9] Most children with autism acquire language by age five or younger, though a few have developed communication skills in later years.[192] Most children with autism lack social support, meaningful relationships, future employment opportunities or self-determination.[31] Although core difficulties tend to persist, symptoms often become less severe with age.[22]

Few high-quality studies address long-term prognosis. Some adults show modest improvement in communication skills, but a few decline; no study has focused on autism after midlife.[193] Acquiring language before age six, having an IQ above 50, and having a marketable skill all predict better outcomes; independent living is unlikely with severe autism.[194] Most people with autism face significant obstacles in transitioning to adulthood.[195]

## Epidemiology

*Main article: Epidemiology of autism*



Reports of autism cases per 1,000 children grew dramatically in the US from 1996 to 2007. It is unknown how much, if any, growth came from changes in rates of autism.

Most recent reviews tend to estimate a prevalence of 1–2 per 1,000 for autism and close to 6 per 1,000 for ASD,[17] and 11 per 1,000 children in the United States for ASD as of 2008;[14][143] because of inadequate data, these numbers may underestimate ASD's true rate.[118] Globally, autism affects an estimated 21.7 million people as of 2013, while Asperger syndrome affects a further 31.1 million.[12] In 2012, the NHS estimated that the overall prevalence of autism among adults aged 18 years and over in the UK was 1.1%.[16] Rates of PDD-NOS's has been estimated at 3.7 per 1,000, Asperger syndrome at roughly 0.6 per 1,000, and childhood disintegrative disorder at 0.02 per 1,000.[196] CDC's most recent estimate is that 1 out of every 68 children, or 14.7 per 1,000, has an ASD as of 2010.[197]

The number of reported cases of autism increased dramatically in the 1990s and early 2000s. This increase is largely attributable to changes in diagnostic practices, referral patterns, availability of services, age at diagnosis, and public awareness,[196][198] though unidentified environmental risk factors cannot be ruled out.[6] The available evidence does not rule out the possibility that autism's true prevalence has increased;[196] a real increase would suggest directing more attention and funding toward changing environmental factors instead of continuing to focus on genetics.[199]

Boys are at higher risk for ASD than girls. The sex ratio averages 4.3:1 and is greatly modified by cognitive impairment: it may be close to 2:1 with intellectual disability and more than 5.5:1 without.[17] Several theories

about the higher prevalence in males have been investigated, but the cause of the difference is unconfirmed;[83] one theory is that females are underdiagnosed.[200]

Although the evidence does not implicate any single pregnancy-related risk factor as a cause of autism, the risk of autism is associated with advanced age in either parent, and with diabetes, bleeding, and use of psychiatric drugs in the mother during pregnancy.[83][201] The risk is greater with older fathers than with older mothers; two potential explanations are the known increase in mutation burden in older sperm, and the hypothesis that men marry later if they carry genetic liability and show some signs of autism.[42] Most professionals believe that race, ethnicity, and socioeconomic background do not affect the occurrence of autism.[202]

Several other conditions are common in children with autism.[7] They include:

- **Genetic disorders**. About 10–15% of autism cases have an identifiable Mendelian (single-gene) condition, chromosome abnormality, or other genetic syndrome,[203] and ASD is associated with several genetic disorders.[204]
- **Intellectual disability**. The percentage of autistic individuals who also meet criteria for intellectual disability has been reported as anywhere from 25% to 70%, a wide variation illustrating the difficulty of assessing autistic intelligence.[205] In comparison, for PDD-NOS the association with intellectual disability is much weaker,[206] and by definition, the diagnosis of Asperger's excludes intellectual disability.[207]
- **Anxiety disorders** are common among children with ASD; there are no firm data, but studies have reported prevalences ranging from 11% to 84%. Many anxiety disorders have symptoms that are better explained by ASD itself, or are hard to distinguish from ASD's symptoms.[208]
- **Epilepsy**, with variations in risk of epilepsy due to age, cognitive level, and type of language disorder.[209]
- Several **metabolic defects**, such as phenylketonuria, are associated with autistic symptoms.[89]
- **Minor physical anomalies** are significantly increased in the autistic population.[210]
- **Preempted diagnoses**. Although the DSM-IV rules out concurrent diagnosis of many other conditions along with autism, the full criteria for Attention deficit hyperactivity disorder (ADHD), Tourette syndrome, and other of these conditions are often present and these comorbid diagnoses are increasingly accepted.[211]
- **Sleep problems** affect about two-thirds of individuals with ASD at some point in childhood. These most commonly include symptoms of insomnia such as difficulty in falling asleep, frequent nocturnal awakenings, and early morning awakenings. Sleep problems are associated with difficult behaviors and family stress, and are often a focus of clinical attention over and above the primary ASD diagnosis.[212]

## History

*Further information: History of Asperger syndrome*

A few examples of autistic symptoms and treatments were described long before autism was named. The *Table Talk* of Martin Luther, compiled by his notetaker, Mathesius, contains the story of a 12-year-old boy who may have been severely autistic.[213] Luther reportedly thought the boy was a soulless mass of flesh possessed by the devil, and suggested that he be suffocated, although a later critic has cast doubt on the veracity of this report.[214] The earliest well-documented case of autism is that of Hugh Blair of Borgue, as detailed in a 1747 court case in which his brother successfully petitioned to annul Blair's marriage to gain Blair's inheritance.[215] The Wild Boy of Aveyron, a feral child caught in 1798, showed several signs of autism; the medical student Jean Itard treated him with a behavioral program designed to help him form social attachments and to induce speech via imitation.[216]

Leo Kanner introduced the label *early infantile autism* in 1943.

The New Latin word *autismus* (English translation *autism*) was coined by the Swiss psychiatrist Eugen Bleuler in 1910 as he was defining symptoms of schizophrenia. He derived it from the Greek word *autós* (αὐτός, meaning "self"), and used it to mean morbid self-admiration, referring to "autistic withdrawal of the patient to his fantasies, against which any influence from outside becomes an intolerable disturbance".[217]

The word *autism* first took its modern sense in 1938 when Hans Asperger of the Vienna University Hospital adopted Bleuler's terminology *autistic psychopaths* in a lecture in German about child psychology.[218] Asperger was investigating an ASD now known as Asperger syndrome, though for various reasons it was not widely recognized as a separate diagnosis until 1981.[216] Leo Kanner of the Johns Hopkins Hospital first used *autism* in its modern sense in English when he introduced the label *early infantile autism* in a 1943 report of 11 children with striking behavioral similarities.[36] Almost all the characteristics described in Kanner's first paper on the subject, notably "autistic aloneness" and

"insistence on sameness", are still regarded as typical of the autistic spectrum of disorders.[51] It is not known whether Kanner derived the term independently of Asperger.[219]

Kanner's reuse of *autism* led to decades of confused terminology like *infantile schizophrenia*, and child psychiatry's focus on maternal deprivation led to misconceptions of autism as an infant's response to "refrigerator mothers". Starting in the late 1960s autism was established as a separate syndrome by demonstrating that it is lifelong, distinguishing it from intellectual disability and schizophrenia and from other developmental disorders, and demonstrating the benefits of involving parents in active programs of therapy.[220] As late as the mid-1970s there was little evidence of a genetic role in autism; now it is thought to be one of the most heritable of all psychiatric conditions.[221] Although the rise of parent organizations and the destigmatization of childhood ASD have deeply affected how we view ASD,[216] parents continue to feel social stigma in situations where their child's autistic behavior is perceived negatively by others,[222] and many primary care physicians and medical specialists still express some beliefs consistent with outdated autism research.[223]

The Internet has helped autistic individuals bypass nonverbal cues and emotional sharing that they find so hard to deal with, and has given them a way to form online communities and work remotely.[224] Sociological and cultural aspects of autism have developed: some in the community seek a cure, while others believe that autism is simply another way of being.[11][225]

"Non-Celiac Gluten sensitivity: the new frontier of gluten related disorders". *Nutrients*. **5** (10): 3839–53. doi:10.3390/nu5103839. PMC 3820047. PMID 24077239. "The above data suggest that removing gluten from the diet may positively affect the clinical outcome in some children diagnosed with ASD, indicating that autism may be part of the spectrum of NCGS, at least in some cases. However, a word of caution is necessary to stress the fact that only a small, selected sub-group of children affected by ASD may benefit from an elimination diet. Additional investigations are required in order to identify phenotypes based on best- and non-response to dietary modifications and assess any biological correlates including anthropometry before considering a dietary intervention."

# Bipolar disorder

From Wikipedia, the free encyclopedia

*"Manic depression" redirects here. For other uses, see Manic depression (disambiguation).*
*"Bipolar disorders" redirects here. For the medical journal, see Bipolar Disorders (journal).*

**Bipolar disorder**, also known as **manic depression**, is a mental disorder with periods of depression and periods of elevated mood.[2][3] The elevated mood is significant and is known as mania or hypomania, depending on its severity, or whether symptoms of psychosis are present. During mania, an individual behaves or feels abnormally energetic, happy or irritable.[2] Individuals often make poorly thought out decisions with little regard to the consequences. The need for sleep is usually reduced during manic phases.[3] During periods of depression there may be crying, a negative outlook on life, and poor eye contact with others.[2] The risk of suicide among those with the illness is high at greater than 6 percent over 20 years, while self-harm occurs in 30–40 percent.[2] Other mental health issues such as anxiety disorders and substance use disorder are commonly associated.[2]

The causes are not clearly understood, but both environmental and genetic factors play a role.[2] Many genes of small effect contribute to risk.[2][4] Environmental factors include a history of childhood abuse, and long-term stress.[2] The condition is divided into bipolar I disorder if there is at least one manic episode and bipolar II disorder if there are at least one hypomanic episode and one major depressive episode. In those with less severe symptoms of a prolonged duration the condition cyclothymic disorder may be diagnosed. If due to drugs or medical problems it is classified separately.[3] Other conditions that may present in a similar manner include attention deficit hyperactivity disorder, personality disorders, schizophrenia, and substance use disorder as well as a number of medical conditions.[2] Medical testing is not required for a diagnosis, though blood tests or medical imaging can be done to rule out other problems.[5]

Treatment commonly includes psychotherapy, as well as medications such as mood stabilizers and antipsychotics. Examples of mood stabilizers that are commonly used include lithium and various anticonvulsants. Treatment in hospital against a person's consent may be required if a person is at risk to themselves or others but refuses treatment. Severe behavioral problems may be managed with short term antipsychotics or benzodiazepines. In periods of mania it is recommended that antidepressants be stopped. If antidepressants are used for

periods of depression they should be used with a mood stabilizer. Electroconvulsive therapy (ECT) may be helpful for those who do not respond to other treatments. If treatments are stopped, it is recommended that this be done slowly. Many individuals have financial, social or work-related problems due to the illness. These difficulties occur a quarter to a third of the time on average. The risk of death from natural causes such as heart disease is twice that of the general population. This is due to poor lifestyle choices and the side effects from medications.[2]

About 3 percent of people in the US are estimated to have bipolar disorder at some point in their life.[6] Lower rates of around 1 percent are found in other countries. The most common age at which symptoms begin is 25.[2] Rates appear to be similar in females and males.[7] The economic costs of the disorder has been estimated at $45 billion for the United States in 1991.[8] A large proportion of this was related to a higher number of missed work days, estimated at 50 per year.[8] People with bipolar disorder often face problems with social stigma.[2]

Video explanation

# Signs and symptoms

[9]

Mania is the defining feature of bipolar disorder, and can occur with different levels of severity. With milder levels of mania, known as hypomania, individuals are energetic, excitable, and may be highly productive.[10] As hypomania worsens, individuals begin to exhibit erratic and impulsive behavior, often making poor decisions due to unrealistic ideas about the future, and sleep very reduced.[10] At the extreme, manic individuals can experience distorted or delusional beliefs about the universe, hallucinate, hear voices, to the point of psychosis.[10] A depressive episode commonly follows an episode of mania.[10] The biological mechanisms responsible for switching from a manic or hypomanic episode to a depressive episode, or vice versa, remain poorly understood.[11]

## Manic episodes

Nineteenth-century drawing of a woman deprived of her dignity in old age.

Mania is a distinct period of at least one week of elevated or irritable mood, which can range from euphoria to delirium, and those experiencing hypo- or mania may exhibit three or more of the following behaviors: speak in a rapid, uninterruptible manner, short attention span, racing thoughts, increased goal-oriented activities, agitation, or they may exhibit behaviors characterized as impulsive or high-risk, such as hypersexuality or excessive spending.[9] To meet the definition for a manic episode, these behaviors must impair the individual's ability to socialize or work.[9][10] If untreated, a manic episode usually lasts three to six months.[12]

People with hypomania or mania may experience a decreased need of sleep, speak excessively in addition to speaking rapidly, and impaired judgment.[10][13] Manic individuals often have a history of substance abuse developed over years as a form of "self-medication".[14] At the more extreme, a person in a full blown manic state can experience psychosis; a break with reality, a state in which thinking is affected along with mood.[10] They may feel unstoppable, or as if they have been "chosen" and are on a "special mission", or have other grandiose or delusional ideas.[15] This may lead to violent behavior and, sometimes, hospitalization in an inpatient psychiatric hospital.[10][13] The severity of manic symptoms can be measured by rating scales such as the Young Mania Rating Scale, though questions remain about their reliability.[16]

The onset of a manic (or depressive) episode is often foreshadowed by sleep disturbances.[17] Mood changes, psychomotor and appetite changes, and an increase in anxiety can also occur up to three weeks before a manic episode develops.[18]

## Hypomanic episodes

Hypomania is the milder form of mania, defined as at least four days of the same criteria as mania,[10] but does not cause a significant decrease in the individual's ability to socialize or work, lacks psychotic features such as delusions or hallucinations, and does not require psychiatric hospitalization.[9] Overall functioning may actually increase during episodes of hypomania and is thought to serve as a defense mechanism against depression by some.[19] Hypomanic episodes rarely progress to full blown manic episodes.[19] Some people who experience hypomania show increased creativity[10] while others are irritable or demonstrate poor judgment.

Hypomania may feel good to some persons who experience it, though most people who experience hypomania state that the stress of the experience is very painful.[10] Bipolar people who go hypo, however, tend to forget the effects of their actions on those around them. Even when family and friends recognize mood swings, the individual will often deny that anything is wrong.[20] What might be called a "hypomanic event", if not accompanied by depressive episodes, is often not deemed problematic, unless the mood changes are uncontrollable, volatile or mercurial.[19] Most commonly, symptoms continue for a few weeks to a few months.[21]

## Depressive episodes

Symptoms of the depressive phase of bipolar disorder include persistent feelings of sadness, irritability or anger, loss of interest in previously enjoyed activities, excessive or inappropriate guilt, hopelessness, sleeping too much or not enough, changes in appetite and/or weight, fatigue, problems concentrating, self-loathing or feelings of worthlessness, and thoughts of death or suicidal ideation.[22] In severe cases, the individual may develop symptoms of psychosis, a condition also known as severe bipolar disorder with psychotic features. These symptoms include delusions and hallucinations. A major depressive episode persists for at least two weeks, and may result in suicide if left untreated.[23]

Depression.

The earlier the age of onset, the more likely the first few episodes are to be depressive.[24] Because a bipolar diagnosis requires a manic or hypomanic episode, many patients are initially diagnosed and treated as having major depression and then incorrectly prescribed antidepressants.[25]

## Mixed affective episodes

*Main article: Mixed affective state*

In bipolar disorder, mixed state is a condition during which symptoms of both mania and depression occur simultaneously.[26] Individuals experiencing a mixed state may have manic symptoms such as grandiose thoughts while simultaneously experiencing depressive symptoms such as excessive guilt or feeling suicidal.[26] Mixed states are considered to be high-risk for suicidal behavior since depressive emotions such as hopelessness are often paired with mood swings or difficulties with impulse control.[26] Anxiety disorder occurs more frequently as a comorbidity in mixed bipolar episodes than in non-mixed bipolar depression or mania.[26] Substance abuse (including alcohol) also follows this trend, thereby appearing to depict bipolar symptoms as no more than a consequence of substance abuse.[26]

## Associated features

*Main article: Associated features of bipolar disorder*

Associated features are clinical phenomena that often accompany the disorder but are not part of the diagnostic criteria. In adults with the condition, bipolar disorder is often accompanied by changes in cognitive processes and abilities. These include reduced attentional and executive capabilities and impaired memory. How the individual processes the universe also depends on the phase of the disorder, with differential characteristics between the manic, hypomanic and depressive states.[18] Some studies have found a significant association between bipolar disorder and creativity.[27] Those with bipolar disorder may have difficulty in maintaining relationships.[28] There are several common childhood precursors seen in children who later receive a diagnosis of bipolar disorder; these disorders include mood abnormalities, full major depressive episodes, and attention deficit hyperactivity disorder (ADHD).[29]

## Comorbid conditions

The diagnosis of bipolar disorder can be complicated by coexisting (comorbid) psychiatric conditions including the following: obsessive-compulsive disorder, substance abuse, eating disorders, attention deficit hyperactivity disorder, social phobia, premenstrual syndrome (including premenstrual dysphoric disorder), or panic disorder.[14][22][30][31] A careful longitudinal analysis of symptoms and episodes, enriched if possible by discussions with friends and family members, is crucial to establishing a treatment plan where these comorbidities exist.[32]

# Causes

The causes of bipolar disorder likely vary between individuals and the exact mechanism underlying the disorder remains unclear.[33] Genetic influences are believed to account for 60–80 percent of the risk of developing the disorder indicating a strong hereditary component.[30] The overall heritability of the bipolar spectrum has been estimated at 0.71.[34] Twin studies have been limited by relatively small sample sizes but have indicated a substantial genetic contribution, as well as environmental influence. For bipolar disorder type I, the (probandwise) concordance rates in modern studies have been consistently estimated at around 40 percent in identical twins (same genes), compared to about 5 percent in fraternal twins.[9][35] A combination of bipolar I, II and cyclothymia produced concordance rates of 42 percent vs. 11 percent, with a relatively lower ratio for bipolar II that likely reflects heterogeneity. There is overlap with unipolar depression and if this is also counted in the co-twin the concordance with bipolar disorder rises to 67 percent in monozygotic twins and 19 percent in dizygotic.[36] The relatively low concordance between dizygotic twins brought up together suggests that shared family environmental effects are limited, although the ability to detect them has been limited by small sample sizes.[34]

## Genetic

Genetic studies have suggested that many chromosomal regions and candidate genes are related to bipolar disorder susceptibility with each gene exerting a mild to moderate effect.[30] The risk of bipolar disorder is nearly ten-fold higher in first degree-relatives of those affected with bipolar disorder when compared to the general population; similarly, the risk of major depressive disorder is three times higher in relatives of those with bipolar disorder when compared to the general population.[9]

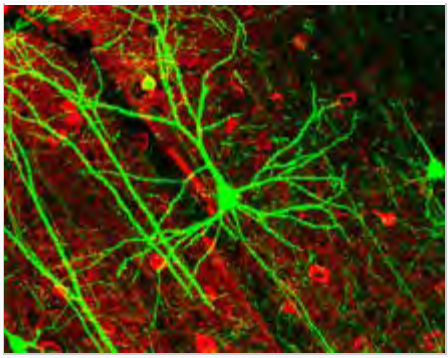
Although the first genetic linkage finding for mania was in 1969,[37] the linkage studies have been inconsistent.[9] The largest and most recent genome-wide association study failed to find any particular locus that exerts a large effect reinforcing the idea that no single gene is responsible for bipolar disorder in most cases.[38]

Findings point strongly to heterogeneity, with different genes being implicated in different families.[39] Robust and replicable genome-wide significant associations showed several common single nucleotide polymorphisms, including variants within the genes CACNA1C, ODZ4, and NCAN.[30][38]

Advanced paternal age has been linked to a somewhat increased chance of bipolar disorder in offspring, consistent with a hypothesis of increased new genetic mutations.[40]

## Physiological

Abnormalities in the structure and/or function of certain brain circuits could underlie bipolar. Meta-analyses of structural MRI studies in bipolar disorder report an increase in the volume of the lateral ventricles, globus pallidus and increase in the rates of deep white matter hyperintensities.[41][42][43] Functional MRI findings suggest that abnormal modulation between ventral prefrontal and limbic regions, especially the amygdala, are likely contribute to poor emotional [44]



Brain imaging studies have revealed differences in the volume of various brain regions between BD patients and healthy control subjects

regulation and mood symptoms.

Euthymic bipolar people show decreased activity in the lingual gyrus, while people who are manic demonstrated decreased activity in the inferior frontal cortex, while no differences were found in people with depressed bipolar.[45] People with bipolar have increased activation of left hemisphere ventral limbic areas and decreased activation of right hemisphere cortical structures related to cognition.[46]

One proposed model for bipolar suggests that hypersensitivity of reward circuits consisting of fronto-striatal circuits causes mania and hyposensitivity of these circuits cause depression.[47]

According to the "kindling" hypothesis, when people who are genetically predisposed toward bipolar disorder experience stressful events, the stress threshold at which mood changes occur becomes progressively lower, until the episodes eventually start (and recur) spontaneously. There is evidence supporting an association between early-life stress and dysfunction of the hypothalamic-pituitary-adrenal axis (HPA axis) leading to its over activation, which may play a role in the pathogenesis of bipolar disorder.[48][49]

Other brain components which have been proposed to play a role are the mitochondria[33] and a sodium ATPase pump.[50] Circadian rhythms and melatonin activity also seem to be altered.[51]

## Environmental

Environmental factors play a significant role in the development and course of bipolar disorder, and individual psychosocial variables may interact with genetic dispositions.[52] It is probable that recent life events and interpersonal relationships contribute to the likelihood of onsets and recurrences of bipolar mood episodes, as they do for onsets and recurrences of unipolar depression.[53] In surveys, 30–50 percent of adults diagnosed with bipolar disorder report traumatic/abusive experiences in childhood, which is associated on average with earlier onset, a higher rate of suicide attempts, and more co-occurring disorders such as PTSD.[54] The number of reported stressful events in childhood is higher in those with an adult diagnosis of bipolar spectrum disorder compared to those without, particularly events stemming from a harsh environment rather than from the child's own behavior.[55]

## Neurological

Less commonly bipolar disorder, or a bipolar-like disorder, may occur as a result of or in association with a neurological condition or injury. Such conditions and injuries include (but are not limited to) stroke, traumatic brain injury, HIV infection, multiple sclerosis, porphyria, and rarely temporal lobe epilepsy.[56]

## Neurochemical

Dopamine, a known neurotransmitter responsible for mood cycling, has been shown to have increased transmission during the manic phase.[11][57] The dopamine hypothesis states that the increase in dopamine results in secondary homeostatic down regulation of key systems and receptors such as an increase in dopamine mediated G protein-coupled receptors. This results in decreased dopamine transmission characteristic of the depressive phase.[11] The depressive phase ends with homeostatic up regulation potentially restarting the cycle over again.[58]

Glutamate is significantly increased within the left dorsolateral prefrontal cortex during the manic phase of bipolar disorder, and returns to normal levels once the phase is over.[59] The increase in GABA is possibly caused by a disturbance in early development causing a disturbance of cell migration and the formation of normal lamination, the layering of brain structures commonly associated with the cerebral cortex.[60]

Medications use to treat bipolar may exert their effect by modulating intracellular signaling, such as through depleting myo-inositol levels, inhibition of cAMP signaling, and through altering G coupled proteins[61]

Decreased levels of 5-HIAA in the CSF of bipolar patients during both depressed and manic phases. Increased dopaminergic activity has been hypothesized in manic states due to the ability of dopamine agonist to stimulant mania in bipolar patients. Decreased sensitivity of regulatory a2 adrenergic receptors as well as increased cell counts in the locus coeruleus indicated increased noradrenergic activity in manic patients. Low plasma GABA levels on both sides of the mood spectrum have been found.[62] One review found no difference in monoamine levels, but found abnormal norepinephrine turnover in bipolar patients.[63] Tyrosine depletion was found to attenuate the effects of methamphetamine in bipolar patients as well as symptoms of mania, implicating dopamine in mania. VMAT2 binding was found to be increased in one study of bipolar manic patients.[64]

# Prevention

Attempts at prevention of bipolar disorder have focused on stress (such as childhood adversity or highly conflictual families) which, although not a diagnostically specific causal agent for bipolar, does place genetically and biologically vulnerable individuals at risk for a more pernicious course of illness.[65] There has been debate regarding the causal relationship between usage of cannabis and bipolar disorder.[66]

# Diagnosis

Bipolar disorder is commonly diagnosed during adolescence or early adulthood, but onset can occur throughout the life cycle.[3][67] The disorder can be difficult to distinguish from unipolar depression and the average delay in diagnosis is 5–10 years after symptoms begin.[68] Diagnosis of bipolar disorder takes several factors into account and considers the self-reported experiences of the symptomatic individual, abnormal behavior reported by family members, friends or co-workers, observable signs of illness as assessed by a clinician, and often a medical work-up to rule-out medical causes. In diagnosis, caregiver-scored rating scales, specifically the mother, has been found to be more accurate than teacher and youth report in predicting identifying youths with bipolar disorder.[69] Assessment is usually done on an outpatient basis; admission to an inpatient facility is considered if there is a risk to oneself or others. The most widely used criteria for diagnosing bipolar disorder are from the American Psychiatric Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) and the World Health Organization's (WHO) *International Statistical Classification of Diseases and Related Health Problems*, 10th Edition (ICD-10). The ICD-10 criteria are used more often in clinical settings outside of the U.S. while the DSM criteria are used clinically within the U.S. and are the prevailing criteria used internationally in research studies. The DSM-5, published in 2013, included further and more accurate specifiers compared to its predecessor, the DSM-IV-TR.[70] Semi structured interviews such as the Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS) and the Structured Clinical Interview for DSM-IV (SCID) are used for diagnostic confirmation of bipolar disorder.

Several rating scales for the screening and evaluation of bipolar disorder exist,[71] including the Bipolar spectrum diagnostic scale, Mood Disorder Questionnaire, the General Behavior Inventory and the Hypomania Checklist.[72] The use of evaluation scales can not substitute a full clinical interview but they serve to systematize the recollection of symptoms.[72] On the other hand, instruments for screening bipolar disorder tend to have lower sensitivity.[71]

## Differential diagnosis

There are several other mental disorders with symptoms similar to those seen in bipolar disorder. These disorders include schizophrenia, major depressive disorder,[73] attention deficit hyperactivity disorder (ADHD), and certain personality disorders, such as borderline personality disorder.[74][75][76]

Although there are no biological tests that are diagnostic of bipolar disorder,[38] blood tests and/or imaging may be carried out to exclude medical illnesses with clinical presentations similar to that of bipolar disorder such as hypothyroidism or hyperthyroidism, metabolic disturbance, a chronic disease, or an infection such as HIV or syphilis.[67] A review of current and recent medications and drug use is considered to rule out these causes; common medications that can cause manic symptoms include antidepressants, prednisone, Parkinson's disease medications, thyroid hormone, stimulants (including cocaine and methamphetamine), and certain antibiotics.[77] An EEG may be used to exclude neurological disorders such as epilepsy, and a CT scan or MRI of the head may be used to exclude brain lesions.[67] Additional testing is especially indicated when age of first onset is mid to late life.[3] Investigations are not generally repeated for a relapse unless there is a specific medical indication.[*citation needed*]

## Bipolar spectrum

Bipolar spectrum disorders includes: bipolar I disorder, bipolar II disorder, cyclothymic disorder and cases where subthreshold symptoms are found to cause clinically significant impairment or distress.[3][67] These disorders involve major depressive episodes that alternate with manic or hypomanic episodes, or with mixed episodes that feature symptoms of both mood states.[3] The concept of the bipolar spectrum is similar to that of Emil Kraepelin's original concept of manic depressive illness.[78]

Unipolar hypomania without accompanying depression has been noted in the medical literature.[79] There is speculation as to whether this condition may occur with greater frequency in the general, untreated population; successful social function of these potentially high-achieving individuals may lead to being labeled as normal, rather than as individuals with substantial dysregulation.

## Criteria and subtypes

The DSM and the ICD characterize bipolar disorder as a spectrum of disorders occurring on a continuum. The DSM-5 lists three specific subtypes:[3]

- Bipolar I disorder: At least one manic episode is necessary to make the diagnosis;[80] depressive episodes are common in the vast majority of cases with bipolar disorder I, but are unnecessary for the diagnosis.[9] Specifiers such as "mild, moderate, moderate-severe, severe" and "with psychotic features" should be added as applicable to indicate the presentation and course of the disorder.[3]
- Bipolar II disorder: No manic episodes and one or more hypomanic episodes and one or more major depressive episode.[80] Hypomanic episodes do not go to the full extremes of mania (*i.e.*, do not usually cause severe social or occupational impairment, and are without psychosis), and this can make bipolar II more difficult to diagnose, since the hypomanic episodes may simply appear as periods of successful high productivity and are reported less frequently than a distressing, crippling depression.
- Cyclothymia: A history of hypomanic episodes with periods of depression that do not meet criteria for major depressive episodes.[81]

When relevant, specifiers for *peripartum onset* and *with rapid cycling* should be used with any subtype. Individuals who have subthreshold symptoms that cause clinically significant distress or impairment, but do not meet full criteria for one of the three subtypes may be diagnosed with other specified or unspecified bipolar disorder. Other specified bipolar disorder is used when a clinician chooses to provide an explanation for why the full criteria were not met (e.g., hypomania without a prior major depressive episode).[3]

## Rapid cycling

Most people who meet criteria for bipolar disorder experience a number of episodes, on average 0.4 to 0.7 per year, lasting three to six months.[82] *Rapid cycling*, however, is a course specifier that may be applied to any of the above subtypes. It is defined as having four or more mood disturbance episodes within a one-

year span and is found in a significant proportion of individuals with bipolar disorder.[22] These episodes are separated from each other by a remission (partial or full) for at least two months or a switch in mood polarity (i.e., from a depressive episode to a manic episode or vice versa).[9] The definition of rapid cycling most frequently cited in the literature (including the DSM) is that of Dunner and Fieve: at least four major depressive, manic, hypomanic or mixed episodes are required to have occurred during a 12-month period.[83] Ultra-rapid (days) and ultra-ultra rapid or ultradian (within a day) cycling have also been described.[84] The literature examining the pharmacological treatment of rapid cycling is sparse and there is no clear consensus with respect to its optimal pharmacological management.[85]

# Management

*Main article: Treatment of bipolar disorder*

There are a number of pharmacological and psychotherapeutic techniques used to treat bipolar disorder. Individuals may use self-help and pursue recovery.

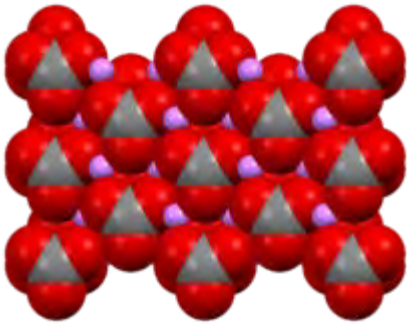
Hospitalization may be required especially with the manic episodes present in bipolar I. This can be voluntary or (if mental health legislation allows and varying state-to-state regulations in the USA) involuntary (called civil or involuntary commitment). Long-term inpatient stays are now less common due to deinstitutionalization, although these can still occur.[86] Following (or in lieu of) a hospital admission, support services available can include drop-in centers, visits from members of a community mental health team or an Assertive Community Treatment team, supported employment and patient-led support groups, intensive outpatient programs. These are sometimes referred to as partial-inpatient programs.[87]

## Psychosocial

Psychotherapy is aimed at alleviating core symptoms, recognizing episode triggers, reducing negative expressed emotion in relationships, recognizing prodromal symptoms before full-blown recurrence, and, practicing the factors that lead to maintenance of remission.[88][89][90] Cognitive behavioral therapy, family-focused therapy, and psychoeducation have the most evidence for efficacy in regard to relapse prevention, while interpersonal and social rhythm therapy and cognitive-behavioral therapy appear the most effective in regard to residual depressive symptoms. Most studies have been based only on bipolar I, however, and treatment during the acute phase can be a particular challenge.[91] Some clinicians emphasize the need to talk with individuals experiencing mania, to develop a therapeutic alliance in support of recovery.[92]

## Medication

A number of medications are used to treat bipolar disorder.[53] The medication with the best evidence is lithium, which is effective in treating acute manic episodes and preventing relapses; lithium is also an effective treatment for bipolar depression.[93] Lithium reduces the risk of suicide, self-harm, and death in people with bipolar disorder.[94] It is unclear if ketamine is useful in bipolar as of 2015.[95]



Lithium carbonate is one of many treatments for bipolar disorder

Four anticonvulsants are used in the treatment of bipolar disorder. Carbamazepine effectively treats manic episodes, with some evidence it has greater benefit in rapid-cycling bipolar disorder, or those with more psychotic symptoms or a more schizoaffective clinical picture. It is less effective in preventing relapse than lithium or valproate.[96][97] Carbamazepine became a popular treatment option for bipolar in the late 1980s and early 1990s, but was displaced by sodium valproate in the 1990s.[*citation needed*] Since then, valproate has become a commonly prescribed treatment, and is effective in treating manic episodes.[98] Lamotrigine has some efficacy in treating bipolar depression, and this benefit is greatest in more severe [99]

depression. It has also been shown to have some benefit in preventing further episodes, though there are concerns about the studies done, and is of no benefit in rapid cycling disorder.[100] The effectiveness of topiramate is unknown.[101] Depending on the severity of the case, anticonvulsants may be used in combination with lithium or on their own.[*citation needed*]

Antipsychotic medications are effective for short-term treatment of bipolar manic episodes and appear to be superior to lithium and anticonvulsants for this purpose.[53] However, other medications such as lithium are preferred for long-term use.[53] Olanzapine is effective in preventing relapses, although the evidence is not as solid as the evidence for lithium.[102] Antidepressants have not been found to be of any benefit over that found with mood stabilizers.[103]

Short courses of benzodiazepines may be used in addition to other medications until mood stabilizing become effective.[104]

### Alternative medicine

Several studies have suggested that omega 3 fatty acids may have beneficial effects on depressive symptoms, but not manic symptoms. However, only a few small studies of variable quality have been published and there is not enough evidence to draw any firm conclusions.[105]

## Prognosis

A lifelong condition with periods of partial or full recovery in between recurrent episodes of relapse,[22][105] bipolar disorder is considered to be a major health problem worldwide because of the increased rates of disability and premature mortality.[105] It is also associated with co-occurring psychiatric and medical problems and high rates of initial under- or misdiagnosis, causing a delay in appropriate treatment interventions and contributing to poorer prognoses.[24] After a diagnosis is made, it remains is difficult to achieve complete remission of all symptoms with the currently available psychiatric medications and symptoms often become progressively more severe over time.[71][106]

Compliance with medications is one of the most significant factors that can decrease the rate and severity of relapse and have a positive impact on overall prognosis.[107] However, the types of medications used in treating BD commonly cause side effects[108] and more than 75% of individuals with BD inconsistently take their medications for various reasons.[107]

Of the various types of the disorder, rapid cycling (four or more episodes in one year) is associated with the worst prognosis due to higher rates of self-harm and suicide.[22] Individuals diagnosed with bipolar who have a family history of bipolar disorder are at a greater risk for more frequent manic/hypomanic episodes.[109] Early onset and psychotic features are also associated with worse outcomes,[110][111] as well as subtypes that are nonresponsive to lithium.[106]

Early recognition and intervention also improve prognosis as the symptoms in earlier stages are less severe and more responsive to treatment.[106] Onset after adolescence is connected to better prognoses for both genders, and being male is a protective factor against higher levels of depression. For women, better social functioning prior to developing bipolar disorder and being a parent are protective towards suicide attempts.[109]

### Functioning

People with bipolar disorder often experience a decline in cognitive functioning during (or possibly before) their first episode, after which a certain degree of cognitive dysfunction typically becomes permanent, with more severe impairment during acute phases and moderate impairment during periods of remission. As a result, two-thirds of people with BD continue to experience impaired psychosocial functioning in between episodes even when their mood symptoms are in full remission. A similar pattern in seen in both BD-I and BD-II, but people with BD-II experience a lesser degree of impairment.[108] Cognitive deficits typically

increase over the course of the illness. Higher degrees of impairment correlate with the number of previous manic episodes and hospitalizations, and with the presence psychotic symptoms.[112] Early intervention can slow the progression of cognitive impairment, while treatment at later stages can help reduce distress and negative consequences related to cognitive dysfunction.[106]

Despite the overly ambitious goals that are frequently part of manic episodes, symptoms of mania undermine the ability to achieve these goals and often interfere an individual's social and occupational functioning. One third of people with BD remain unemployed for one year following a hospitalization for mania.[113] Depressive symptoms during and between episodes, which occur much more frequently for most people than hypomanic or manic symptoms over the course of illness, are associated with lower functional recovery in between episodes, including unemployment or underemployment for both BD-I and BD-II.[3][114] However, the course of illness (duration, age of onset, number of hospitalizations, and presence or not of rapid cycling) and cognitive performance are the best predictors of employment outcomes in individuals with bipolar disorder, followed by symptoms of depression and years of education.[114]

### Recovery and recurrence

A naturalistic study from first admission for mania or mixed episode (representing the hospitalized and therefore most severe cases) found that 50 percent achieved syndromal recovery (no longer meeting criteria for the diagnosis) within six weeks and 98 percent within two years. Within two years, 72 percent achieved symptomatic recovery (no symptoms at all) and 43 percent achieved functional recovery (regaining of prior occupational and residential status). However, 40 percent went on to experience a new episode of mania or depression within 2 years of syndromal recovery, and 19 percent switched phases without recovery.[115]

Symptoms preceding a relapse (prodromal), specially those related to mania, can be reliably identified by people with bipolar disorder.[116] There have been intents to teach patients coping strategies when noticing such symptoms with encouraging results.[117]

### Suicide

Bipolar disorder can cause suicidal ideation that leads to suicidal attempts. Individuals whose bipolar disorder begins with a depressive or mixed affective episode seem to have a poorer prognosis and an increased risk of suicide.[73] One out of two people with bipolar disorder attempt suicide at least once during their lifetime and many attempts are successfully completed.[30] The annual average suicide rate is 0.4 percent, which is 10–20 times that of the general population.[118] The standardized mortality ratio from suicide in bipolar disorder is between 18 and 25.[119] The lifetime risk of suicide has been estimated to be as high as 20 percent in those with bipolar disorder.[9]

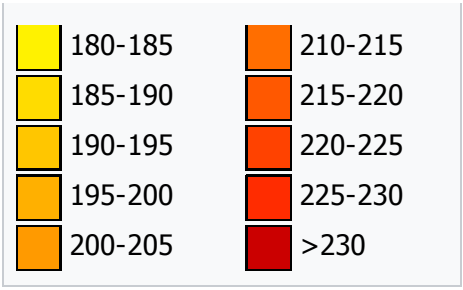
## Epidemiology

Bipolar disorder is the sixth leading cause of disability worldwide and has a lifetime prevalence of about 3 percent in the general population.[6][120] However, a reanalysis of data from the National Epidemiological Catchment Area survey in the United States suggested that 0.8 percent of the population experience a manic episode at least once (the diagnostic threshold for bipolar I) and a further 0.5 percent have a hypomanic episode (the diagnostic threshold for bipolar II or cyclothymia). Including sub-threshold diagnostic criteria, such as one or two symptoms over a short time-period, an additional 5.1 percent of the population, adding up to a total of 6.4 percent, were classified as having a bipolar spectrum disorder.[121] A more recent analysis of data from a second US National Comorbidity Survey found that 1 percent met

Burden of bipolar disorder around the world: disability-adjusted life years per 100,000 inhabitants in 2004.

<180 205-210

lifetime prevalence criteria for bipolar I, 1.1 percent for bipolar II, and 2.4 percent for subthreshold symptoms.[122]



There are conceptual and methodological limitations and variations in the findings. Prevalence studies of bipolar disorder are typically carried out by lay interviewers who follow fully structured/fixed interview schemes; responses to single items from such interviews may suffer limited validity. In addition, diagnoses (and therefore estimates of prevalence) vary depending on whether a categorical or spectrum approach is used. This consideration has led to concerns about the potential for both underdiagnosis and overdiagnosis.[123]

The incidence of bipolar disorder is similar in men and women[124] as well as across different cultures and ethnic groups.[125] A 2000 study by the World Health Organization found that prevalence and incidence of bipolar disorder are very similar across the world. Age-standardized prevalence per 100,000 ranged from 421.0 in South Asia to 481.7 in Africa and Europe for men and from 450.3 in Africa and Europe to 491.6 in Oceania for women. However, severity may differ widely across the globe. Disability-adjusted life year rates, for example, appear to be higher in developing countries, where medical coverage may be poorer and medication less available.[126] Within the United States, Asian Americans have significantly lower rates than their African and European American counterparts.[127]

Late adolescence and early adulthood are peak years for the onset of bipolar disorder.[128][129] One study also found that in 10 percent of bipolar cases, the onset of mania had happened after the patient had turned 50.[130]

## History

*Main article: History of bipolar disorder*

German psychiatrist Emil Kraepelin first distinguished between manic–depressive illness and "dementia praecox" (now known as schizophrenia) in the late 19th century

Variations in moods and energy levels have been observed as part of the human experience since throughout history. The words "melancholia", an old word for depression, and "mania" originated in Ancient Greece. The word melancholia is derived from *melas* (μελας), meaning "black", and *chole* (χολη), meaning "bile" or "gall",[131] indicative of the term's origins in pre-Hippocratic humoral theory. Within the humoral theories, mania was viewed as arising from an excess of yellow bile, or a mixture of black and yellow bile. The linguistic origins of mania, however, are not so clear-cut. Several etymologies were proposed by the Ancient Roman physician Caelius Aurelianus, including the Greek word *ania*, meaning "to produce great mental anguish", and *manos*, meaning "relaxed" or "loose", which would contextually approximate to an excessive relaxing of the mind or soul.[132] There are at least five other candidates, and part of the confusion surrounding the exact etymology of the word mania is its varied usage in the pre-Hippocratic poetry and mythology.[132]

In the early 1800s, French psychiatrist Jean-Étienne Dominique Esquirol's lypemania, one of his affective monomanias, was the first elaboration on what was to become modern depression.[133] The basis of the current conceptualisation of bipolar illness can be traced back to the 1850s; on January 31, 1854, Jules Baillarger described to the French Imperial Académie Nationale de Médecine a biphasic mental illness causing recurrent oscillations between mania and depression, which he termed *folie à double forme* (dual-form insanity).[134] Two weeks later, on February 14, 1854, Jean-Pierre Falret presented a description to the Academy on what was essentially the same disorder, and which he

called *folie circulaire* (circular insanity).[135]

These concepts were developed by the German psychiatrist Emil Kraepelin (1856–1926), who, using Kahlbaum's concept of cyclothymia,[136] categorized and studied the natural course of untreated bipolar patients. He coined the term *manic depressive psychosis*, after noting that periods of acute illness, manic or depressive, were generally punctuated by relatively symptom-free intervals where the patient was able to function normally.[137]

The term "manic–depressive *reaction*" appeared in the first version of the DSM in 1952, influenced by the legacy of Adolf Meyer.[138] Subtyping into "unipolar" depressive disorders and bipolar disorders was first proposed by German psychiatrists Karl Kleist and Karl Leonhard in the 1950s and they have regarded as a separate conditions since publication of the DSM-III. The subtypes bipolar II and rapid cycling have been included since the DSM-IV, based on work from the 1970s by David Dunner, Elliot Gershon, Frederick Goodwin, Ronald Fieve and Joseph Fleiss.[139][140][141]

## Society and culture

*See also: List of people with bipolar disorder, Category:Books about bipolar disorder, and Category:Films about bipolar disorder*

There are widespread problems with social stigma, stereotypes, and prejudice against individuals with a diagnosis of bipolar disorder.[142]

Kay Redfield Jamison, a clinical psychologist and professor of psychiatry at the Johns Hopkins University School of Medicine, profiled her own bipolar disorder in her memoir *An Unquiet Mind* (1995).[143] In his autobiography *Manicdotes: There's Madness in His Method* (2008) Chris Joseph describes his struggle between the creative dynamism which allowed the creation of his multimillion-pound advertising agency Hook Advertising, and the money-squandering dark despair of his bipolar illness.[144]

Several dramatic works have portrayed characters with traits suggestive of the diagnosis that has been the subject of discussion by psychiatrists and film experts alike. A notable example is *Mr. Jones* (1993), in which Mr. Jones (Richard Gere) swings from a manic episode into a depressive phase and back again, spending time in a psychiatric hospital and displaying many of the features of the syndrome.[145] In *The Mosquito Coast* (1986), Allie Fox (Harrison Ford) displays some features including recklessness, grandiosity, increased goal-directed activity and mood lability, as well as some paranoia.[146] Psychiatrists have suggested that Willy Loman, the main character in Arthur Miller's classic play *Death of a Salesman*, suffers from bipolar disorder,[147] though that specific term for the condition did not exist when the play was written.

Singer Rosemary Clooney's public revelation of bipolar disorder in 1977 made her an early celebrity spokeswoman for mental illness[*citation needed*]

TV specials, for example the BBC's *Stephen Fry: The Secret Life of the Manic Depressive*,[148] MTV's *True Life: I'm Bipolar*, talk shows, and public radio shows, and the greater willingness of public figures to discuss their own bipolar disorder, have focused on psychiatric conditions, thereby, raising public awareness.

On April 7, 2009, the nighttime drama *90210* on the CW network, aired a special episode where the character Silver was diagnosed with bipolar disorder.[149] Stacey Slater, a character from the BBC soap EastEnders, has been diagnosed with the disorder. The storyline was developed as part of the BBC's Headroom campaign.[150] The Channel 4 soap *Brookside* had earlier featured a story about bipolar disorder when the character Jimmy Corkhill was diagnosed with the condition.[151] 2011 Showtime's political thriller drama *Homeland* protagonist Carrie Mathison is bipolar, which she has kept secret since her school days.[152] In April 2014, ABC premiered a medical drama, *Black Box*, in which the main character, a world-

renowned neuroscientist, is bipolar.[153]

## Children

*Main article: Bipolar disorder in children*

In the 1920s, Emil Kraepelin noted that manic episodes are rare before puberty.[154] In general, bipolar disorder in children was not recognized in the first half of the twentieth century. This issue diminished with an increased following of the DSM criteria in the last part of the twentieth century.[154][155]

Lithium is the only medication approved by the FDA for treating mania in children

While in adults the course of bipolar disorder is characterized by discrete episodes of depression and mania with no clear symptomatology between them, in children and adolescents very fast mood changes or even chronic symptoms are the norm.[156] Pediatric bipolar disorder is commonly characterized by outbursts of anger, irritability and psychosis, rather than euphoric mania, which is more likely to be seen in adults.[154][156] Early onset bipolar disorder is more likely to manifest as depression rather than mania or hypomania.[157]

The diagnosis of childhood bipolar disorder is controversial,[156] although it is not under discussion that the typical symptoms of bipolar disorder have negative consequences for minors suffering them.[154] The debate is mainly centered on whether what is called bipolar disorder in children refers to the same disorder as when diagnosing adults,[154] and the related question of whether the criteria for diagnosis for adults are useful and accurate when applied to children.[156] Regarding diagnosis of children, some experts recommend following the DSM criteria.[156] Others believe that these criteria do not correctly separate children with bipolar disorder from other problems such as ADHD, and emphasize fast mood cycles.[156] Still others argue that what accurately differentiates children with bipolar disorder is irritability.[156] The practice parameters of the AACAP encourage the first strategy.[154][156] American children and adolescents diagnosed with bipolar disorder in community hospitals increased 4-fold reaching rates of up to 40 percent in 10 years around the beginning of the 21st century, while in outpatient clinics it doubled reaching 6 percent.[156] Studies using DSM criteria show that up to 1 percent of youth may have bipolar disorder.[154]

Treatment involves medication and psychotherapy.[156] Drug prescription usually consists in mood stabilizers and atypical antipsychotics.[156] Among the former, lithium is the only compound approved by the FDA for children.[154] Psychological treatment combines normally education on the disease, group therapy and cognitive behavioral therapy.[156] Chronic medication is often needed.[156]

Current research directions for bipolar disorder in children include optimizing treatments, increasing the knowledge of the genetic and neurobiological basis of the pediatric disorder and improving diagnostic criteria.[156] Some treatment research suggests that psychosocial interventions that involve the family, psychoeducation, and skills building (through therapies such as CBT, DBT, and IPSRT) can benefit in a pharmocotherapy.[158] Unfortunately, the literature and research on the effects of psychosocial therapy on BPSD is scarce, making it difficult to determine the efficacy of various therapies.[158] The DSM-5 has proposed a new diagnosis which is considered to cover some presentations currently thought of as childhood-onset bipolar.[159]

## Elderly

There is a relative lack of knowledge about bipolar disorder in late life. There is evidence that it becomes

less prevalent with age but nevertheless accounts for a similar percentage of psychiatric admissions; that older bipolar patients had first experienced symptoms at a later age; that later onset of mania is associated with more neurologic impairment; that substance abuse is considerably less common in older groups; and that there is probably a greater degree of variation in presentation and course, for instance individuals may develop new-onset mania associated with vascular changes, or become manic only after recurrent depressive episodes, or may have been diagnosed with bipolar disorder at an early age and still meet criteria. There is also some weak and not conclusive evidence that mania is less intense and there is a higher prevalence of mixed episodes, although there may be a reduced response to treatment. Overall, there are likely more similarities than differences from younger adults.[160][161] In the elderly, recognition and treatment of bipolar disorder may be complicated by the presence of dementia or the side effects of medications being taken for other conditions.[162]

# Borderline personality disorder

From Wikipedia, the free encyclopedia

**Borderline personality disorder** (**BPD**), also known as **emotionally unstable personality disorder**, is a long-term pattern of abnormal behavior characterized by unstable relationships with other people, unstable sense of self, and unstable emotions.[3][4] There is often an extreme fear of abandonment, frequent dangerous behavior, a feeling of emptiness, and self-harm. Symptoms may be brought on by seemingly normal events.[3] The behavior typically begins by early adulthood, and occurs across a variety of situations.[4] Substance abuse, depression, and eating disorders are commonly associated with BPD.[3] About 10% of those with BPD die by suicide.[3][4]

BPD's causes are unclear, but seem to involve genetic, brain, environment, and social factors. It occurs about five times more often in a person who has an affected close relative.[3] Adverse life events also appear to play a role. The underlying mechanism appears to involve the frontolimbic network of neurons.[5] BPD is recognized by the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) as a personality disorder, along with nine other such disorders.[4] Diagnosis is based on the symptoms while a medical exam may be done to rule out other problems.[3] The condition must be differentiated from an identity problem or substance use disorders, among other possibilities.[4]

Borderline personality disorder is typically treated with therapy, such as cognitive behavioral therapy (CBT). Another type, dialectical behavior therapy (DBT) has been found to reduce the risk of suicide. Therapy may occur one-on-one, or in a group. While medications do not cure BPD, they may be used to help with the associated symptoms. Some people require care in hospital.[3]

About 1.6% of people have BPD in a given year.[3] Females are diagnosed about three times as often as males. It appears to become less common among older people. Up to half of people improve over a ten-year period. People affected typically use a high amount of healthcare resources.[4] There is an ongoing debate about the naming of the disorder, especially the suitability of the word "borderline".[3]

## Signs and symptoms [edit]

Borderline personality disorder may be characterized by the following signs and symptoms:

- Markedly disturbed sense of identity
- Frantic efforts to avoid real or imagined abandonment and extreme reactions to such
- Splitting ("black-and-white" thinking)
- Severe impulsivity
- Intense or uncontrollable emotional reactions that often seem disproportionate to the event or situation
- Unstable and chaotic interpersonal relationships
- Self-damaging behavior
- Distorted self-image[3]
- Dissociation

- Frequently accompanied by depression, anxiety, anger, substance abuse, or rage

The most distinguishing symptoms of BPD are marked sensitivity to rejection or criticism, and intense fear of possible abandonment.[6] Overall, the features of BPD include unusually intense sensitivity in relationships with others, difficulty regulating emotions, and impulsivity. Other symptoms may include feeling unsure of one's personal identity, morals, and values; having paranoid thoughts when feeling stressed; dissociation and depersonalization; and, in moderate to severe cases, stress-induced breaks with reality or psychotic episodes.

## Emotions [edit]

People with BPD feel emotions more easily, more deeply, and longer than others do.[7][8] In addition, emotions may repeatedly resurge and persist a long time.[8] Consequently, it may take more time for people with BPD than others to return to a stable emotional baseline following an intense emotional experience.[9] People with BPD often engage in idealization and devaluation of others, alternating between high positive regard and great disappointment.[10]

In Marsha Linehan's view, the sensitivity, intensity, and duration with which people with BPD feel emotions have both positive and negative effects.[9] People with BPD are often exceptionally enthusiastic, idealistic, joyful, and loving.[11] However, they may feel overwhelmed by negative emotions ("anxiety, depression, guilt/shame, worry, anger, etc."), experiencing intense grief instead of sadness, shame and humiliation instead of mild embarrassment, rage instead of annoyance, and panic instead of nervousness.[11]

People with BPD are also especially sensitive to feelings of rejection, criticism, isolation, and perceived failure.[12] Before learning other coping mechanisms, their efforts to manage or escape from their very negative emotions may lead to emotional isolation, self-injury or suicidal behavior.[13] They are often aware of the intensity of their negative emotional reactions and, since they cannot regulate them, they shut them down entirely.[9] This can be harmful to people with BPD, since negative emotions alert people to the presence of a problematic situation and move them to address it which the person with BPD would normally be aware of only to cause further distress.[9]

While people with BPD feel joy intensely, they are especially prone to dysphoria, depression, and/or feelings of mental and emotional distress. Zanarini et al. recognized four categories of dysphoria that are typical of this condition: extreme emotions, destructiveness or self-destructiveness, feeling fragmented or lacking identity, and feelings of victimization.[14] Within these categories, a BPD diagnosis is strongly associated with a combination of three specific states: feeling betrayed, "feeling like hurting myself", and feeling out of control.[14] Since there is great variety in the types of dysphoria experienced by people with BPD, the amplitude of the distress is a helpful indicator of borderline personality disorder.[14]

In addition to intense emotions, people with BPD experience emotional lability; or in other words, changeability. Although the term emotional lability suggests rapid changes between depression and elation, the mood swings in people with this condition actually fluctuate more frequently between anger and anxiety and between depression and anxiety.[15]

## Behavior [edit]

Impulsive behavior is common, including substance or alcohol abuse, eating disorders, unprotected sex or indiscriminate sex with multiple partners, reckless spending, and reckless driving.[16] Impulsive behavior may also include leaving jobs or relationships, running away, and self-injury.[17]

People with BPD act impulsively because it gives them immediate relief from their emotional pain.[17] However, in the long term, people with BPD suffer increased pain from the shame and guilt that follow such actions.[17] A cycle often begins in which people with BPD feel emotional pain, engage in impulsive behavior to relieve that pain, feel shame and guilt over their actions, feel emotional pain from the shame and guilt, and then experience stronger urges to engage in impulsive behavior to relieve the new pain.[17] As time goes on, impulsive behavior may become an automatic response to emotional pain.[17]

## Self-harm and suicide [edit]

Self-harming or suicidal behavior is one of the core diagnostic criteria in the DSM-5.[4] The lifetime risk of suicide among people with BPD is between 3% and 10%.[6][18] There is evidence that men diagnosed with BPD are approximately twice as likely to complete suicide as women diagnosed with BPD.[19] There is also evidence that a considerable percentage of men who complete suicide may have undiagnosed BPD.[20]

Self-harm such as cutting oneself is a common sign in borderline personality disorder.[3] Here in different states of wound healing.

Self-harm, such as cutting, is common and takes place with or without suicidal intent.[3][21][22] The reported reasons for non-suicidal self-injury (NSSI) differ from the reasons for suicide attempts.[13] Nearly 70% of people with BPD self-harm without trying to end their life.[23] Reasons for NSSI include expressing anger, self-punishment, generating normal feelings (often in response to dissociation), and distracting oneself from emotional pain or difficult circumstances.[13] In contrast, suicide attempts typically reflect a belief that others will be better off following the suicide.[13] Both suicidal and non-suicidal self-injury are a response to feeling negative emotions.[13]

Sexual abuse can be a particular trigger for suicidal behavior in adolescents with BPD tendencies.[24][*quantify*]

## Interpersonal relationships [edit]

People with BPD can be very sensitive to the way others treat them, by feeling intense joy and gratitude at perceived expressions of kindness, and intense sadness or anger at perceived criticism or hurtfulness.[25] Their feelings about others often shift from admiration or love to anger or dislike after a disappointment, a threat of losing someone, or a perceived loss of esteem in the eyes of someone they value. This phenomenon, sometimes called splitting, includes a shift from idealizing others to devaluing them.[26] Combined with mood disturbances, idealization and devaluation can undermine relationships with family, friends, and co-workers.[27] Self-image can also change rapidly from healthy to unhealthy.

While strongly desiring intimacy, people with BPD tend toward insecure, avoidant or ambivalent, or fearfully preoccupied attachment patterns in relationships,[28] and they often view the world as dangerous and malevolent.[25] BPD, like other personality disorders, is linked to increased levels of chronic stress and conflict in romantic relationships, decreased satisfaction on the part of romantic partners, abuse, and unwanted pregnancy.[29]

## Sense of self [edit]

People with BPD tend to have trouble seeing a clear picture of their identity. In particular, they tend to have difficulty knowing what they value, believe, prefer, and enjoy.[30] They are often unsure about their long-term goals for relationships and jobs. This difficulty with knowing who they are and what they value can cause people with BPD to experience feeling "empty" and "lost".[30]

## Cognitions [edit]

The often intense emotions experienced by people with BPD can make it difficult for them to control the focus of their attention—to concentrate.[30] In addition, people with BPD may tend to dissociate, which can be thought of as an intense form of "zoning out".[31] Dissociation often occurs in response to experiencing a painful event (or experiencing something that triggers the memory of a painful event). It involves the mind automatically redirecting attention away from that event, presumably to protect against experiencing intense emotion and unwanted behavioral impulses that such emotion might otherwise trigger.[31]

Although the mind's habit of blocking out intense painful emotions may provide temporary relief, it can also

have the unwanted side effect of blocking or blunting the experience of ordinary emotions, reducing the access of people with BPD to the information contained in those emotions, which helps guide effective decision-making in daily life.[31] Sometimes, it is possible for another person to tell when someone with BPD is dissociating, because their facial or vocal expressions may become flat or expressionless, or they may appear to be distracted; at other times, dissociation may be barely noticeable.[31]

### Disability [edit]

BPD is related to lower functioning and disability, even when socioeconomic status, medical conditions, and all psychiatric disorders were controlled.[32] Further, it is more common for females with BPD to experience disabilities than males with BPD.[32] More research is necessary to determine if this is due to a genetic sex difference or social reasons, but more females with BPD are diagnosed than males.[32]

## Causes [edit]

As is the case with other mental disorders, the causes of BPD are complex and not fully agreed upon.[33] Evidence suggests that BPD and post-traumatic stress disorder (PTSD) may be related in some way.[34] Most researchers agree that a history of childhood trauma can be a contributing factor,[35] but less attention has historically been paid to investigating the causal roles played by congenital brain abnormalities, genetics, neurobiological factors, and environmental factors other than trauma.[33][36]

Social factors include how people interact in their early development with their family, friends, and other children.[37] Psychological factors include the individual's personality and temperament, shaped by his or her environment and learned coping skills that deal with stress.[37] These different factors together suggest that there are multiple factors that may contribute to the disorder.

### Genetics [edit]

The heritability of BPD has been estimated at 40%.[38] That is, 40 percent of the variability in liability underlying BPD in the population can be explained by genetic differences. Twin studies may overestimate the effect of genes on variability in personality disorders due to the complicating factor of a shared family environment.[39] Nonetheless, the researchers of this study concluded that personality disorders "seem to be more strongly influenced by genetic effects than almost any axis I disorder [e.g., bipolar disorder, depression, eating disorders], and more than most broad personality dimensions."[40] Moreover, the study found that BPD was estimated to be the third most-heritable personality disorder out of the 10 personality disorders reviewed.[40]

Twin, sibling, and other family studies indicate partial heritability for impulsive aggression, but studies of serotonin-related genes have suggested only modest contributions to behavior.[41]

Families with twins in the Netherlands were participants of an ongoing study by Trull and colleagues, in which 711 pairs of siblings and 561 parents were examined to identify the location of genetic traits that influenced the development of BPD.[42] Research collaborators found that genetic material on chromosome nine was linked to BPD features.[42] The researchers concluded "that genetic factors play a major role in individual differences of borderline personality disorder features."[42] These same researchers had earlier concluded in a previous study that 42 percent of variation in BPD features was attributable to genetic influences and 58 percent was attributable to environmental influences.[42]

Genes currently under investigation include the 7-repeat polymorphism of the dopamine D4 receptor (DRD4), which has been linked to disorganized attachment, whilst the combined effect of the 7-repeat polymorphism and the 10/10 dopamine transporter (DAT) genotype has been linked to abnormalities in inhibitory control, both noted features of BPD.[43] There is a possible connection to chromosome 5.[44]

### Brain abnormalities [edit]

A number of neuroimaging studies in BPD have reported findings of reductions in regions of the brain involved in the regulation of stress responses and emotion, affecting the hippocampus, the orbitofrontal cortex, and the amygdala, amongst other areas.[43] A smaller number of studies have used magnetic resonance spectroscopy to explore changes in the concentrations of neurometabolites in certain brain regions of BPD patients, looking specifically at neurometabolites such as N-acetylaspartate, creatine, glutamate-related compounds, and choline-containing compounds.[43]

### Hippocampus [edit]

The hippocampus tends to be smaller in people with BPD, as it is in people with post-traumatic stress disorder (PTSD). However, in BPD, unlike PTSD, the amygdala also tends to be smaller.[45]

### Amygdala [edit]

The amygdalas are smaller and more active in people with BPD.[45] Decreased amygdala volume has also been found in people with obsessive-compulsive disorder.[46] One study has found unusually strong activity in the left amygdalas of people with BPD when they experience and view displays of negative emotions.[47] Since the amygdala generates all emotions (including unpleasant ones), this unusually strong activity may explain the unusual strength and longevity of fear, sadness, anger, and shame experienced by people with BPD, as well as their heightened sensitivity to displays of these emotions in others.[45]

### Prefrontal cortex [edit]

The prefrontal cortex tends to be less active in people with BPD, especially when recalling memories of abandonment.[48] This relative inactivity occurs in the right anterior cingulate (areas 24 and 32).[48] Given its role in regulating emotional arousal, the relative inactivity of the prefrontal cortex might explain the difficulties people with BPD experience in regulating their emotions and responses to stress.[49]

### Hypothalamic-pituitary-adrenal axis [edit]

The hypothalamic-pituitary-adrenal axis (HPA axis) regulates cortisol production, which is released in response to stress. Cortisol production tends to be elevated in people with BPD, indicating a hyperactive HPA axis in these individuals.[50] This causes them to experience a greater biological stress response, which might explain their greater vulnerability to irritability.[51] Since traumatic events can increase cortisol production and HPA axis activity, one possibility is that the prevalence of higher than average activity in the HPA axis of people with BPD may simply be a reflection of the higher than average prevalence of traumatic childhood and maturational events among people with BPD.[51] Another possibility is that, by heightening their sensitivity to stressful events, increased cortisol production may predispose those with BPD to experience stressful childhood and maturational events as traumatic.

Increased cortisol production is also associated with an increased risk of suicidal behavior.[52]

## Neurobiological factors [edit]

### Estrogen [edit]

Individual differences in women's estrogen cycles may be related to the expression of BPD symptoms in female patients.[53] A 2003 study found that women's BPD symptoms were predicted by changes in estrogen levels throughout their menstrual cycles, an effect that remained significant when the results were controlled for a general increase in negative affect.[54]

## Developmental factors [edit]

### Childhood trauma [edit]

There is a strong correlation between child abuse, especially child sexual abuse, and development of BPD.[55][56][57] Many individuals with BPD report a history of abuse and neglect as young children, but causation is still debated.[58] Patients with BPD have been found to be significantly more likely to report having been verbally, emotionally, physically, or sexually abused by caregivers of either gender. They also report a high incidence of incest and loss of caregivers in early childhood.[59]

Individuals with BPD were also likely to report having caregivers of both sexes deny the validity of their thoughts and feelings. Caregivers were also reported to have failed to provide needed protection and to have neglected their child's physical care. Parents of both sexes were typically reported to have withdrawn from the child emotionally and to have treated the child inconsistently.[59] Additionally, women with BPD who reported a previous history of neglect by a female caregiver and abuse by a male caregiver were significantly more likely to experience sexual abuse by a non-caregiver.[59]

It has been suggested that children who experience chronic early maltreatment and attachment difficulties may go on to develop borderline personality disorder.[60]

Writing in the psychoanalytic tradition, Otto Kernberg argues that a child's failure to achieve the developmental task of psychic clarification of self and other and failure to overcome splitting might increase the risk of developing a borderline personality.[61]

A child's inability to tolerate delayed gratification at age 4 does not predict later development of BPD.[62]

## Neurological patterns [edit]

The intensity and reactivity of a person's negative affectivity, or tendency to feel negative emotions, predicts BPD symptoms more strongly than does childhood sexual abuse.[63] This finding, differences in brain structure (see Brain abnormalities), and the fact that some patients with BPD do not report a traumatic history,[64] suggest that BPD is distinct from the post-traumatic stress disorder which frequently accompanies it. Thus, researchers examine developmental causes in addition to childhood trauma.

Research published in January 2013 by Dr. Anthony Ruocco at the University of Toronto has highlighted two patterns of brain activity that may underlie the dysregulation of emotion indicated in this disorder: (1) increased activity in the brain circuits responsible for the experience of heightened emotional pain, coupled with (2) reduced activation of the brain circuits that normally regulate or suppress these generated painful emotions. These two neural networks are seen to be dysfunctionally operative in the frontolimbic regions, but the specific regions vary widely in individuals, which calls for the analysis of more neuroimaging studies.[65]

Also (contrary to the results of earlier studies) sufferers of BPD showed less activation in the amygdala in situations of increased negative emotionality than the control group. Dr. John Krystal, editor of the journal *Biological Psychiatry*, wrote that these results "[added] to the impression that people with borderline personality disorder are 'set-up' by their brains to have stormy emotional lives, although not necessarily unhappy or unproductive lives".[65] Their emotional instability has been found to correlate with differences in several brain regions.[66]

## Mediating and moderating factors [edit]

### Executive function [edit]

While high rejection sensitivity is associated with stronger symptoms of borderline personality disorder, executive function appears to mediate the relationship between rejection sensitivity and BPD symptoms.[62] That is, a group of cognitive processes that include planning, working memory, attention, and problem-solving might be the mechanism through which rejection sensitivity impacts BPD symptoms. A 2008 study found that the relationship between a person's rejection sensitivity and BPD symptoms was stronger when executive function was lower and that the relationship was weaker when executive function was higher.[62] This suggests that high executive function might help protect people with high rejection sensitivity against symptoms of BPD.[62]

A 2012 study found that problems in working memory might contribute to greater impulsivity in people with BPD.[67]

### Family environment [edit]

Family environment mediates the effect of child sexual abuse on the development of BPD. An unstable family environment predicts the development of the disorder, while a stable family environment predicts a lower risk. One possible explanation is that a stable environment buffers against its development.[68]

### Self-complexity [edit]

Self-complexity, or considering one's self to have many different characteristics, appears to moderate the relationship between Actual-Ideal self-discrepancy and the development of BPD symptoms. That is, for individuals who believe that their actual characteristics do not match the characteristics that they hope to acquire, high self-complexity reduces the impact of their conflicted self-image on BPD symptoms.[69]

However, self-complexity does not moderate the relationship between Actual-Ought self-discrepancy and the development of BPD symptoms. That is, for individuals who believe that their actual characteristics do not match the characteristics that they should already have, high self-complexity does not reduce the impact of their conflicted self-image on BPD symptoms. The protective role of self-complexity in Actual-Ideal self-discrepancy, but not in Actual-Ought self-discrepancy, suggests that the impact of conflicted or unstable self-image in BPD depends on whether the individual views self in terms of characteristics that they hope to acquire, or in terms of characteristics that they should already have acquired.[69]

### Thought suppression [edit]

A 2005 study found that thought suppression, or conscious attempts to avoid thinking certain thoughts, mediates the relationship between emotional vulnerability and BPD symptoms.[63] A later study found that the relationship between emotional vulnerability and BPD symptoms is not necessarily mediated by thought suppression. However, this study did find that thought suppression mediates the relationship between an invalidating environment and BPD symptoms.[70]

## Diagnosis [edit]

Diagnosis of borderline personality disorder is based on a clinical assessment by a mental health professional. The best method is to present the criteria of the disorder to a person and to ask them if they feel that these characteristics accurately describe them.[6] Actively involving people with BPD in determining their diagnosis can help them become more willing to accept it.[6] Although some clinicians prefer not to tell people with BPD what their diagnosis is, either from concern about the stigma attached to this condition or because BPD used to be considered untreatable, it is usually helpful for the person with BPD to know their diagnosis.[6] This helps them know that others have had similar experiences and can point them toward effective treatments.[6]

In general, the psychological evaluation includes asking the patient about the beginning and severity of symptoms, as well as other questions about how symptoms impact the patient's quality of life. Issues of particular note are suicidal ideations, experiences with self-harm, and thoughts about harming others.[71] Diagnosis is based both on the person's report of their symptoms and on the clinician's own observations.[71] Additional tests for BPD can include a physical exam and laboratory tests to rule out other possible triggers for symptoms, such as thyroid conditions or substance abuse.[71]

The ICD-10 manual refers to the disorder as *emotionally unstable personality disorder* and has similar diagnostic criteria. In the DSM-5, the name of the disorder remains the same as in the previous editions.[4]

### Diagnostic and Statistical Manual [edit]

The Diagnostic and Statistical Manual of Mental Disorders fifth edition (DSM-5) has removed the multiaxial system. Consequently, all disorders, including personality disorders, are listed in Section II of the manual. A person must meet 5 of 9 criteria to receive a diagnosis of borderline personality disorder.[72] The DSM-5 defines the main features of BPD as a pervasive pattern of instability in interpersonal relationships, self image, and affect, as well as markedly impulsive behavior.[72]

In addition, the DSM-5 proposes alternative diagnostic criteria for Borderline personality disorder in section III, "Alternative DSM-5 Model for Personality Disorders." These alternative criteria are based on trait research and include specifying at least four of seven maladaptive traits.[73]

According to Marsha Linehan, many mental health professionals find it challenging to diagnose BPD using the DSM criteria, since these criteria describe such a wide variety of behaviors.[74] To address this issue, Linehan has grouped the symptoms of BPD under five main areas of dysregulation: emotions, behavior, interpersonal relationships, sense of self, and cognition.[74]

## International Classification of Disease [edit]

The World Health Organization's ICD-10 defines a disorder that is conceptually similar to borderline personality disorder, called *(F60.3) Emotionally unstable personality disorder*. Its two subtypes are described below.[75]

### F60.30 Impulsive type

At least three of the following must be present, one of which must be (2):

1. marked tendency to act unexpectedly and without consideration of the consequences;
2. marked tendency to engage in quarrelsome behavior and to have conflicts with others, especially when impulsive acts are thwarted or criticized;
3. liability to outbursts of anger or violence, with inability to control the resulting behavioral explosions;
4. difficulty in maintaining any course of action that offers no immediate reward;
5. unstable and capricious (impulsive, whimsical) mood.

### F60.31 Borderline type

At least three of the symptoms mentioned in *F60.30 Impulsive type* must be present [see above], with at least two of the following in addition:

1. disturbances in and uncertainty about self-image, aims, and internal preferences;
2. liability to become involved in intense and unstable relationships, often leading to emotional crisis;
3. excessive efforts to avoid abandonment;
4. recurrent threats or acts of self-harm;
5. chronic feelings of emptiness.
6. demonstrates impulsive behavior, e.g., speeding, substance abuse[76]

The ICD-10 also describes some general criteria that define what is considered a Personality disorder.

## Millon's subtypes [edit]

Theodore Millon has proposed four subtypes of BPD. He suggests that an individual diagnosed with BPD may exhibit none, one, or more of the following:[77]

| Subtype | Features |
|---|---|
| **Discouraged** (including avoidant features) | Pliant, submissive, loyal, humble; feels vulnerable and in constant jeopardy; feels hopeless, depressed, helpless, and powerless. |
| **Petulant** (including negativistic features) | Negativistic, impatient, restless, as well as stubborn, defiant, sullen, pessimistic, and resentful; easily slighted and quickly disillusioned. |
| **Impulsive** (including histrionic or antisocial features) | Capricious, superficial, flighty, distractible, frenetic, and seductive; fearing loss, becomes agitated, and gloomy and irritable; potentially suicidal. |

| | |
|---|---|
| **Self-destructive** (including depressive or masochistic features) | Inward-turning, intropunitively angry; conforming, deferential, and ingratiating behaviors have deteriorated; increasingly high-strung and moody; possible suicide. |

## Misdiagnosis [edit]

People with BPD may be misdiagnosed for a variety of reasons. One reason for misdiagnosis is BPD has symptoms that coexist with other disorders such as depression, PTSD, and bipolar disorder. The tests to narrow down what disorder a person has are also similar in questions that if the patient doesn't respond with the answers that have the word usually, then the disorder will go untreated due to improper diagnosis.[78][79]

## Family members [edit]

People with BPD are prone to feeling angry at members of their family and alienated from them. On their part, family members often feel angry and helpless at how their BPD family members relate to them.[6]

Parents of adults with BPD are often both over-involved and under-involved in family interactions.[80] In romantic relationships, BPD is linked to increased levels of chronic stress and conflict, decreased satisfaction of romantic partners, abuse, and unwanted pregnancy. However, these links may apply to personality disorders in general.[29]

## Adolescence [edit]

Onset of symptoms typically occurs during adolescence or young adulthood, although symptoms suggestive of this disorder can sometimes be observed in children.[81] Symptoms among adolescents that predict the development of BPD in adulthood may include problems with body-image, extreme sensitivity to rejection, behavioral problems, non-suicidal self-injury, attempts to find exclusive relationships, and severe shame.[6] Many adolescents experience these symptoms without going on to develop BPD, but those who experience them are 9 times as likely as their peers to develop BPD. They are also more likely to develop other forms of long-term social disabilities.[6]

Clinicians are discouraged from diagnosing anyone with BPD before the age of 18, due to the normal ups and downs of adolescence and a still-developing personality. However, BPD can sometimes be diagnosed before age 18, in which case the features must have been present and consistent for at least 1 year.[82]

A BPD diagnosis in adolescence might predict that the disorder will continue into adulthood.[82][83] Among adolescents who warrant a BPD diagnosis, there appears to be one group in which the disorder remains stable over time and another group in which the individuals move in and out of the diagnosis.[84] Earlier diagnoses may be helpful in creating a more effective treatment plan for the adolescent.[82][83] Family therapy is considered a helpful component of treatment for adolescents with BPD.[85]

## Differential diagnosis and comorbidity [edit]

Lifetime comorbid (co-occurring) conditions are common in BPD. Compared to those diagnosed with other personality disorders, people with BPD showed a higher rate of also meeting criteria for[86]

- mood disorders, including major depression and bipolar disorder
- anxiety disorders, including panic disorder, social anxiety disorder, and post-traumatic stress disorder (PTSD)
- other personality disorders
- substance abuse
- eating disorders, including anorexia nervosa and bulimia
- attention deficit hyperactivity disorder[87][*non-primary source needed*]
- somatoform disorders

dissociative disorders

A diagnosis of a personality disorder should not be made during an untreated mood episode/disorder, unless the lifetime history supports the presence of a personality disorder.

## Comorbid Axis I disorders [edit]

A 2008 study found that at some point in their lives, 75 percent of people with BPD meet criteria for mood disorders, especially major depression and Bipolar I, and nearly 75 percent meet criteria for an anxiety disorder.[88] Nearly 73 percent meet criteria for substance abuse or dependency, and about 40 percent for PTSD.[88] It is noteworthy that less than half of the participants with BPD in this study presented with PTSD, a prevalence similar to that reported in an earlier study.[86] The finding that less than half of patients with BPD experience PTSD during their lives challenges the theory that BPD and PTSD are the same disorder.[86]

**Gender differences in Axis I lifetime comorbid diagnosis, 2008[88] and 1998[86]**

| Axis I diagnosis | Overall (%) | Male (%) | Female (%) |
|---|---|---|---|
| **Mood disorders** | **75.0** | **68.7** | **80.2** |
| Major depressive disorder | 32.1 | 27.2 | 36.1 |
| Dysthymia | 9.7 | 7.1 | 11.9 |
| Bipolar I disorder | 31.8 | 30.6 | 32.7 |
| Bipolar II disorder | 7.7 | 6.7 | 8.5 |
| **Anxiety disorders** | **74.2** | **66.1** | **81.1** |
| Panic disorder with agoraphobia | 11.5 | 7.7 | 14.6 |
| Panic disorder without agoraphobia | 18.8 | 16.2 | 20.9 |
| Social phobia | 29.3 | 25.2 | 32.7 |
| Specific phobia | 37.5 | 26.6 | 46.6 |
| PTSD | 39.2 | 29.5 | 47.2 |
| Generalized anxiety disorder | 35.1 | 27.3 | 41.6 |
| Obsessive-compulsive disorder** | 15.6 | --- | --- |
| **Substance use disorders** | **72.9** | **80.9** | **66.2** |
| Any alcohol use disorder | 57.3 | 71.2 | 45.6 |
| Any drug use disorder | 36.2 | 44.0 | 29.8 |
| **Eating disorders**** | **53.0** | **20.5** | **62.2** |
| Anorexia nervosa** | 20.8 | 7 * | 25 * |
| Bulimia nervosa** | 25.6 | 10 * | 30 * |
| Eating disorder not otherwise specified** | 26.1 | 10.8 | 30.4 |
| **Somatoform disorders**** | **10.3** | **10 *** | **10 *** |
| Somatization disorder** | 4.2 | --- | --- |
| Hypochondriasis** | 4.7 | --- | --- |
| Somatoform pain disorder** | 4.2 | --- | --- |
| **Psychotic disorders**** | **1.3** | **1 *** | **1 *** |

* Approximate values
** Values from 1998 study[86]
--- Value not provided by study

There are marked gender differences in the types of comorbid conditions a person with BPD is likely to have—[86] a higher percentage of males with BPD meet criteria for substance-use disorders, while a higher percentage of females with BPD meet criteria for PTSD and eating disorders.[86][88][89] In one study, 38% of participants with BPD met the criteria for a diagnosis of ADHD.[87] In another study, 6 of 41 participants (15%) met the criteria for an autism spectrum disorder (a subgroup that had significantly more frequent suicide attempts).[90]

Regardless that it is an infradiagnosed disorder, a few studies have shown that the "lower expressions" of it might lead to wrong diagnoses. The many and shifting Axis I disorders in people with BPD can sometimes cause clinicians to miss the presence of the underlying personality disorder. However, since a complex pattern of Axis I diagnoses has been found to strongly predict the presence of BPD, clinicians can use the feature of a complex pattern of comorbidity as a clue that BPD might be present.[86]

### Mood disorders [edit]

Many people with borderline personality disorder also have mood disorders, such as major depressive disorder or a bipolar disorder.[27] Some characteristics of BPD are similar to those of mood disorders, which can complicate the diagnosis.[91][92][93] It is especially common for people to be misdiagnosed with bipolar disorder when they have borderline personality disorder or vice versa.[94] For someone with bipolar disorder, behavior suggestive of BPD might appear while the client is experiencing an episode of major depression or mania, only to disappear once the client's mood has stabilized.[95] For this reason, it is ideal to wait until the client's mood has stabilized before attempting to make a diagnosis.[95]

At face value, the affective lability of BPD and the rapid mood cycling of bipolar disorders can seem very similar.[96] It can be difficult even for experienced clinicians, if they are unfamiliar with BPD, to differentiate between the mood swings of these two conditions.[97] However, there are some clear differences.[94]

First, the mood swings of BPD and bipolar disorder tend to have different durations. In some people with bipolar disorder, episodes of depression or mania last for at least two weeks at a time, which is much longer than moods last in people with BPD.[94] Even among those who experience bipolar disorder with more rapid mood shifts, their moods usually last for days, while the moods of people with BPD can change in minutes or hours.[97] So while euphoria and impulsivity in someone with BPD might resemble a manic episode, the experience would be too brief to qualify as a manic episode.[95][97]

Second, the moods of bipolar disorder do not respond to changes in the environment, while the moods of BPD do respond to changes in the environment.[95] That is, a positive event would not lift the depressed mood caused by bipolar disorder, but a positive event would potentially lift the depressed mood of someone with BPD. Similarly, an undesirable event would not dampen the euphoria caused by bipolar disorder, but an undesirable event would dampen the euphoria of someone with borderline personality disorder.[95]

Third, when people with BPD experience euphoria, it is usually without the racing thoughts and decreased need for sleep that are typical of hypomania,[95] though a later 2013 study of data collected in 2004 found that borderline personality disorder diagnosis and symptoms were associated with chronic sleep disturbances, including difficulty initiating sleep, difficulty maintaining sleep, and waking earlier than desired, as well as with the consequences of poor sleep, and noted that "[f]ew studies have examined the experience of chronic sleep disturbances in those with borderline personality disorder".[98]

Because the two conditions have a number of similar symptoms, BPD was once considered to be a mild form of bipolar disorder[99][100] or to exist on the bipolar spectrum. However, this would require that the underlying mechanism causing these symptoms be the same for both conditions. Differences in phenomenology, family history, longitudinal course, and responses to treatment indicate that this is not the case.[101] Researchers have found "only a modest association" between bipolar disorder and borderline personality disorder, with "a strong spectrum relationship with [BPD and] bipolar disorder extremely unlikely."[102] Benazzi et al. suggest that the DSM-IV BPD diagnosis combines two unrelated characteristics: an affective instability dimension related to Bipolar II and an impulsivity dimension not related to Bipolar II.[103]

### Premenstrual dysphoric disorder [edit]

Premenstrual dysphoric disorder (PMDD) occurs in 3–8 percent of women.[104] Symptoms begin 5–11 days before menstruation and cease a few days after it begins.[*citation needed*] Symptoms may include marked mood swings, irritability, depressed mood, feeling hopeless or suicidal, a subjective sense of being overwhelmed or out of control, anxiety, binge eating, difficulty concentrating, and substantial impairment of

interpersonal relationships.[105][106] People with PMDD typically begin to experience symptoms in their early twenties, although many do not seek treatment until their early thirties.[105]

Although some of the symptoms of PMDD and BPD are similar, they are different disorders. They are distinguishable by the timing and duration of symptoms, which are markedly different: the symptoms of PMDD occur only during the luteal phase of the menstrual cycle,[105] whereas BPD symptoms occur persistently at all stages of the menstrual cycle. In addition, the symptoms of PMDD do not include impulsivity.[105]

### Comorbid Axis II disorders [edit]

More than two-thirds of people diagnosed with BPD also meet the criteria for another Axis II personality disorder at some point in their lives. (In a 2008 study, the rate was 73.9 percent.)[88] Cluster A disorders, which include paranoid, schizoid, and schizotypal, are the most common, with a prevalence of 50.4 percent in people with BPD.[88]

**Percentage of people with BPD and a lifetime comorbid Axis II diagnosis, 2008**[88]

| Axis II diagnosis | Overall ( % ) | Male ( % ) | Female ( % ) |
|---|---|---|---|
| **Any Cluster A** | **50.4** | **49.5** | **51.1** |
| Paranoid | 21.3 | 16.5 | 25.4 |
| Schizoid | 12.4 | 11.1 | 13.5 |
| Schizotypal | 36.7 | 38.9 | 34.9 |
| **Any Other Cluster B** | **49.2** | **57.8** | **42.1** |
| Antisocial | 13.7 | 19.4 | _9.0 |
| Histrionic | 10.3 | 10.3 | 10.3 |
| Narcissistic | 38.9 | 47.0 | 32.2 |
| **Any Cluster C** | **29.9** | **27.0** | **32.3** |
| Avoidant | 13.4 | 10.8 | 15.6 |
| Dependent | _3.1 | _2.6 | _3.5 |
| Obsessive-compulsive | 22.7 | 21.7 | 23.6 |

The second most common is another Cluster B disorder, which includes antisocial, histrionic, and narcissistic. These have an overall prevalence of 49.2 percent in people with BPD, with narcissistic being the most common, at 38.9 percent; antisocial the second most common, at 13.7 percent; and histrionic the least common, at 10.3 percent.[88] The least common are Cluster C disorders, which include avoidant, dependent, and obsessive-compulsive, and have a prevalence of 29.9 percent in people with BPD.[88] The percentages for specific comorbid Axis II disorders can be found in the adjacent table.

## Management [edit]

*Main article: Management of borderline personality disorder*

Psychotherapy is the primary treatment for borderline personality disorder.[5] Treatments should be based on the needs of the individual, rather than upon the general diagnosis of BPD. Medications are useful for treating comorbid disorders, such as depression and anxiety.[107] Short-term hospitalization has not been found to be more effective than community care for improving outcomes or long-term prevention of suicidal behavior in those with BPD.[108]

### Psychotherapy [edit]

Long-term psychotherapy is currently the treatment of choice for BPD.[109] There are six such treatments available: dynamic deconstructive psychotherapy (DDP),[110] mentalization-based treatment (MBT), transference-focused psychotherapy, dialectical behavior therapy (DBT), general psychiatric management, and schema-focused therapy.[6] While DBT is the therapy that has been studied the most, empirical research and case studies have shown that all of these treatments are effective for treating BPD, except for

schema-focused therapy.[6][*ambiguous*] Long-term therapy of any kind, including schema-focused therapy, is better than no treatment, especially in reducing urges to self-injure.[109]

Cognitive behavioral therapy (CBT) is also a type of psychotherapy used for treatment of BPD. This type of therapy relies on changing people's behaviors and beliefs by identifying problems from the disorder. CBT is known to reduce some anxiety and mood symptoms as well as reduce suicidal thoughts and self-harming behaviors.[3]

Mentalization-based therapy and transference-focused psychotherapy are based on psychodynamic principles, and dialectical behavior therapy is based on cognitive-behavioral principles and mindfulness.[109] General psychiatric management combines the core principles from each of these treatments, and it is considered easier to learn and less intensive.[6] Randomized controlled trials have shown that DBT and MBT may be the most effective, and the two share many similarities.[111][112] However, a naturalistic study indicated that DDP may be more effective than DBT.[113] Researchers are interested in developing shorter versions of these therapies to increase accessibility, to relieve the financial burden on patients, and to relieve the resource burden on treatment providers.[109][112]

From a psychodynamic perspective, a special problem of psychotherapy with people with BPD is intense projection. It requires the psychotherapist to be flexible in considering negative attributions by the patient rather than quickly interpreting the projection.[114]

Some research indicates that mindfulness meditation may bring about favorable structural changes in the brain, including changes in brain structures that are associated with BPD.[115][116][117] Mindfulness-based interventions also appear to bring about an improvement in symptoms characteristic of BPD, and some clients who underwent mindfulness-based treatment no longer met a minimum of five of the DSM-IV-TR diagnostic criteria for BPD.[117][118]

## Medications [edit]

A 2010 review by the Cochrane collaboration found that no medications show promise for "the core BPD symptoms of chronic feelings of emptiness, identity disturbance and abandonment." However, the authors found that some medications may impact isolated symptoms associated with BPD or the symptoms of comorbid conditions.[119][*needs update*]

Of the typical antipsychotics studied in relation to BPD, haloperidol may reduce anger and flupenthixol may reduce the likelihood of suicidal behavior. Among the atypical antipsychotics, one trial found that aripiprazole may reduce interpersonal problems and impulsivity.[119] Olanzapine may decrease affective instability, anger, psychotic paranoid symptoms, and anxiety, but a placebo had a greater ameliorative impact on suicidal ideation than olanzapine did. The effect of ziprasidone was not significant.[119]

Of the mood stabilizers studied, valproate semisodium may ameliorate depression, interpersonal problems, and anger. Lamotrigine may reduce impulsivity and anger; topiramate may ameliorate interpersonal problems, impulsivity, anxiety, anger, and general psychiatric pathology. The effect of carbamazepine was not significant. Of the antidepressants, amitriptyline may reduce depression, but mianserin, fluoxetine, fluvoxamine, and phenelzine sulfate showed no effect. Omega-3 fatty acid may ameliorate suicidality and improve depression. As of 2010, trials with these medications had not been replicated and the effect of long-term use had not been assessed.[119]

Because of weak evidence and the potential for serious side effects from some of these medications, the UK National Institute for Health and Clinical Excellence (NICE) 2009 clinical guideline for the treatment and management of BPD recommends, "Drug treatment should not be used specifically for borderline personality disorder or for the individual symptoms or behavior associated with the disorder." However, "drug treatment may be considered in the overall treatment of comorbid conditions." They suggest a "review of the treatment of people with borderline personality disorder who do not have a diagnosed comorbid mental or physical illness and who are currently being prescribed drugs, with the aim of reducing and stopping unnecessary drug treatment."[120]

### Services [edit]

There is a significant difference between the number of those who would benefit from treatment and the number of those who are treated. The so-called "treatment gap" is a function of the disinclination of the afflicted to submit for treatment, an underdiagnosing of the disorder by healthcare providers, and the limited availability and access to state-of-the-art treatments.[121] Nonetheless, individuals with BPD accounted for about 20 percent of psychiatric hospitalizations in one survey.[122] The majority of individuals with BPD who are in treatment continue to use outpatient treatment in a sustained manner for several years, but the number using the more restrictive and costly forms of treatment, such as inpatient admission, declines with time.[123]

Experience of services varies.[124] Assessing suicide risk can be a challenge for clinicians, and patients themselves tend to underestimate the lethality of self-injurious behaviors. People with BPD typically have a chronically elevated risk of suicide much above that of the general population and a history of multiple attempts when in crisis.[125] Approximately half the individuals who commit suicide meet criteria for a personality disorder. Borderline personality disorder remains the most commonly associated personality disorder with suicide.[126]

## Prognosis [edit]

With treatment, the majority of people with BPD can find relief from distressing symptoms and achieve remission, defined as a consistent relief from symptoms for at least two years.[127][128] This longitudinal study tracking the symptoms of people with BPD found that 34.5% achieved remission within two years from the beginning of the study. Within four years, 49.4% had achieved remission, and within six years, 68.6% had achieved remission. By the end of the study, 73.5% of participants were found to be in remission.[127] Moreover, of those who achieved recovery from symptoms, only 5.9% experienced recurrences. A later study found that ten years from baseline (during a hospitalization), 86% of patients had sustained a stable recovery from symptoms.[129]

Patient personality can play an important role during the therapeutic process, leading to better clinical outcomes. Recent research has shown that BPD patients undergoing Dialectical Behavior Therapy (DBT) exhibit better clinical outcomes correlated with higher levels of the trait of agreeableness in the patient, compared to patients either low in agreeableness or not being treated with DBT. This association was mediated through the strength of a working alliance between patient and therapist; that is, more agreeable patients developed stronger working alliances with their therapists, which in turn, led to better clinical outcomes.[130]

In addition to recovering from distressing symptoms, people with BPD also achieve high levels of psychosocial functioning. A longitudinal study tracking the social and work abilities of participants with BPD found that six years after diagnosis, 56% of participants had good function in work and social environments, compared to 26% of participants when they were first diagnosed. Vocational achievement was generally more limited, even compared to those with other personality disorders. However, those whose symptoms had remitted were significantly more likely to have good relationships with a romantic partner and at least one parent, good performance at work and school, a sustained work and school history, and good psychosocial functioning overall.[131]

## Epidemiology [edit]

The prevalence of BPD was initially estimated to be 1 to 2 percent of the general population[128][132] and to occur three times more often in women than in men.[133][134] However, the lifetime prevalence of BPD in a 2008 study was found to be 5.9% of the general population, occurring in 5.6% of men and 6.2% of women.[88] The difference in rates between men and women in this study was not found to be statistically significant.[88]

Borderline personality disorder is estimated to contribute to 20 percent of psychiatric hospitalizations and to

occur among 10 percent of outpatients.[135]

29.5 percent of new inmates in Iowa USA, fit a diagnosis of borderline personality disorder in 2007,[136] and the overall prevalence of BPD in the U.S.-prison population is thought to be 17 percent.[135] These high numbers may be related to the high frequency of substance abuse and substance use disorders among people with BPD, which is estimated at 38 percent.[135]

## History [edit]

The coexistence of intense, divergent moods within an individual was recognized by Homer, Hippocrates, and Aretaeus, the latter describing the vacillating presence of impulsive anger, melancholia, and mania within a single person. The concept was revived by Swiss physician Théophile Bonet in 1684 who, using the term *folie maniaco-mélancolique*,[140] described the phenomenon of unstable moods that followed an unpredictable course. Other writers noted the same pattern, including the American psychiatrist C. Hughes in 1884 and J.C. Rosse in 1890, who called the disorder "borderline insanity".[141] In 1921, Kraepelin identified an "excitable personality" that closely parallels the borderline features outlined in the current concept of BPD.[142]

Idealization in Edvard Munch's *The Brooch. Eva Mudocci* (1903)

The first significant psychoanalytic work to use the term "borderline" was written by Adolf Stern in 1938.[143] It described a group of patients suffering from what he thought to be a mild form of schizophrenia, on the *borderline* between neurosis and psychosis.

The 1960s and 1970s saw a shift from thinking of the condition as borderline schizophrenia to thinking of it as a borderline affective disorder (mood disorder), on the fringes of bipolar disorder, cyclothymia, and dysthymia. In the DSM-II, stressing the intensity and variability of moods, it was called cyclothymic personality (affective personality).[82] While the term "borderline" was evolving to refer to a distinct category of disorder, psychoanalysts such as Otto Kernberg were using it to refer to a broad spectrum of issues, describing an intermediate level of personality organization[142] between neurosis and psychosis.[144]

Devaluation in Edvard Munch's *Salome* (1903). Idealization and devaluation of others in personal relations is a highly specific trait in BPD (introduction and main text). The painter Edvard Munch depicted his new friend, the violinist Eva Mudocci, in both ways

After standardized criteria were developed[145] to distinguish it from mood disorders and other Axis I disorders, BPD became a personality disorder diagnosis in 1980 with the publication of the DSM-III.[128] The diagnosis was distinguished from sub-syndromal schizophrenia, which was termed "Schizotypal personality disorder".[144] The DSM-IV Axis II Work Group of the American Psychiatric Association finally decided on the name "borderline personality disorder," which is still in use by the DSM-5 today.[4] However, the term "borderline" has been described as uniquely inadequate for describing the symptoms characteristic of this disorder.[146]

## Controversies [edit]

### Credibility and validity of testimony [edit]

The credibility of individuals with personality disorders has been questioned at least since the 1960s.[147] Two concerns are the incidence of dissociation episodes among people with BPD and the belief that lying is a key component of this condition.

within days. First as "a woman seen by a man in love", then as "a bloodthirsty and cannibalistic Salome".[137] In modern times, Munch has been diagnosed by psychiatrists as having had BPD, including by an authority in the field, James F. Masterson.[138][139]

## Dissociation [edit]

Researchers disagree about whether dissociation, or a sense of detachment from emotions and physical experiences, impacts the ability of people with BPD to recall the specifics of past events. A 1999 study reported that the specificity of autobiographical memory was decreased in BPD patients.[148] The researchers found that decreased ability to recall specifics was correlated with patients' levels of dissociation.[148]

## Lying as a feature [edit]

Some theorists argue that patients with BPD often lie.[149] However, others write that they have rarely seen lying among patients with BPD in clinical practice.[149] Regardless, lying is not one of the diagnostic criteria for BPD.

The belief that lying is a distinguishing characteristic of BPD can impact the quality of care that people with this diagnosis receive in the legal and healthcare systems. For instance, Jean Goodwin relates an anecdote of a patient with multiple personality disorder, now called dissociative identity disorder, who suffered from pelvic pain due to traumatic events in her childhood.[150] Due to their disbelief in her accounts of these events, physicians diagnosed her with borderline personality disorder, reflecting a belief that lying is a key feature of BPD. Based upon her BPD diagnosis, the physicians then disregarded the patient's assertion that she was allergic to adhesive tape. The patient was in fact allergic to adhesive tape, which later caused complications in the surgery to relieve her pelvic pain.[150]

## Gender [edit]

Since BPD can be a stigmatizing diagnosis even within the mental health community, some survivors of childhood abuse who are diagnosed with BPD are re-traumatized by the negative responses they receive from healthcare providers.[151] One camp argues that it would be better to diagnose these men or women with post-traumatic stress disorder, as this would acknowledge the impact of abuse on their behavior. Critics of the PTSD diagnosis argue that it medicalizes abuse rather than addressing the root causes in society.[152] Regardless, a diagnosis of PTSD does not encompass all aspects of the disorder (see Brain abnormalities and Terminology).

Joel Paris states that "In the clinic ... Up to 80% of patients are women. That may not be true in the community."[153] He offers the following explanations regarding these gender discrepancies:

> "The most probable explanation for gender differences in clinical samples is that women are more likely to develop the kind of symptoms that bring patients in for treatment. Twice as many women as men in the community suffer from depression (Weissman & Klerman, 1985). In contrast, there is a preponderance of men meeting criteria for substance abuse and psychopathy (Robins & Regier, 1991), and males with these disorders do not necessarily present in the mental health system. Men and women with similar psychological problems may express distress differently. Men tend to drink more and carry out more crimes. Women tend to turn their anger on themselves, leading to depression as well as the cutting and overdosing that characterize BPD. Thus, anti-social personality disorder (ASPD) and borderline personality disorders might derive from similar underlying pathology but present with symptoms strongly influenced by gender (Paris, 1997a; Looper & Paris, 2000). We have even more specific evidence that men with BPD may not seek help. In a study of completed suicides among people aged 18 to 35 years (Lesage et al., 1994), 30% of the suicides involved individuals with BPD (as confirmed by psychological autopsy, in which symptoms were assessed by interviews with family members). Most of the suicide completers were men, and very few were in treatment. Similar findings emerged from a later study conducted by our own research group (McGirr, Paris, Lesage, Renaud, & Turecki, 2007)."[20]

In short, men are less likely to seek or accept appropriate treatment, more likely to be treated for symptoms of BPD such as substance abuse rather than BPD itself (furthermore, the symptoms of BPD and ASPD may derive from a similar underlying aetiology) and possibly men are simply more likely to commit suicide prior to diagnosis.

Among men diagnosed with BPD there is also evidence of a higher suicide rate: "men are more than twice as likely as women—18 percent versus 8 percent"—to die by suicide.[19]

There are also sex differences in borderline personality disorders.[154] Men with BPD are more likely to abuse substances, have explosive temper, high levels of novelty seeking and have anti-social, narcissistic, passive-aggressive or sadistic personality traits.[154] Women with BPD are more likely to have eating disorders, mood disorders, anxiety and post-traumatic stress.[154]

## Manipulative behavior [edit]

Manipulative behavior to obtain nurturance is considered by the DSM-IV-TR and many mental health professionals to be a defining characteristic of borderline personality disorder.[155] However, Marsha Linehan notes that doing so relies upon the assumption that people with BPD who communicate intense pain, or who engage in self-harm and suicidal behavior, do so with the intention of influencing the behavior of others.[156] The impact of such behavior on others—often an intense emotional reaction in concerned friends, family members, and therapists—is thus assumed to have been the person's intention.[156]

However, since people with BPD lack the ability to successfully manage painful emotions and interpersonal challenges, their frequent expressions of intense pain, self-harming, or suicidal behavior may instead represent a method of mood regulation or an escape mechanism from situations that feel unbearable.[157] Linehan notes that if, for example, one were to withhold pain medication from burn victims and cancer patients, leaving them unable to regulate their severe pain, they would also exhibit "attention-seeking" and self-destructive behavior in order to cope.[158]

## Stigma [edit]

The features of BPD include emotional instability; intense, unstable interpersonal relationships; a need for intimacy; and a fear of rejection. As a result, people with BPD often evoke intense emotions in those around them. Pejorative terms to describe people with BPD, such as "difficult", "treatment resistant", "manipulative", "demanding", and "attention seeking", are often used and may become a self-fulfilling prophecy, as the negative treatment of these individuals triggers further self-destructive behavior.[159]

## Physical violence [edit]

The stigma surrounding borderline personality disorder includes the belief that people with BPD are prone to violence toward others.[160] While movies and visual media often sensationalize people with BPD by portraying them as violent, the majority of researchers agree that people with BPD are unlikely to physically harm others.[160] Although people with BPD often struggle with experiences of intense anger, a defining characteristic of BPD is that they direct it inward toward themselves.[161] One of the key differences between BPD and antisocial personality disorder (ASPD) is that people with BPD tend to internalize anger by hurting themselves, while people with ASPD tend to externalize it by hurting others.[161]

In addition, adults with BPD have often experienced abuse in childhood, so many people with BPD adopt a "no-tolerance" policy toward expressions of anger of any kind.[161] Their extreme aversion to violence can cause many people with BPD to overcompensate and experience difficulties being assertive and expressing their needs.[161] This is one way in which people with BPD choose to harm themselves over potentially causing harm to others.[161] Another way in which people with BPD avoid expressing their anger through violence is by causing physical damage to themselves, such as engaging in non-suicidal self-injury.[13][160]

## Mental healthcare providers [edit]

People with BPD are considered to be among the most challenging groups of patients to work with in therapy, requiring a high level of skill and training in the psychiatrists, therapists and nurses involved in their treatment.[162] A majority of psychiatric staff report finding individuals with BPD moderately to extremely difficult to work with and more difficult than other client groups.[163] Efforts are ongoing to improve public and staff attitudes toward people with BPD.[164][165]

In psychoanalytic theory, the stigmatization among mental healthcare providers may be thought to reflect countertransference (when a therapist projects his or her own feelings on to a client). Thus, a diagnosis of BPD "often says more about the clinician's negative reaction to the patient than it does about the patient" and "explains away the breakdown in empathy between the therapist and the patient and becomes an institutional epithet in the guise of pseudoscientific jargon".[144] This inadvertent countertransference can give rise to inappropriate clinical responses, including excessive use of medication, inappropriate mothering, and punitive use of limit setting and interpretation.[166]

Some clients feel the diagnosis is helpful, allowing them to understand that they are not alone and to connect with others with BPD who have developed helpful coping mechanisms. However, others experience the term "borderline personality disorder" as a pejorative label rather than an informative diagnosis. They report concerns that their self-destructive behavior is incorrectly perceived as manipulative and that the stigma surrounding this disorder limits their access to healthcare.[167][*non-primary source needed*] Indeed, mental health professionals frequently refuse to provide services to those who have received a BPD diagnosis.[168]

### Terminology [edit]

Because of the above concerns, and because of a move away from the original theoretical basis for the term (see history), there is ongoing debate about renaming borderline personality disorder. While some clinicians agree with the current name, others argue that it should be changed,[169] since many who are labelled with borderline personality disorder find the name unhelpful, stigmatizing, or inaccurate.[169][170] Valerie Porr, president of Treatment and Research Advancement Association for Personality Disorders states that "the name BPD is confusing, imparts no relevant or descriptive information, and reinforces existing stigma."[171]

Alternative suggestions for names include *emotional regulation disorder* or *emotional dysregulation disorder*. *Impulse disorder* and *interpersonal regulatory disorder* are other valid alternatives, according to John Gunderson of McLean Hospital in the United States.[172] Another term suggested by psychiatrist Carolyn Quadrio is *post traumatic personality disorganization* (PTPD), reflecting the condition's status as (often) both a form of chronic post traumatic stress disorder (PTSD) as well as a personality disorder.[57] However, although many with BPD do have traumatic histories, some do not report any kind of traumatic event, which suggests that BPD is not necessarily a trauma spectrum disorder.[64]

The Treatment and Research Advancements National Association for Personality Disorders (TARA-APD) campaigned unsuccessfully to change the name and designation of BPD in DSM-5, published in May 2013, in which the name "borderline personality disorder" remains unchanged and it is not considered a trauma- and stressor-related disorder.[173]

## Society and culture [edit]

### Film and television [edit]

There are several films and television shows that portray characters either explicitly diagnosed or with traits suggestive of BPD. These may be misleading if they are thought to depict this disorder accurately. Unfortunately, dramatic portrayals of people with BPD in movies and other forms of visual media contribute to the stigma surrounding borderline personality disorder, especially the myth that people with BPD are violent toward others.[160] The majority of researchers agree that in reality, people with BPD are very unlikely to harm others.[160]

The films *Play Misty for Me*[174] and *Girl, Interrupted* (based on the memoir of the same name) both suggest the emotional instability of the disorder; however, the first case shows a person more aggressive to others than to herself, which is not characteristic of the disorder.[175] The 1992 film *Single White Female*, like the first example, also suggests characteristics, some of which are actually atypical of the disorder: the character Hedy had markedly disturbed sense of identity and reacts drastically to abandonment.[176]

Films attempting to depict characters with the disorder include *A Thin Line Between Love and Hate*, *Filth*, *Fatal Attraction*, *The Crush*, *Mad Love*, *Malicious*, *Interiors*, *The Cable Guy*, *Mr. Nobody*, *Cracks*,[177] and *Welcome to Me*.[178][179] Psychiatrists Eric Bui and Rachel Rodgers argue that the character of Anakin Skywalker/Darth Vader in the *Star Wars* films meets six of the nine diagnostic criteria; Bui also found Anakin a useful example to explain BPD to medical students. In particular, Bui points to the character's abandonment issues, uncertainty over his identity, and dissociative episodes.[180]

## Awareness [edit]

In early 2008, the United States House of Representatives declared the month of May as Borderline Personality Disorder Awareness Month.[181][182]

# Bulimia nervosa

From Wikipedia, the free encyclopedia

**Bulimia nervosa**, also known as simply **bulimia**, is an eating disorder characterized by binge eating followed by purging. Binge eating refers to eating a large amount of food in a short amount of time. Purging refers to the attempts to get rid of the food consumed. This may be done by vomiting or taking laxatives.[1] Other efforts to lose weight may include the use of diuretics, stimulants, water fasting, or excessive exercise.[1][2] Most people with bulimia are at a normal weight.[3] The forcing of vomiting may result in thickened skin on the knuckles and breakdown of the teeth. Bulimia is frequently associated with other mental disorders such as depression, anxiety, and problems with drugs or alcohol.[1] There is also a higher risk of suicide and self-harm.[4]

Bulimia is more common among those who have a close relative with the condition.[1] The percentage risk that is estimated to be due to genetics is between 30% and 80%.[2] Other risk factors for the disease include psychological stress, cultural pressure to attain a certain body type, poor self-esteem, and obesity.[1][2] Living in a culture that promotes dieting and having parents that worry about weight are also risks.[2] Diagnosis is based on a person's medical history,[5] however this is difficult as people are usually secretive about their binge eating and purging habits.[2] Furthermore, the diagnosis of anorexia nervosa takes precedence over that of bulimia.[2] Other similar disorders include binge eating disorder, Kleine-Levin syndrome, and borderline personality disorder.[5]

Cognitive behavioral therapy is the primary treatment for bulimia.[1][6] Antidepressants of the selective serotonin reuptake inhibitors (SSRI) or tricyclic antidepressant class may have a modest benefit.[2][7] While outcomes with bulimia are typically better than in those of anorexia, the risk of death among those affected is higher than that of the general population.[4] At 10 years after receiving treatment about 50% of people are fully recovered.[2]

Globally, bulimia was estimated to affect 6.5 million people in 2013.[8] About 1% of young women have bulimia at a given point in time and about 2% to 3% of women have the condition at some point in their lives.[4] The condition is less common in the developing world.[2] Bulimia is about nine times more likely to occur in women than men. Among women, rates are highest in young adults.[5] Bulimia was named and first described by the British psychiatrist Gerald Russell in 1979.[9][10]

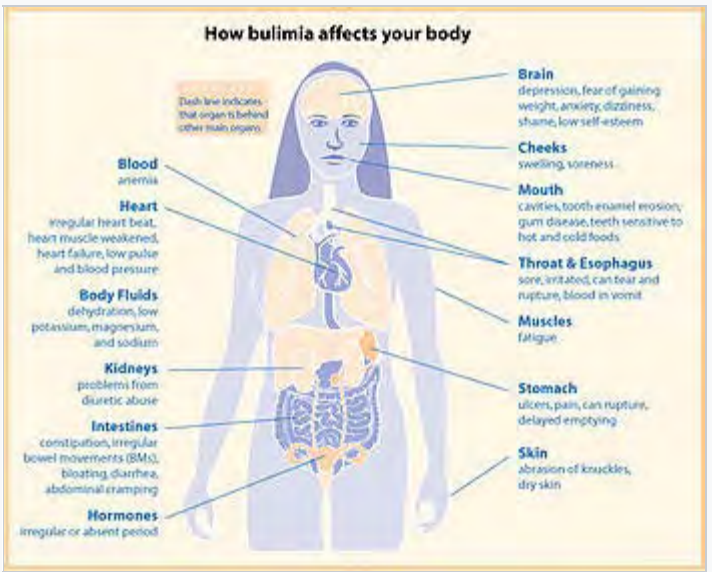
## Signs and symptoms [edit]

Bulimia typically involves rapid and out-of-control eating, which may stop when the bulimic is interrupted by another person or the stomach hurts from over-extension, followed by self-induced vomiting or other forms of purging. This cycle may be repeated several times a week or, in more serious cases, several times a day[12] and may directly cause:

- Chronic gastric reflux after eating, secondary to vomiting[13]
- Dehydration and hypokalemia due to renal potassium loss in the presence of alkalosis and frequent vomiting[14]
- Electrolyte imbalance, which can lead to abnormal heart rhythms, cardiac arrest, and even death
- Esophagitis, or inflammation of the esophagus
- Mallory-Weiss tears
- Boerhaave syndrome, a rupture in the esophageal wall due to vomiting
- Oral trauma, in which repetitive insertion of fingers or other objects causes lacerations to the lining of the mouth or throat
- Russell's sign: calluses on knuckles and back of hands due to repeated trauma from incisors[15][16]
- Perimolysis, or severe dental erosion of tooth enamel[17]
- Swollen salivary glands (for example, in the neck, under the jaw line)[17][18]
- Gastroparesis or delayed emptying
- Constipation
- Peptic ulcers
- Infertility
- Constant weight fluctuations are common



How bulimia affects the body

The erosion on the lower teeth was caused by bulimia. For comparison, the upper teeth were

restored with porcelain veneers.[11]

These are some of the many signs that may indicate whether someone has bulimia nervosa:[19]

- A fixation on the number of calories consumed.
- A fixation on and extreme consciousness of ones weight.
- Low self-esteem and/or self harming.
- Suicidal tendencies
- low blood pressure
- An irregular menstrual cycle in woman.
- Regular trips to the bathroom, especially soon after eating.
- Depression, anxiety disorders and sleep disorders.
- Frequent occurrences involving consumption of abnormally large portions of food.[20]
- The use of laxatives and diet pills.
- Unhealthy/dry skin, hair, nails and lips.
- A lack of energy.

As with many psychiatric illnesses, delusions can occur, in conjunction with other signs and symptoms, leaving the person with a false belief that is not ordinarily accepted by others.[21]

People with bulimia nervosa may also exercise to a point that excludes other activities.[21]

### Related disorders [edit]

Bulimics are much more likely than non-bulimics to have an affective disorder, such as depression or general anxiety disorder: A 1985 Columbia University study on female bulimics at New York State Psychiatric Institute found 70% had suffered depression some time in their lives (as opposed to 25.8% for adult females in a control sample from the general population), rising to 88% for all affective disorders combined.[22] Another study by the Royal Children's Hospital in Melbourne on a cohort of 2,000 adolescents similarly found that those meeting at least two of the DSM-IV criteria for bulimia nervosa or anorexia nervosa had a sixfold increase in risk of anxiety and a doubled risk for substance dependency.[23] Some sufferers of anorexia nervosa exhibit episodes of bulimic tendencies through purging (either through self-induced vomiting or laxatives) as a way to quickly remove food in their system.[24] Bulimia also has negative effects on the sufferer's dental health due to the acid passed through the mouth from frequent vomiting causing acid erosion, mainly on the posterior dental surface.

## Diagnosis [edit]

The onset of bulimia nervosa is often during adolescence, between 13 and 20 years of age, and many cases have previously suffered from obesity, with many sufferers relapsing in adulthood into episodic bingeing and purging even after initially successful treatment and remission.[25] A lifetime prevalence of 0.5 percent and 0.9 percent for adult and adolescent sufferers, respectively, is estimated among the United States population.[26] Bulimia nervosa may affect up to 1% of young women and, after 10 years of diagnosis, half will recover fully, a third will recover partially, and 10–20% will still have symptoms.[2]

Adolescents with bulimia nervosa are more likely to have self-imposed perfectionism and compulsivity issues in eating compared to their peers. This means that the high expectations and unrealistic goals that these individuals set for themselves are internally motivated rather than by social views or expectations.[27]

### Criteria [edit]

Bulimia nervosa can be difficult to detect, compared to anorexia nervosa, because bulimics tend to be of average or slightly above or below average weight. Many bulimics may also engage in significantly disordered eating and exercise patterns without meeting the full diagnostic criteria for bulimia nervosa.[28] Recently, the *Diagnostic and Statistical Manual of Mental Disorders* was revised, which resulted in the loosening of criteria regarding the diagnoses of bulimia nervosa and anorexia nervosa.[29] The diagnostic

criteria utilized by the DSM-5 includes repetitive episodes of binge eating (a discrete episode of overeating during which the individual feels out of control of consumption) compensated for by excessive or inappropriate measures taken to avoid gaining weight.[30] The diagnosis also requires the episodes of compensatory behaviors and binge eating to happen a minimum of once a week for a consistent time period of 3 months.[31] The diagnosis is made only when the behavior is not a part of the symptom complex of anorexia nervosa and when the behavior reflects an overemphasis on physical mass or appearance. Purging often is a common characteristic of a more severe case of bulimia nervosa.[32]

## Causes [edit]

### Biological [edit]

As with anorexia nervosa, there is evidence of genetic predispositions contributing to the onset of this eating disorder.[33] Abnormal levels of many hormones, notably serotonin, have been shown to be responsible for some disordered eating behaviors. Brain-derived neurotrophic factor (BDNF) is under investigation as a possible mechanism.[34][35]

There is evidence that sex hormones may influence appetite and eating in women, and the onset of bulimia nervosa. Studies have shown that women with hyperandrogenism and polycystic ovary syndrome have a dysregulation of appetite, along with carbohydrates and fats. This dysregulation of appetite is also seen in women with bulimia nervosa. In addition, gene knockout studies in mice have shown that mice that have the gene encoding estrogen receptors have decreased fertility due to ovarian dysfunction and dysregulation of androgen receptors. In humans, there is evidence that there is an association between polymorphisms in the ERβ (estrogen receptor β) and bulimia, suggesting there is a correlation between sex hormones and bulimia nervosa.[36]

Bulimia has been compared to drug addiction, though the empirical support for this characterization is limited.[37] However, people with bulimia nervosa may share dopamine D2 receptor-related vulnerabilities with those with substance abuse disorders.[38]

Dieting, a common behaviour in bulimics, is associated with lower plasma tryptophan levels.[*citation needed*] Decreased tryptophan levels in the brain, and thus the synthesis of serotonin, increases bulimic urges in currently and formerly bulimic individuals within hours.[39][40]

### Social [edit]

Media portrayals of an 'ideal' body shape are widely considered to be a contributing factor to bulimia.[21] In a 1991 study by Weltzin, Hsu, Pollicle, and Kaye, it was stated that 19% of bulimics undereat, 37% of bulimics eat an amount of food that is normal for an average human being, and 44% of bulimics overeat.[41] A survey of 15- to 18-year-old high school girls in Nadroga, Fiji, found the self-reported incidence of purging rose from 0% in 1995 (a few weeks after the introduction of television in the province) to 11.3% in 1998.[42] In addition, the suicide rate among people with bulimia nervosa is 7.5 times higher than in the general population.[43]

When attempting to decipher the origin of bulimia nervosa in a cognitive context, Christopher Fairburn *et al.*'s cognitive behavioral model is often considered the golden standard. Fairburn et al.'s model discusses the process in which an individual falls into the binge-purge cycle and thus develops bulimia. Fairburn *et al.* argue that extreme concern with weight and shape coupled with low self-esteem will result in strict, rigid, and inflexible dietary rules. Accordingly, this would lead to unrealistically restricted eating, which may consequently induce an eventual "slip" where the individual commits a minor infraction of the strict and inflexible dietary rules. Moreover, the cognitive distortion due to dichotomous thinking leads the individual to binge. The binge subsequently should trigger a perceived loss of control, promoting the individual to purge in hope of counteracting the binge. However, Fairburn *et al.* assert the cycle repeats itself, and thus consider the binge-purge cycle to be self-perpetuating.[44][*citation needed*]

In contrast, Byrne and Mclean's findings differed slightly from Fairburn *et al.*'s cognitive behavioral model of bulimia nervosa in that the drive for thinness was the major cause of purging as a way of controlling weight. In turn, Byrne and Mclean argued that this makes the individual vulnerable to binging, indicating that it is not a binge-purge cycle but rather a purge-binge cycle in that purging comes before bingeing. Similarly, Fairburn *et al.*'s cognitive behavioral model of bulimia nervosa is not necessarily applicable to every individual and is certainly reductionist. Everyone differs from another, and taking such a complex behavior like bulimia and applying the same one theory to everyone would certainly be invalid. In addition, the cognitive behavioral model of bulimia nervosa is very cultural bound in that it may not be necessarily applicable to cultures outside of the Western society. To evaluate, Fairburn *et al*.'s model and more generally the cognitive explanation of bulimia nervosa is more descriptive than explanatory, as it does not necessarily explain how bulimia arises. Furthermore, it is difficult to ascertain cause and effect, because it may be that distorted eating leads to distorted cognition rather than vice versa.[45][46]

A considerable amount of literature has identified a correlation between sexual abuse and the development of bulimia nervosa. The reported incident rate of unwanted sexual contact is higher among those with bulimia nervosa than anorexia nervosa.[47]

When exploring the etiology of bulimia through a socio-cultural perspective, the "thin ideal internalization" is significantly responsible. The thin ideal internalization is the extent to which individuals adapt to the societal ideals of attractiveness. Studies have shown that young females that read fashion magazines tend to have more bulimic symptoms than those females who do not. This further demonstrates the impact of media on the likelihood of developing the disorder.[48] Individuals first accept and "buy into" the ideals, and then attempt to transform themselves in order to reflect the societal ideals of attractiveness. J. Kevin Thompson and Eric Stice claim that family, peers, and most evidently media reinforce the thin ideal, which may lead to an individual accepting and "buying into" the thin ideal. In turn, Thompson and Stice assert that if the thin ideal is accepted, one could begin to feel uncomfortable with their body shape or size since it may not necessarily reflect the thin ideal set out by society. Thus, people feeling uncomfortable with their bodies may result in suffering from body dissatisfaction and may develop a certain drive for thinness. Consequently, body dissatisfaction coupled with a drive for thinness is thought to promote dieting and negative effects, which could eventually lead to bulimic symptoms such as purging or bingeing. Binges lead to self-disgust which causes purging to prevent weight gain.[49]

A study dedicated to investigating the thin ideal internalization as a factor of bulimia nervosa is Thompson's and Stice's research. The aim of their study was to investigate how and to what degree does media affect the thin ideal internalization. Thompson and Stice used randomized experiments (more specifically programs) dedicated to teaching young women how to be more critical when it comes to media, in order to reduce thin ideal internalization. The results showed that by creating more awareness of the media's control of the societal ideal of attractiveness, the thin ideal internalization significantly dropped. In other words, less thin ideal images portrayed by the media resulted in less thin ideal internalization. Therefore, Thompson and Stice concluded that media affected greatly the thin ideal internalization.[50] Papies showed that it is not the thin ideal itself, but rather the self-association with other persons of a certain weight that decide how someone with bulimia nervosa feels. People that associate themselves with thin models get in a positive attitude when they see thin models and people that associate with overweight get in a negative attitude when they see thin models. Moreover, it can be taught to associate with thinner people.[51]

## Treatment [edit]

There are two main types of treatment given to those suffering with bulimia nervosa; psychopharmacological and psychosocial treatments.[52]

### Psychotherapy [edit]

There are several supported psychosocial treatments for bulimia. Cognitive behavioral therapy (CBT), which involves teaching a person to challenge automatic thoughts and engage in behavioral experiments (for example, in session eating of "forbidden foods") has a small amount of evidence supporting its use.[53]

By using CBT people record how much food they eat and periods of vomiting with the purpose of

identifying and avoiding emotional fluctuations that bring on episodes of bulimia on a regular basis.[54] Barker (2003) states that research has found 40–60% of people using cognitive behaviour therapy to become symptom free. He states in order for the therapy to work, all parties must work together to discuss, record and develop coping strategies. Barker (2003) claims by making people aware of their actions they will think of alternatives.[55][56] People undergoing CBT who exhibit early behavioral changes are most likely to achieve the best treatment outcomes in the long run.[57] Researchers have also reported some positive outcomes for interpersonal psychotherapy and dialectical behavior therapy.[58][59]

Maudsley family therapy, developed at the Maudsley Hospital in London for the treatment of anorexia has been shown promising results in bulimia.[60]

The use of Cognitive Behavioral Therapy (CBT) has been shown to be quite effective for treating bulimia nervosa (BN) in adults, but little research has been done on effective treatments of BN for adolescents.[61] Although CBT is seen as more cost efficient and helps individuals with BN in self-guided care, Family Based Treatment (FBT) might be more helpful to younger adolescents who need more support and guidance from their families. Adolescents are at the stage where their brains are still quite malleable and developing gradually.[62] Therefore, young adolescents with BN are less likely to realize the detrimental consequences of becoming bulimic and have less motivation to change,[63] which is why FBT would be useful to have families intervene and support the teens.[61] Working with BN patients and their families in FBT can empower the families by having them involved in their adolescent's food choices and behaviors, taking more control of the situation in the beginning and gradually letting the adolescent become more autonomous when they have learned healthier eating habits.[61]

### Medication [edit]

Antidepressants of the selective serotonin reuptake inhibitors (SSRI) class may have a modest benefit.[7] This includes fluoxetine, which is FDA approved, for the treatment of bulimia, other antidepressants such as sertraline may also be effective against bulimia. Topiramate may also be useful but has greater side effects.[7]

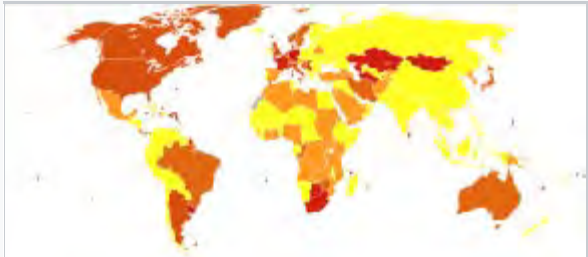
It is not known if combining medication with counseling improve the outcomes. Any trials which originally suggested that such combinations should improve the outcome have not proven to be exceptionally powerful. Some positive outcomes of treatments can include: abstinence from binge eating, a decrease in obsessive behaviors to lose weight and in shape preoccupation, less severe psychiatric symptoms, a desire to counter the effects of binge eating, as well as an improvement in social functioning and reduced relapse rates.[2]

### Alternative medicine [edit]

Some researchers have also claimed positive outcomes in hypnotherapy.[64]

## Epidemiology [edit]

There is little data on the percentage of people with bulimia in general populations. Most studies conducted thus far have been on convenience samples from hospital patients, high school or university students. These have yielded a wide range of results: between 0.1% and 1.4% of males, and between 0.3% and 9.4% of females.[65] Studies on time trends in the prevalence of bulimia nervosa have also yielded inconsistent results.[66] According to Gelder, Mayou and Geddes (2005) bulimia nervosa is prevalent between 1 and 2 percent of women aged 15–40 years. Bulimia nervosa occurs more frequently in developed countries[54] and in cities, with one



Deaths due to eating disorders per million persons in 2012

0-0 2-2 4-25

study finding that bulimia is five times more prevalent in cities than in rural areas.[67] There is a perception that bulimia is most prevalent amongst girls from middle-class families;[68] however, in a 2009 study girls from families in the lowest income bracket studied were 153 percent more likely to be bulimic than girls from the highest income bracket.[69]

There are higher rates of eating disorders in groups involved in activities which idealize a slim physique, such as dance,[70] gymnastics, modeling, cheerleading, running, acting, swimming, diving, rowing and figure skating. Bulimia is thought to be more prevalent among Caucasians;[71] however, a more recent study showed that African-American teenage girls were 50 percent more likely than white girls to exhibit bulimic behavior, including both binging and purging.[72]

| Country | Year | Sample size and type | % affected | |
|---|---|---|---|---|
| Australia | 2008 | 1,943 adolescents (ages 15–17) | 1.0% male | 6.4% female[23] |
| Portugal | 2006 | 2,028 high school students | | 0.3% female[73] |

## History [edit]

### Etymology [edit]

The term *bulimia* comes from Greek βουλιμία *boulīmia*, "ravenous hunger", a compound of βοῦς *bous*, "ox" and λιμός, *līmos*, "hunger".[82] Literally, the scientific name of the disorder, *bulimia nervosa*, translates to "nervous ravenous hunger".

### Before the 20th century [edit]

Although diagnostic criteria for bulimia nervosa did not appear until 1979, evidence suggests that binging and purging were popular in certain ancient cultures. The first documented account of behavior resembling bulimia nervosa was recorded in Xenophon's Anabasis around 370 B.C, in which Greek soldiers purged themselves in the mountains of Asia Minor. It is unclear whether this purging was preceded by binging.[83] In ancient Egypt, physicians recommended purging once a month for three days in order to preserve health.[84] This practice stemmed from the belief that human diseases were caused by the food itself. In ancient Rome, elite society members would vomit in order to "make room" in their stomachs for more food at all day banquets.[84] Emperors Claudius and Vitellius both were gluttonous and obese, and they often resorted to habitual purging.[84]

Historical records also suggest that some saints who developed anorexia (as a result of a life of asceticism)

may also have displayed bulimic behaviors.[84] Saint Mary Magdalen de Pazzi (1566–1607) and Saint Veronica Giuliani (1660–1727) were both observed binge eating—giving in, as they believed, to the temptations of the devil.[84] Saint Catherine of Siena (1347–1380) is known to have supplemented her strict abstinence from food by purging as reparation for her sins. Catherine died from starvation at age thirty-three.[84]

While the psychological disorder "bulimia nervosa" is relatively new, the word "bulimia," signifying overeating, has been present for centuries.[84] The Babylon Talmud referenced practices of "bulimia," yet scholars believe that this simply referred to overeating without the purging or the psychological implications bulimia nervosa.[84] In fact, a search for evidence of bulimia nervosa from the 17th to late 19th century revealed that only a quarter of the overeating cases they examined actually vomited after the binges. There was no evidence of deliberate vomiting or an attempt to control weight.[84]

## 20th century [edit]

At the turn of the century, bulimia (overeating) was described as a clinical symptom, but rarely in the context of weight control.[85] Purging, however, was seen in anorexic patients and attributed to gastric pain rather than another method of weight control.[85]

In 1930, admissions of anorexia nervosa patients to the Mayo Clinic from 1917 to 1929 were compiled. Fifty-five to sixty-five percent of these patients were reported to be voluntarily vomiting in order to relieve weight anxiety.[85] Records show that purging for weight control continued throughout the mid-1900s. Several case studies from this era reveal patients suffering from the modern description of bulimia nervosa.[85] In 1939, Rahman and Richardson reported that out of their six anorexic patients, one had periods of overeating and another practiced self-induced vomiting.[85] Wulff, in 1932, treated "Patient D," who would have periods of intense cravings for food and overeat for weeks, which often resulted in frequent vomiting.[84] Patient D, who grew up with a tyrannical father, was repulsed by her weight and would fast for a few days, rapidly losing weight. Ellen West, a patient described by Ludwig Binswanger in 1958, was teased by friends for being fat and excessively took thyroid pills to lose weight, later using laxatives and vomiting.[84] She reportedly consumed dozens of oranges and several pounds of tomatoes each day, yet would skip meals. After being admitted to a psychiatric facility for depression, Ellen ate ravenously yet lost weight, presumably due to self-induced vomiting.[84] However, while these patients may have met modern criteria for bulimia nervosa, they cannot technically be diagnosed with the disorder, as it had not yet appeared in the Diagnostic and Statistical Manual of Mental Disorders at the time of their treatment.[84]

An explanation for the increased instances of bulimic symptoms may be due to the 20th century's new ideals of thinness.[85] The shame of being fat emerged in the 1940s, when teasing remarks about weight became more common. The 1950s, however, truly introduced the trend of an aspiration for thinness.[85]

In 1979, Gerald Russell first published a description of bulimia nervosa, in which he studied patients with a "morbid fear of becoming fat" who overate and purged afterwards.[9] He specified treatment options and indicated the seriousness of the disease, which can be accompanied by depression and suicide.[9] In 1980, bulimia nervosa first appeared in the DSM-III.[9]

After its appearance in the DSM-III, there was a sudden rise in the documented incidences of bulimia nervosa.[84] In the early 1980s, incidences of the disorder rose to about 40 in every 100,000 people.[84] This decreased to about 27 in every 100,000 people at the end of the 1980s/early 1990s.[84] However, bulimia nervosa's prevalence was still much higher than anorexia nervosa's, which at the time occurred in about 14 people per 100,000.[84]

In 1991, Kendler et al. documented the cumulative risk for bulimia nervosa for those born before 1950, from 1950 to 1959, and after 1959.[86] The risk for those born after 1959 is much higher than those in either of the other cohorts.[86]

# Eating disorder

From Wikipedia, the free encyclopedia

**Eating disorders** are mental disorders defined by abnormal eating habits that negatively affect a person's physical or mental health. They include binge eating disorder where people eat a large amount in a short period of time, anorexia nervosa where people eat very little and thus have a low body weight, bulimia nervosa where people eat a lot and then try to rid themselves of the food, pica where people eat non-food items, rumination disorder where people regurgitate food, avoidant/restrictive food intake disorder where people have a lack of interest in food, and a group of other specified feeding or eating disorders. Anxiety disorders, depression, and substance abuse are common among people with eating disorders.[1] These disorders do not include obesity.[2]

[edit on Wikidata]

The cause of eating disorders is not clear.[3] Both biological and environmental factors appear to play a role.[1][3] Cultural idealization of thinness is believed to contribute.[3] Eating disorders affect about 12 percent of dancers.[4] Those who have experienced sexual abuse are also more likely to develop eating disorders.[5] Some disorders such as pica and rumination disorder occur more often in people with intellectual disabilities. Only one eating disorder can be diagnosed at a given time.[2]

Treatment can be effective for many eating disorders. This typically involves counselling, a proper diet, a normal amount of exercise, and the reduction of efforts to eliminate food. Hospitalization is occasionally needed. Medications may be used to help with some of the associated symptoms.[1] At five years about 70% of people with anorexia and 50% of people with bulimia recover. Recovery from binge eating disorder is less clear and estimated at 20% to 60%. Both anorexia and bulimia increase the risk of death.[6]

In the developed world binge eating disorder affects about 1.6% of women and 0.8% of men in a given year. Anorexia affects about 0.4% and bulimia affects about 1.3% of young women in a given year.[2] During the entire life up to 4% of women have anorexia, 2% have bulimia, and 2% have binge eating disorder.[6] Anorexia and bulimia occur nearly ten times more often in females than males.[2] Typically they begin in late childhood or early adulthood.[1] Rates of other eating disorders are not clear.[2] Rates of eating disorders appear to be lower in less developed countries.[7]

Contents

## Classification [edit]

Bulimia nervosa is a disorder characterized by binge eating and purging, as well as excessive evaluation of one's self-worth in terms of body weight or shape.[8] Purging can include self-induced vomiting, over-exercising, and the use of diuretics, enemas, and laxatives. Anorexia nervosa is characterized by extreme food restriction and excessive weight loss, accompanied by the fear of being fat.[9] The extreme weight loss often causes women and girls who have begun menstruating to stop having menstrual periods, a condition known as amenorrhea. Although amenorrhea was once a required criterion for the disorder, it is no longer required to meet criteria for anorexia nervosa due to its exclusive nature for sufferers who are male, post-menopause, or who do not menstruate for other reasons.[10] The DSM-5 specifies two subtypes of anorexia nervosa—the restricting type and the binge/purge type. Those who suffer from the restricting type of anorexia nervosa restrict food intake and do not engage in binge eating, whereas those suffering from the binge/purge type lose control over their eating at least occasionally and may compensate for these binge episodes.[11] The most notable difference between anorexia nervosa binge/purge type and bulimia nervosa is the body weight of the person. Those diagnosed with anorexia nervosa binge/purge type are underweight, while those with bulimia nervosa may have a body weight that falls within the range from normal to obese.[12][13]

### ICD and DSM [edit]

These eating disorders are specified as mental disorders in standard medical manuals, such as in the ICD-10,[14] the DSM-5, or both.

- Anorexia nervosa (AN), characterized by lack of maintenance of a healthy body weight, an obsessive fear of gaining weight or refusal to do so, and an unrealistic perception, or non-recognition of the seriousness, of current low body weight.[15] Anorexia can cause menstruation to stop, and often leads to bone loss, loss of skin integrity, etc. It greatly stresses the heart, increasing the risk of heart attacks and related heart problems. The risk of death is greatly increased in individuals with this disease.[16] The most underlining factor researchers are starting to take notice of is that it may not just be a vanity, social, or media issue, but it could also be related to biological and or genetic components.[17] The DSM-5 contains many changes that better represent patients with these conditions. The DSM-IV required amenorrhea (the absence of the menstrual cycle) to be present in order to diagnose a patient with anorexia.[18] This is no longer a requirement in the DSM-5.
- Bulimia nervosa (BN), characterized by recurrent binge eating followed by compensatory behaviors such as purging (self-induced vomiting, eating to the point of vomiting, excessive use of laxatives/diuretics, or excessive exercise). Fasting and over-exercising may also be used as a method of purging following a binge.
- Muscle dysmorphia is characterized by appearance preoccupation that one's own body is too small, too skinny, insufficiently muscular, or insufficiently lean. Muscle dysmorphia affects mostly males.

- Binge Eating Disorder (BED), characterized by recurring binge eating at least once a week for over a period of 3 months while experiencing lack of control[18] and guilt after overeating.[19] The disorder can develop within individuals of a wide range of ages and socioeconomic classes.[20][21]
- Other Specified Feeding or Eating Disorder (OSFED) is an eating or feeding disorder that does not meet full DSM-5 criteria for AN, BN, or BED. Examples of otherwise-specified eating disorders include individuals with atypical anorexia nervosa, who meet all criteria for AN except being underweight, despite substantial weight loss; atypical bulimia nervosa, who meet all criteria for BN except that bulimic behaviors are less frequent or have not been ongoing for long enough; purging disorder; and night eating syndrome.

### Other [edit]

- Compulsive overeating (COE), in which individuals habitually graze on large quantities of food rather than binging, as would be typical of binge eating disorder.
- Prader-Willi syndrome
- Diabulimia, characterized by the deliberate manipulation of insulin levels by diabetics in an effort to control their weight.
- Food maintenance, characterized by a set of aberrant eating behaviors of children in foster care.[22]
- Orthorexia nervosa, a term used by Steven Bratman to characterize an obsession with a "pure" diet, in which people develop an obsession with avoiding unhealthy foods to the point where it interferes with a person's life.[23]
- Selective eating disorder, also called picky eating, is an extreme sensitivity to how something tastes. A person with SED may or may not be a supertaster.
- Drunkorexia, commonly characterized by purposely restricting food intake in order to reserve food calories for alcoholic calories, exercising excessively in order to burn calories consumed from drinking, and over-drinking alcohols in order to purge previously consumed food.[24]
- Pregorexia, characterized by extreme dieting and over-exercising in order to control pregnancy weight gain. Undernutrition during pregnancy is associated with low birth weight, coronary heart disease, type 2 diabetes, stroke, hypertension, cardiovascular disease risk, and depression.[25]
- Gourmand syndrome, a rare condition occurring after damage to the frontal lobe, resulting in an obsessive focus on fine foods.[26]

## Signs and symptoms [edit]

Symptoms and complications vary according to the nature and severity of the eating disorder:[27]

**Possible Symptoms and Complications of Eating Disorders**

| | | | |
|---|---|---|---|
| acne | xerosis | amenorrhoea | tooth loss, cavities |
| constipation | diarrhea | water retention and/or edema | lanugo |
| telogen effluvium | cardiac arrest | hypokalemia | death |
| osteoporosis[28] | electrolyte imbalance | hyponatremia | brain atrophy[29][30] |
| pellagra[31] | scurvy | kidney failure | suicide[32][33][34] |

Some physical symptoms of eating disorders are weakness, fatigue, sensitivity to cold, reduced beard growth in men, reduction in waking erections, reduced libido, weight loss and failure of growth.[35] Unexplained hoarseness may be a symptom of an underlying eating disorder, as the result of acid reflux, or entry of acidic gastric material into the laryngoesophageal tract. Patients who induce vomiting, such as those with anorexia nervosa, binge eating-purging type or those with purging-type bulimia nervosa are at risk for acid reflux.[36] Polycystic ovary syndrome (PCOS) is the most common endocrine disorder to affect women. Though often associated with obesity it can occur in normal weight individuals. PCOS has been associated with binge eating and bulimic behavior.[37][38][39][40][41][42]

### Pro-Ana subculture [edit]

Several websites promote eating disorders, and can provide a means for individuals to communicate in order to maintain eating disorders. Members of these websites typically feel that their eating disorder is the only aspect of a chaotic life that they can control.[43] These websites are often interactive and have discussion boards where individuals can share strategies, ideas, and experiences, such as diet and exercise plans that achieve extremely low weights.[44] A study comparing the personal web-blogs that were pro-eating disorder with those focused on recovery found that the pro-eating disorder blogs contained language reflecting lower cognitive processing, used a more closed-minded writing style, contained less emotional expression and fewer social references, and focused more on eating-related contents than did the recovery blogs.[45]

### Psychopathology [edit]

The psychopathology of eating disorders centers around body image disturbance, such as concerns with weight and shape; self-worth being too dependent on weight and shape; fear of gaining weight even when underweight; denial of how severe the symptoms are and a distortion in the way the body is experienced.[35]

## Causes [edit]

The cause of eating disorder is not clear.

Many people with eating disorders suffer also from body dysmorphic disorder, altering the way a person sees themself.[46][47] Studies have found that a high proportion of individuals diagnosed with body dysmorphic disorder also had some type of eating disorder, with 15% of individuals having either anorexia nervosa or bulimia nervosa.[46] This link between body dysmorphic disorder and anorexia stems from the fact that both BDD and anorexia nervosa are characterized by a preoccupation with physical appearance and a distortion of body image.[47] There are also many other possibilities such as environmental, social and interpersonal issues that could promote and sustain these illnesses.}[48] Also, the media are oftentimes blamed for the rise in the incidence of eating disorders due to the fact that media images of idealized slim physical shape of people such as models and celebrities motivate or even force people to attempt to achieve slimness themselves. The media are accused of distorting reality, in the sense that people portrayed in the media are either naturally thin and thus unrepresentative of normality or unnaturally thin by forcing their bodies to look like the ideal image by putting excessive pressure on themselves to look a certain way. While past findings have described the causes of eating disorders as primarily psychological, environmental, and sociocultural, new studies have uncovered evidence that there is a prevalent genetic/heritable aspect of the causes of eating disorders.[49]

### Genetics [edit]

- Genetic: Numerous studies have been undertaken that show a possible genetic predisposition toward eating disorders as a result of Mendelian inheritance.[50][50][51] It has also been shown that eating disorders can be heritable. Recent twin studies have found slight instances of genetic variance when considering the different criterion of both anorexia nervosa and bulimia nervosa as endophenotypes contributing to the disorders as a whole.[48] In another recent study, twin and family studies led researchers to discover a genetic link on chromosome 1 that can be found in multiple family members of an individual with anorexia nervosa, indicating an inheritance pattern found between family members of others that have been previously diagnosed with an eating disorder.[49] A study found that an individual who is a first degree relative of someone who has suffered or currently suffers from an eating disorder is seven to twelve times more likely to suffer from an eating disorder themselves.[52] Twin studies also have shown that at least a portion of the vulnerability to develop eating disorders can be inherited, and there has been sufficient evidence to show that there is a genetic locus that shows susceptibility for developing anorexia nervosa.[52]

- Epigenetics: Epigenetic mechanisms are means by which environmental effects alter gene expression via methods such as DNA methylation; these are independent of and do not alter the underlying DNA sequence. They are heritable, but also may occur throughout the lifespan, and are potentially reversible. Dysregulation of dopaminergic neurotransmission due to epigenetic mechanisms has been implicated in various eating disorders.[53][54] One study has found that "epigenetic mechanisms may contribute to the known alterations of ANP homeostasis in women with eating disorders."[53][55] Other candidate genes for epigenetic studies in eating disorders include leptin, pro-opiomelanocortin (POMC) and brain-derived neurotrophic factor (BDNF).[56]

## Psychological [edit]

Eating disorders are classified as Axis I[57] disorders in the Diagnostic and Statistical Manual of Mental Health Disorders (DSM-IV) published by the American Psychiatric Association. There are various other psychological issues that may factor into eating disorders, some fulfill the criteria for a separate Axis I diagnosis or a personality disorder which is coded Axis II and thus are considered comorbid to the diagnosed eating disorder. Axis II disorders are subtyped into 3 "clusters": A, B and C. The causality between personality disorders and eating disorders has yet to be fully established.[58] Some people have a previous disorder which may increase their vulnerability to developing an eating disorder.[59][60][61] Some develop them afterwards.[62] The severity and type of eating disorder symptoms have been shown to affect comorbidity.[63] The DSM-IV should not be used by laypersons to diagnose themselves, even when used by professionals there has been considerable controversy over the diagnostic criteria used for various diagnoses, including eating disorders. There has been controversy over various editions of the DSM including the latest edition, DSM-V, due in May 2013.[64][65][66][67][68]

## Cognitive attentional bias issues [edit]

Attentional bias may have an effect on eating disorders. Many studies have been performed to test this theory.

**Comorbid Disorders**

| Axis I | Axis II |
|---|---|
| depression[69] | obsessive compulsive personality disorder[70] |
| substance abuse, alcoholism[71] | borderline personality disorder[72] |
| anxiety disorders[73] | narcissistic personality disorder[74] |
| obsessive compulsive disorder[75][76] | histrionic personality disorder[77] |
| Attention-deficit hyperactivity disorder[78][79][80][81] | avoidant personality disorder[82] |

## Personality traits [edit]

There are various childhood personality traits associated with the development of eating disorders.[83] During adolescence these traits may become intensified due to a variety of physiological and cultural influences such as the hormonal changes associated with puberty, stress related to the approaching demands of maturity and socio-cultural influences and perceived expectations, especially in areas that concern body image. Eating disorders have been associated with a fragile sense of self and with disordered mentalization.[84] Many personality traits have a genetic component and are highly heritable. Maladaptive levels of certain traits may be acquired as a result of anoxic or traumatic brain injury, neurodegenerative diseases such as Parkinson's disease, neurotoxicity such as lead exposure, bacterial infection such as Lyme disease or viral infection such as Toxoplasma gondii as well as hormonal influences. While studies are still continuing via the use of various imaging techniques such as fMRI; these traits have been shown to originate in various regions of the brain[85] such as the amygdala[86][87] and the prefrontal cortex.[88] Disorders in the prefrontal cortex and the executive functioning system have been shown to affect eating [89][90]

behavior.

## Celiac disease [edit]

People with gastrointestinal disorders may be more risk of developing disordered eating practices than the general population, principally restrictive eating disturbances.[91] An association of anorexia nervosa with celiac disease has been found.[92] The role that gastrointestinal symptoms play in the development of eating disorders seems rather complex. Some authors report that unresolved symptoms prior to gastrointestinal disease diagnosis may create a food aversion in these persons, causing alterations to their eating patterns. Other authors report that greater symptoms throughout their diagnosis led to greater risk. It has been documented that some people with celiac disease, irritable bowel syndrome or inflammatory bowel disease who are not conscious about the importance of strictly following their diet, choose to consume their trigger foods to promote weight loss. On the other hand, individuals with good dietary management may develop anxiety, food aversion and eating disorders because of concerns around cross contamination of their foods.[91] Some authors suggest that medical professionals should evaluate the presence of an unrecognized celiac disease in all people with eating disorder, especially if they present any gastrointestinal symptom (such as decreased appetite, abdominal pain, bloating, distension, vomiting, diarrhea or constipation), weight loss, or growth failure; and also routinely ask celiac patients about weight or body shape concerns, dieting or vomiting for weight control, to evaluate the possible presence of eating disorders,[92] specially in women.[93]

## Environmental influences [edit]

## Child maltreatment [edit]

Child abuse which encompasses physical, psychological and sexual abuse, as well as neglect has been shown to approximately triple the risk of an eating disorder.[94] Sexual abuse appears to about double the risk of bulimia; however, the association is less clear for anorexia.[94]

## Social isolation [edit]

Social isolation has been shown to have a deleterious effect on an individual's physical and emotional well-being. Those that are socially isolated have a higher mortality rate in general as compared to individuals that have established social relationships. This effect on mortality is markedly increased in those with pre-existing medical or psychiatric conditions, and has been especially noted in cases of coronary heart disease. "The magnitude of risk associated with social isolation is comparable with that of cigarette smoking and other major biomedical and psychosocial risk factors." (Brummett *et al.*)

Social isolation can be inherently stressful, depressing and anxiety-provoking. In an attempt to ameliorate these distressful feelings an individual may engage in emotional eating in which food serves as a source of comfort. The loneliness of social isolation and the inherent stressors thus associated have been implicated as triggering factors in binge eating as well.[95][96][97][98]

Waller, Kennerley and Ohanian (2007) argued that both bingeing–vomiting and restriction are emotion suppression strategies, but they are just utilized at different times. For example, restriction is used to pre-empt any emotion activation, while bingeing–vomiting is used after an emotion has been activated.[99]

## Parental influence [edit]

Parental influence has been shown to be an intrinsic component in the development of eating behaviors of children. This influence is manifested and shaped by a variety of diverse factors such as familial genetic predisposition, dietary choices as dictated by cultural or ethnic preferences, the parents' own body shape and eating patterns, the degree of involvement and expectations of their children's eating behavior as well as the interpersonal relationship of parent and child. This is in addition to the general psychosocial climate of the home and the presence or absence of a nurturing stable environment. It has been shown that maladaptive parental behavior has an important role in the development of eating disorders. As to the more

subtle aspects of parental influence, it has been shown that eating patterns are established in early childhood and that children should be allowed to decide when their appetite is satisfied as early as the age of two. A direct link has been shown between obesity and parental pressure to eat more.

Coercive tactics in regard to diet have not been proven to be efficacious in controlling a child's eating behavior. Affection and attention have been shown to affect the degree of a child's finickiness and their acceptance of a more varied diet.[100][101][102][103][104][105]

Hilde Bruch, a pioneer in the field of studying eating disorders, asserts that anorexia nervosa often occurs in girls who are high achievers, obedient, and always trying to please their parents. Their parents have a tendency to be over-controlling and fail to encourage the expression of emotions, inhibiting daughters from accepting their own feelings and desires. Adolescent females in these overbearing families lack the ability to be independent from their families, yet realize the need to, often resulting in rebellion. Controlling their food intake may make them feel better, as it provides them with a sense of control.[106]

## Peer pressure [edit]

In various studies such as one conducted by The McKnight Investigators, peer pressure was shown to be a significant contributor to body image concerns and attitudes toward eating among subjects in their teens and early twenties.

Eleanor Mackey and co-author, Annette M. La Greca of the University of Miami, studied 236 teen girls from public high schools in southeast Florida. "Teen girls' concerns about their own weight, about how they appear to others and their perceptions that their peers want them to be thin are significantly related to weight-control behavior", says psychologist Eleanor Mackey of the Children's National Medical Center in Washington and lead author of the study. "Those are really important."

According to one study, 40% of 9- and 10-year-old girls are already trying to lose weight.[107] Such dieting is reported to be influenced by peer behavior, with many of those individuals on a diet reporting that their friends also were dieting. The number of friends dieting and the number of friends who pressured them to diet also played a significant role in their own choices.[108][109][110][111]

Elite athletes have a significantly higher rate in eating disorders. Female athletes in sports such as gymnastics, ballet, diving, etc. are found to be at the highest risk among all athletes. Women are more likely than men to acquire an eating disorder between the ages of 13–30. 0–15% of those with bulimia and anorexia are men.[112]

## Cultural pressure [edit]

There is a cultural emphasis on thinness which is especially pervasive in western society. There is an unrealistic stereotype of what constitutes beauty and the ideal body type as portrayed by the media, fashion and entertainment industries. "The cultural pressure on men and women to be 'perfect' is an important predisposing factor for the development of eating disorders".[113][114] Further, when women of all races base their evaluation of their self upon what is considered the culturally ideal body, the incidence of eating disorders increases.[115] Eating disorders are becoming more prevalent in non-Western countries where thinness is not seen as the ideal, showing that social and cultural pressures are not the only causes of eating disorders.[116] For example, observations of anorexia in all of the non-Western regions of the world point to the disorder not being "culture-bound" as once thought.[117] However, studies on rates of bulimia suggest that it might be culturally bound. In non-Western countries, bulimia is less prevalent than anorexia, but these non-Western countries where it is observed can be said to have probably or definitely been influenced or exposed to Western culture and ideology.[118]

Socioeconomic status (SES) has been viewed as a risk factor for eating disorders, presuming that possessing more resources allows for an individual to actively choose to diet and reduce body weight.[119] Some studies have also shown a relationship between increasing body dissatisfaction with increasing SES.[120] However, once high socioeconomic status has been achieved, this relationship weakens and, in some cases, no longer exists.[117]

The media plays a major role in the way in which people view themselves. Countless magazine ads and commercials depict thin celebrities like Lindsay Lohan, Nicole Richie, Victoria Beckham and Mary Kate Olsen, who appear to gain nothing but attention from their looks. Society has taught people that being accepted by others is necessary at all costs.[121] Unfortunately this has led to the belief that in order to fit in one must look a certain way. Televised beauty competitions such as the Miss America Competition contribute to the idea of what it means to be beautiful because competitors are evaluated on the basis of their opinion.[122]

In addition to socioeconomic status being considered a cultural risk factor so is the world of sports. Athletes and eating disorders tend to go hand in hand, especially the sports where weight is a competitive factor. Gymnastics, horse back riding, wrestling, body building, and dancing are just a few that fall into this category of weight dependent sports. Eating disorders among individuals that participate in competitive activities, especially women, often lead to having physical and biological changes related to their weight that often mimic prepubescent stages. Oftentimes as women's bodies change they lose their competitive edge which leads them to taking extreme measures to maintain their younger body shape. Men often struggle with binge eating followed by excessive exercise while focusing on building muscle rather than losing fat, but this goal of gaining muscle is just as much an eating disorder as obsessing over thinness. The following statistics taken from Susan Nolen-Hoeksema's book, *(ab)normal psychology*, shows the estimated percentage of athletes that struggle with eating disorders based on the category of sport.

- Aesthetic sports (dance, figure skating, gymnastics) – 35%
- Weight dependent sports (judo, wrestling) – 29%
- Endurance sports (cycling, swimming, running) – 20%
- Technical sports (golf, high jumping) – 14%
- Ball game sports (volleyball, soccer) – 12%

Although most of these athletes develop eating disorders to keep their competitive edge, others use exercise as a way to maintain their weight and figure. This is just as serious as regulating food intake for competition. Even though there is mixed evidence showing at what point athletes are challenged with eating disorders, studies show that regardless of competition level all athletes are at higher risk for developing eating disorders that non-athletes, especially those that participate in sports where thinness is a factor.[123]

Pressure from society is also seen within the homosexual community. Homosexual men are at greater risk of eating disorder symptoms than heterosexual men.[124] Within the gay culture, muscularity gives the advantages of both social and sexual desirability and also power.[125] These pressures and ideas that another homosexual male may desire a mate who is thinner or muscular can possibly lead to eating disorders. The higher eating disorder symptom score reported, the more concern about how others perceive them and the more frequent and excessive exercise sessions occur.[125] High levels of body dissatisfaction are also linked to external motivation to working out and old age; however, having a thin and muscular body occurs within younger homosexual males than older.[124][125]

It is important to realize some of the limitations and challenges of many studies that try to examine the roles of culture, ethnicity, and SES. For starters, most of the cross-cultural studies use definitions from the DSM-IV-TR, which has been criticized as reflecting a Western cultural bias. Thus, assessments and questionnaires may not be constructed to detect some of the cultural differences associated with different disorders. Also, when looking at individuals in areas potentially influenced by Western culture, few studies have attempted to measure how much an individual has adopted the mainstream culture or retained the traditional cultural values of the area. Lastly, the majority of the cross-cultural studies on eating disorders and body image disturbances occurred in Western nations and not in the countries or regions being examined.[126]

While there are many influences to how an individual processes their body image, the media does play a major role. Along with the media, parental influence, peer influence, and self-efficacy beliefs also play a large role in an individual's view of themselves. The way the media presents images can have a lasting effect on an individual's perception of their body image. Eating disorders are a worldwide issue and while women are more likely to be affected by an eating disorder it still affects both genders (Schwitzer 2012). The media influences eating disorders whether shown in a positive or negative light, it then has a

responsibility to use caution when promoting images that projects an ideal that many turn to eating disorders to attain.[127]

To try to address unhealthy body image in the fashion world, in 2015, France passed a law requiring models to be declared healthy by a doctor to participate in fashion shows. It also requires re-touched images to be marked as such in magazines.[128]

There is a relationship between "thin ideal" social media content and body dissatisfaction and eating disorders among young adult women, especially in the Western hemisphere.[129] New research points to an "internalization" of distorted images online, as well as negative comparisons among young adult women.[130] Most studies have been based in the U.S, the U.K, and Australia, these are places where the thin ideal is strong among women, as well as the strive for the "perfect" body.[130]

In addition to mere media exposure, there is an online "pro-eating disorder" community. Through personal blogs and Twitter, this community promotes eating disorders as a "lifestyle", and continuously posts pictures of emaciated bodies, and tips on how to stay thin. The hashtag "#proana" (pro-anorexia), is a product of this community,[131] as well as images promoting weight loss, tagged with the term "thinspiration". According to social comparison theory, young women have a tendency to compare their appearance to others, which can result in a negative view of their own bodies and altering of eating behaviors, that in turn can develop disordered eating behaviors.[132]

When body parts are isolated and displayed in the media as objects to be looked at, it is called objectification, and women are affected most by this phenomenon. Objectification increases self-objectification, where women judge their own body parts as a mean of praise and pleasure for others. There is a significant link between self-objectification, body dissatisfaction, and disordered eating, as the beauty ideal is altered through social media.[129]

## Mechanisms [edit]

- Biochemical: Eating behavior is a complex process controlled by the neuroendocrine system, of which the Hypothalamus-pituitary-adrenal-axis (HPA axis) is a major component. Dysregulation of the HPA axis has been associated with eating disorders,[133][134] such as irregularities in the manufacture, amount or transmission of certain neurotransmitters, hormones[135] or neuropeptides[136] and amino acids such as homocysteine, elevated levels of which are found in AN and BN as well as depression.[137]
  - Serotonin: a neurotransmitter involved in depression also has an inhibitory effect on eating behavior.[138][139][140][141][142]
  - Norepinephrine is both a neurotransmitter and a hormone; abnormalities in either capacity may affect eating behavior.[143][144]
  - Dopamine: which in addition to being a precursor of norepinephrine and epinephrine is also a neurotransmitter which regulates the rewarding property of food.[145][146]
  - Neuropeptide Y also known as NPY is a hormone that encourages eating and decreases metabolic rate.[147] Blood levels of NPY are elevated in patients with anorexia nervosa, and studies have shown that injection of this hormone into the brain of rats with restricted food intake increases their time spent running on a wheel. Normally the hormone stimulates eating in healthy patients, but under conditions of starvation it increases their activity rate, probably to increase the chance of finding food.[147] The increased levels of NPY in the blood of patients with eating disorders can in some ways explain the instances of extreme over-exercising found in most anorexia nervosa patients.
- Leptin and ghrelin: leptin is a hormone produced primarily by the fat cells in the body; it has an inhibitory effect on appetite by inducing a feeling of satiety. Ghrelin is an appetite inducing hormone produced in the stomach and the upper portion of the small intestine. Circulating levels of both hormones are an important factor in weight control. While often associated with obesity, both hormones and their respective effects have been implicated in the pathophysiology of anorexia nervosa and bulimia nervosa.[148] Leptin can also be used to distinguish between constitutional thinness found in a [48][149]

healthy person with a low BMI and an individual with anorexia nervosa.
- Gut bacteria and immune system: studies have shown that a majority of patients with anorexia and bulimia nervosa have elevated levels of autoantibodies that affect hormones and neuropeptides that regulate appetite control and the stress response. There may be a direct correlation between autoantibody levels and associated psychological traits.[150][151] Later study revealed that autoantibodies reactive with alpha-MSH are, in fact, generated against ClpB, a protein produced by certain gut bacteria e.g. Escherichia coli. ClpB protein was identified as a conformational antigen-mimetic of alpha-MSH. In patients with eating disorders plasma levels of anti-ClpB IgG and IgM correalated with patients' psychological traits[152]
- Infection: PANDAS, is an abbreviation for Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections. Children with PANDAS "have obsessive-compulsive disorder (OCD) and/or tic disorders such as Tourette syndrome, and in whom symptoms worsen following infections such as "strep throat" and scarlet fever". (NIMH) There is a possibility that PANDAS may be a precipitating factor in the development of anorexia nervosa in some cases, (PANDAS AN).[153]
- Lesions: studies have shown that lesions to the right frontal lobe or temporal lobe can cause the pathological symptoms of an eating disorder.[154][155][156]
- Tumors: tumors in various regions of the brain have been implicated in the development of abnormal eating patterns.[157][158][159][160][161]
- Brain calcification: a study highlights a case in which prior calcification of the right thalumus may have contributed to development of anorexia nervosa.[162]
- somatosensory homunculus: is the representation of the body located in the somatosensory cortex, first described by renowned neurosurgeon Wilder Penfield. The illustration was originally termed "Penfield's Homunculus", homunculus meaning little man. "In normal development this representation should adapt as the body goes through its pubertal growth spurt. However, in AN it is hypothesized that there is a lack of plasticity in this area, which may result in impairments of sensory processing and distortion of body image". (Bryan Lask, also proposed by VS Ramachandran)
- Obstetric complications: There have been studies done which show maternal smoking, obstetric and perinatal complications such as maternal anemia, very pre-term birth (less than 32 weeks), being born small for gestational age, neonatal cardiac problems, preeclampsia, placental infarction and sustaining a cephalhematoma at birth increase the risk factor for developing either anorexia nervosa or bulimia nervosa. Some of this developmental risk as in the case of placental infarction, maternal anemia and cardiac problems may cause intrauterine hypoxia, umbilical cord occlusion or cord prolapse may cause ischemia, resulting in cerebral injury, the prefrontal cortex in the fetus and neonate is highly susceptible to damage as a result of oxygen deprivation which has been shown to contribute to executive dysfunction, ADHD, and may affect personality traits associated with both eating disorders and comorbid disorders such as impulsivity, mental rigidity and obsessionality. The problem of perinatal brain injury, in terms of the costs to society and to the affected individuals and their families, is extraordinary. (Yafeng Dong, PhD)[163][164][165][166][167][168][169][170][171][172][173]
- Symptom of starvation: Evidence suggests that the symptoms of eating disorders are actually symptoms of the starvation itself, not of a mental disorder. In a study involving thirty-six healthy young men that were subjected to semi-starvation, the men soon began displaying symptoms commonly found in patients with eating disorders.[147][174] In this study, the healthy men ate approximately half of what they had become accustomed to eating and soon began developing symptoms and thought patterns (preoccupation with food and eating, ritualistic eating, impaired cognitive ability, other physiological changes such as decreased body temperature) that are characteristic symptoms of anorexia nervosa.[147] The men used in the study also developed hoarding and obsessive collecting behaviors, even though they had no use for the items, which revealed a possible connection between eating disorders and obsessive compulsive disorder.[147]

## Diagnosis [edit]

The initial diagnosis should be made by a competent medical professional. "The medical history is the most powerful tool for diagnosing eating disorders"(American Family Physician).[175] There are many medical disorders that mimic eating disorders and comorbid psychiatric disorders. All organic causes should be ruled

out prior to a diagnosis of an eating disorder or any other psychiatric disorder. In the past 30 years eating disorders have become increasingly conspicuous and it is uncertain whether the changes in presentation reflect a true increase.[*citation needed*] Anorexia nervosa and bulimia nervosa are the most clearly defined subgroups of a wider range of eating disorders. Many patients present with subthreshold expressions of the two main diagnoses: others with different patterns and symptoms.[176]

## Medical [edit]

The diagnostic workup typically includes complete medical and psychosocial history and follows a rational and formulaic approach to the diagnosis. Neuroimaging using fMRI, MRI, PET and SPECT scans have been used to detect cases in which a lesion, tumor or other organic condition has been either the sole causative or contributory factor in an eating disorder. "Right frontal intracerebral lesions with their close relationship to the limbic system could be causative for eating disorders, we therefore recommend performing a cranial MRI in all patients with suspected eating disorders" (Trummer M *et al.* 2002), "intracranial pathology should also be considered however certain is the diagnosis of early-onset anorexia nervosa. Second, neuroimaging plays an important part in diagnosing early-onset anorexia nervosa, both from a clinical and a research prospective".(O'Brien *et al.* 2001).[156][177]

## Psychological [edit]

**Eating Disorder Specific Psychometric Tests**

| | |
|---|---|
| Eating Attitudes Test[178] | SCOFF questionnaire[179] |
| Body Attitudes Test[180] | Body Attitudes Questionnaire[181] |
| Eating Disorder Inventory[182] | Eating Disorder Examination Interview[183] |

After ruling out organic causes and the initial diagnosis of an eating disorder being made by a medical professional, a trained mental health professional aids in the assessment and treatment of the underlying psychological components of the eating disorder and any comorbid psychological conditions. The clinician conducts a clinical interview and may employ various psychometric tests. Some are general in nature while others were devised specifically for use in the assessment of eating disorders. Some of the general tests that may be used are the Hamilton Depression Rating Scale[184] and the Beck Depression Inventory.[185][186] longitudinal research showed that there is an increase in chance that a young adult female would develop bulimia due to their current psychological pressure and as the person ages and matures, their emotional problems change or are resolved and then the symptoms decline.[187]

## Differential diagnoses [edit]

There are multiple medical conditions which may be misdiagnosed as a primary psychiatric disorder, complicating or delaying treatment. These may have a synergistic effect on conditions which mimic an eating disorder or on a properly diagnosed eating disorder.

- Lyme disease which is known as the "great imitator", as it may present as a variety of psychiatric or neurological disorders including anorexia nervosa.[188][189]
- Gastrointestinal diseases,[91] such as celiac disease, Crohn's disease, peptic ulcer, eosinophilic esophagitis[92] or non-celiac gluten sensitivity,[190] among others. Celiac disease is also known as the "great imitator", because it may involve several organs and cause an extensive variety of non-gastrointestinal symptoms, such as psychiatric and neurological disorders,[191][192][193] including anorexia nervosa.[92]
- Addison's Disease is a disorder of the adrenal cortex which results in decreased hormonal production. Addison's disease, even in subclinical form may mimic many of the symptoms of anorexia nervosa.[194]
- Gastric adenocarcinoma is one of the most common forms of cancer in the world. Complications due to this condition have been misdiagnosed as an eating disorder.[195]
- Hypothyroidism, hyperthyroidism, hypoparathyroidism and hyperparathyroidism may mimic some of the symptoms of, can occur concurrently with, be masked by or exacerbate an eating

disorder.[196][197][198][199][200][201][202][203]

- Toxoplasma seropositivity: even in the absence of symptomatic toxoplasmosis, toxoplasma gondii exposure has been linked to changes in human behavior and psychiatric disorders including those comorbid with eating disorders such as depression. In reported case studies the response to antidepressant treatment improved only after adequate treatment for toxoplasma.[204]
- Neurosyphilis: It is estimated that there may be up to one million cases of untreated syphilis in the US alone. "The disease can present with psychiatric symptoms alone, psychiatric symptoms that can mimic any other psychiatric illness". Many of the manifestations may appear atypical. Up to 1.3% of short term psychiatric admissions may be attributable to neurosyphilis, with a much higher rate in the general psychiatric population. (Ritchie, M Perdigao J,)[205]
- Dysautonomia: a wide variety of autonomic nervous system (ANS) disorders may cause a wide variety of psychiatric symptoms including anxiety, panic attacks and depression. Dysautonomia usually involves failure of sympathetic or parasympathetic components of the ANS system but may also include excessive ANS activity. Dysautonomia can occur in conditions such as diabetes and alcoholism.

Psychological disorders which may be confused with an eating disorder, or be co-morbid with one:

- Emetophobia is an anxiety disorder characterized by an intense fear of vomiting. A person so afflicted may develop rigorous standards of food hygiene, such as not touching food with their hands. They may become socially withdrawn to avoid situations which in their perception may make them vomit. Many who suffer from emetophobia are diagnosed with anorexia or self-starvation. In severe cases of emetophobia they may drastically reduce their food intake.[206][207]
- Phagophobia is an anxiety disorder characterized by a fear of eating, it is usually initiated by an adverse experience while eating such as choking or vomiting. Persons with this disorder may present with complaints of pain while swallowing.[208]
- Body dysmorphic disorder (BDD) is listed as a somatoform disorder that affects up to 2% of the population. BDD is characterized by excessive rumination over an actual or perceived physical flaw. BDD has been diagnosed equally among men and women. While BDD has been misdiagnosed as anorexia nervosa, it also occurs comorbidly in 39% of eating disorder cases. BDD is a chronic and debilitating condition which may lead to social isolation, major depression and suicidal ideation and attempts. Neuroimaging studies to measure response to facial recognition have shown activity predominately in the left hemisphere in the left lateral prefrontal cortex, lateral temporal lobe and left parietal lobe showing hemispheric imbalance in information processing. There is a reported case of the development of BDD in a 21-year-old male following an inflammatory brain process. Neuroimaging showed the presence of a new atrophy in the frontotemporal region.[209][210][211][212]

## Prevention [edit]

Prevention aims to promote a healthy development before the occurrence of eating disorders. It also intends early identification of an eating disorder before it is too late to treat. Children as young as ages 5–7 are aware of the cultural messages regarding body image and dieting. Prevention comes in bringing these issues to the light. The following topics can be discussed with young children (as well as teens and young adults).

- Emotional Bites: a simple way to discuss emotional eating is to ask children about why they might eat besides being hungry. Talk about more effective ways to cope with emotions, emphasizing the value of sharing feelings with a trusted adult.
- Say No to Teasing: another concept is to emphasize that it is wrong to say hurtful things about other people's body sizes.
- Body Talk: emphasize the importance of listening to one's body. That is, eating when you are hungry (not starving) and stopping when you are satisfied (not stuffed). Children intuitively grasp these concepts.
- Fitness Comes in All Sizes: educate children about the genetics of body size and the normal changes occurring in the body. Discuss their fears and hopes about growing bigger. Focus on fitness and a balanced diet.[213]

Internet and modern technologies provide new opportunities for prevention. On-line programs have the

potential to increase the use of prevention programs. The development and practice of prevention programs via on-line sources make it possible to reach a wide range of people at minimal cost.[214] Such an approach can also make prevention programs to be sustainable.

## Treatment [edit]

Treatment varies according to type and severity of eating disorder, and usually more than one treatment option is utilized.[215] There is no well-established treatment for eating disorders, meaning that current views about treatment are based mainly on clinical experience. Family doctors play an important role in early treatment of people with eating disorders by encouraging those who are also reluctant to see a psychiatrist.[216] Treatment can take place in a variety of different settings such as community programs, hospitals, day programs, and groups.[217] That said, some treatment methods are:

- Cognitive behavioral therapy (CBT),[218][219][220] which postulates that an individual's feelings and behaviors are caused by their own thoughts instead of external stimuli such as other people, situations or events; the idea is to change how a person thinks and reacts to a situation even if the situation itself does not change. See Cognitive behavioral treatment of eating disorders.
  - Acceptance and commitment therapy: a type of CBT[221]
  - Cognitive Remediation Therapy (CRT), a set of cognitive drills or compensatory interventions designed to enhance cognitive functioning.[222][223][224][225]
- Dialectical behavior therapy[226]
- Family therapy[227] including "conjoint family therapy" (CFT), "separated family therapy" (SFT) and Maudsley Family Therapy.[228][229]
- Behavioral therapy: focuses on gaining control and changing unwanted behaviors.[230]
- Interpersonal psychotherapy (IPT)[231]
- Cognitive Emotional Behaviour Therapy (CEBT)[232]
- Music Therapy
- Recreation Therapy
- Art therapy[233]
- Nutrition counseling[234] and Medical nutrition therapy[235][236][237]
- Medication: Orlistat is used in obesity treatment. Olanzapine seems to promote weight gain as well as the ability to ameliorate obsessional behaviors concerning weight gain. zinc supplements have been shown to be helpful, and cortisol is also being investigated.[238][239][240][241][242][243]
- Self-help and guided self-help have been shown to be helpful in AN, BN and BED;[220][244][245][246] this includes support groups and self-help groups such as Eating Disorders Anonymous and Overeaters Anonymous.[247][248]
- Psychoanalysis
- Inpatient care

There are few studies on the cost-effectiveness of the various treatments.[249] Treatment can be expensive;[250][251] due to limitations in health care coverage, people hospitalized with anorexia nervosa may be discharged while still underweight, resulting in relapse and rehospitalization.[252]

For children with anorexia, the only well-established treatment is the family treatment-behavior.[253] For other eating disorders in children, however, there is no well-established treatments, though family treatment-behavior has been used in treating bulimia.[253]

## Outcomes [edit]

Outcome estimates are complicated by non-uniform criteria used by various studies, but for anorexia nervosa, bulimia nervosa, and binge eating disorder, there seems to be general agreement that full recovery rates are in the 50% to 85% range, with larger proportions of people experiencing at least partial

remission.[247][254][255][256] The outcomes of eating disorders (ED) vary among the cases. For many, it can be a lifelong struggle or it can be overcome within months. In the United States, twenty million women and ten million men have an eating disorders at least once in their lifetime.[257] The mortality rate for those with anorexia nervosa is 5.4 per 1000 individuals per year. Roughly 1.3 deaths were due to suicide. A person who is or had been in an inpatient setting had a rate of 4.6 deaths per 1000. Of individuals with bulimia nervosa about 2 persons per 1000 persons die per year and among those with EDNOS about 3.3 per 1000 people die per year.[258]

- Miscarriages: Pregnant women with a Binge Eating Disorder have shown to have a greater chance of having a miscarriage compared to pregnant women with any other eating disorders. According to a study done, out of a group of pregnant women being evaluated, 46.7% of the pregnancies ended with a miscarriage in women that were diagnosed with BED, with 23.0% in the control. In the same study, 21.4% of women diagnosed with Bulimia Nervosa had their pregnancies end with miscarriages and only 17.7% of the controls.[259]
- Relapse: An individual who is in remission from BN and EDNOS (Eating Disorder Not Otherwise Specified) is at a high risk of falling back into the habit of self-harming themselves. Factors such as high stress regarding their job, pressures from society, as well as other occurrences that inflict stress on a person, can push a person back to what they feel will ease the pain. A study tracked a group of selected people that were either diagnosed with BN or EDNOS for 60 months. After the 60 months were complete, the researchers recorded whether or not the patients were suffering from a relapse. The results found that the probability of a person previously diagnosed with EDNOS had a 41% chance of relapsing; a person with BN had a 47% chance.[260]
- Attachment insecurity: People who are showing signs of attachment anxiety will most likely have trouble communicating their emotional status as well as having trouble seeking effective social support. Signs that a person has adopted this symptom include not showing recognition to their caregiver or when he/she is feeling pain. In a clinical sample, it is clear that at the pretreatment step of a patient's recovery, more severe eating disorder symptoms directly corresponds to higher attachment anxiety. The more this symptom increases, the more difficult it is to achieve eating disorder reduction prior to treatment.[261]

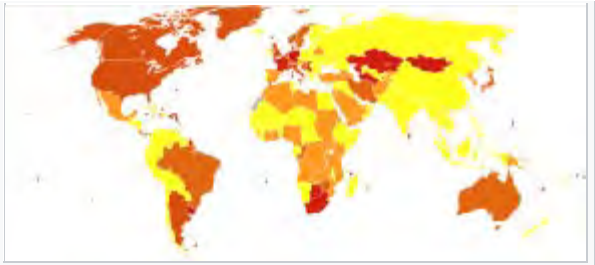
Anorexia Nervosa symptoms include the increasing chance of getting osteoporosis. This disease causes the bones of an individual to become brittle, weak, and low in density. Thinning of the hair as well as dry hair and skin is also very common. The muscles of the heart will also start to change if no treatment is inflicted on the patient. This causes the heart to have an abnormally slow heart rate along with low blood pressure. Heart failure becomes a major consideration when this begins to occur. Muscles throughout the body begin to lose their strength. This will cause the individual to begin feeling faint, drowsy, and weak. Along with these symptoms, the body will begin to grow a layer of hair called lanugo. The human body does this in response to the lack of heat and insulation due to the low percentage of body fat.[257]

Bulimia nervosa symptoms include heart problems like an irregular heartbeat that can lead to heart failure and death may occur. This occurs because of the electrolyte imbalance that is a result of the constant binge and purge process. The probability of a gastric rupture increases. A gastric rupture is when there is a sudden rupture of the stomach lining that can be fatal.The acids that are contained in the vomit can cause a rupture in the esophagus as well as tooth decay. As a result, to laxative abuse, irregular bowel movements may occur along with constipation. Sores along the lining of the stomach called peptic ulcers begin to appear and the chance of developing pancreatitis increases.[257]

Binge eating symptoms include high blood pressure, which can cause heart disease if it is not treated. Many patients recognize an increase in the levels of cholesterol. The chance of being diagnosed with gallbladder disease increases, which affects an individual's digestive tract.[257]

## Epidemiology [edit]

Eating disorders result in about 7,000 deaths a year as of 2010, making them the mental illnesses with the highest mortality rate.[262]



Deaths due to eating disorders per million persons in 2012

0-0 1-1 2-2 3-3 4-25

One study in the United States found a higher rate in college students who are transgender.[263]

## Economics [edit]

- Total costs in USA for hospital stays involving eating disorders rose from $165 million in 1999–2000 to $277 million in 2008–2009; this was a 68% increase. The mean cost per discharge of a person with an eating disorder rose by 29% over the decade, from $7,300 to $9,400.
- Over the decade, hospitalizations involving eating disorders increased among all age groups. The greatest increases occurred among those 45 to 65 years of age (an 88% increase), followed by hospitalizations among people younger than 12 years of age (a 72% increase).
- The majority of eating disorder inpatients were female. During 2008–2009, 88% of cases involved females, and 12% were males. The report also showed a 53% increase in hospitalizations for males with a principal diagnosis of an eating disorder, from 10% to 12% over the decade.[264]

# Major depressive disorder

From Wikipedia, the free encyclopedia

*For other types of depression, see Mood disorder.*

**Major depressive disorder** (**MDD**), also known simply as **depression**, is a mental disorder characterized by at least two weeks of low mood that is present across most situations.[1] It is often accompanied by low self-esteem, loss of interest in normally enjoyable activities, low energy, and pain without a clear cause.[1] People may also occasionally have false beliefs or see or hear things that others cannot.[1] Some people have periods of depression separated by years in which they are normal while others nearly always have symptoms present.[2] Major depressive disorder can negatively affects a person's personal, work, or school life, as well as sleeping, eating habits, and general health.[1][2] Between 2–7% of adults with major depression die by suicide,[3] and up to 60% of people who die by suicide had depression or another mood disorder.[4]

The cause is believed to be a combination of genetic, environmental, and psychological factors.[1] Risk factors include a family history of the condition, major life changes, certain medications, chronic health problems, and substance abuse.[1][2] About 40% of the risk appears to be related to genetics.[2] The diagnosis of major depressive disorder is based on the person's reported experiences and a mental status examination.[5] There is no laboratory test for major depression.[2] Testing, however, may be done to rule out physical conditions that can cause similar symptoms.[5] Major depression should be differentiated from sadness which is a normal part of life and is less severe.[2] The United States Preventive Services Task Force (USPSTF) recommends screening for depression among those over the age 12,[6][7] while a prior Cochrane review found insufficient evidence for screening.[8]

Typically, people are treated with counselling and antidepressant medication.[1] Medication appears to be effective, but the effect may only be significant in the most severely depressed.[9][10] It is unclear whether medications affect the risk of suicide.[11] Types of counselling used include

[edit on Wikidata]

Major depressive disorder affected approximately 253 million (3.6%) of people in 2013.[14] The percentage of people who are affected at one point in their life varies from 7% in Japan to 21% in France.[15] Lifetime rates are higher in the developed world (15%) compared to the developing world (11%).[15] It causes the second most years lived with disability after low back pain.[16] The most common time of onset is in a person in their 20s and 30s. Females are affected about twice as often as males.[2][15] The American Psychiatric Association added "major depressive disorder" to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) in 1980.[17] It was a split of the previous depressive neurosis in the DSM-II which also encompassed the conditions now known as dysthymia and adjustment disorder with depressed mood.[17] Those currently or previously affected may be stigmatized.[18]

Video explanation of depression

# Signs and symptoms

Major depression significantly affects a person's family and personal

relationships, work or school life, sleeping and eating habits, and general health.[19] Its impact on functioning and well-being has been compared to that of other chronic medical conditions such as diabetes.[20]

An 1892 lithograph of a woman diagnosed with depression

A person having a major depressive episode usually exhibits a very low mood, which pervades all aspects of life, and an inability to experience pleasure in activities that were formerly enjoyed. Depressed people may be preoccupied with, or ruminate over, thoughts and feelings of worthlessness, inappropriate guilt or regret, helplessness, hopelessness, and self-hatred.[21] In severe cases, depressed people may have symptoms of psychosis. These symptoms include delusions or, less commonly, hallucinations, usually unpleasant.[22] Other symptoms of depression include poor concentration and memory (especially in those with melancholic or psychotic features),[23] withdrawal from social situations and activities, reduced sex drive, irritability,[24] and thoughts of death or suicide. Insomnia is common among the depressed. In the typical pattern, a person wakes very early and cannot get back to sleep.[25] Hypersomnia, or oversleeping, can also happen.[25] Some antidepressants may also cause insomnia due to their stimulating effect.[26]

A depressed person may report multiple physical symptoms such as fatigue, headaches, or digestive problems; physical complaints are the most common presenting problem in developing countries, according to the World Health Organization's criteria for depression.[27] Appetite often decreases, with resulting weight loss, although increased appetite and weight gain occasionally occur.[21] Family and friends may notice that the person's behavior is either agitated or lethargic.[25] Older depressed people may have cognitive symptoms of recent onset, such as forgetfulness,[23] and a more noticeable slowing of movements.[28] Depression often coexists with physical disorders common among the elderly, such as stroke, other cardiovascular diseases, Parkinson's disease, and chronic obstructive pulmonary disease.[29]

Depressed children may often display an irritable mood rather than a depressed mood,[21] and show varying symptoms depending on age and situation.[30] Most lose interest in school and show a decline in academic performance. They may be described as clingy, demanding, dependent, or insecure.[25] Diagnosis may be delayed or missed when symptoms are interpreted as normal moodiness.[21]

## Associated conditions

Major depression frequently co-occurs with other psychiatric problems. The 1990–92 *National Comorbidity Survey* (US) reports that half of those with major depression also have lifetime anxiety and its associated disorders such as generalized anxiety disorder.[31] Anxiety symptoms can have a major impact on the course of a depressive illness, with delayed recovery, increased risk of relapse, greater disability and increased suicide attempts.[32] There are increased rates of alcohol and drug abuse and particularly dependence,[33] and around a third of individuals diagnosed with ADHD develop comorbid depression.[34] Post-traumatic stress disorder and depression often co-occur.[19] Depression may also coexist with attention deficit hyperactivity disorder (ADHD), complicating the diagnosis and treatment of both.[35]

Depression and pain often co-occur. One or more pain symptoms are present in 65% of depressed patients, and anywhere from 5 to 85% of patients with pain will be suffering from depression, depending on the setting; there is a lower prevalence in general practice, and higher in specialty clinics. The diagnosis of depression is often delayed or missed, and the outcome worsens. The outcome can also worsen if the depression is noticed but completely misunderstood.[36]

Depression is also associated with a 1.5- to 2-fold increased risk of cardiovascular disease, independent of other known risk factors, and is itself linked directly or indirectly to risk factors such as smoking and

obesity. People with major depression are less likely to follow medical recommendations for treating and preventing cardiovascular disorders, which further increases their risk of medical complications.[37] In addition, cardiologists may not recognize underlying depression that complicates a cardiovascular problem under their care.[38]

# Causes

The biopsychosocial model proposes that biological, psychological, and social factors all play a role in causing depression.[2][39] The diathesis–stress model specifies that depression results when a preexisting vulnerability, or diathesis, is activated by stressful life events. The preexisting vulnerability can be either genetic,[40][41] implying an interaction between nature and nurture, or schematic, resulting from views of the world learned in childhood.[42]

## Biological

*Main article: Biology of depression*

## Monoamine hypothesis

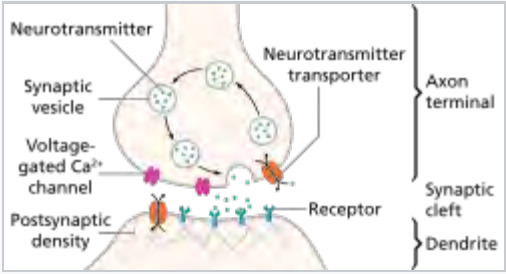

Diagram of a chemical synapse between two neurons. Most antidepressants influence the overall balance of three neurotransmitters: serotonin, norepinephrine, and dopamine. Some antidepressants act on neurotransmitter receptors.

Most antidepressant medications alter the levels of one or more of the monoamines—the neurotransmitters serotonin, norepinephrine and dopamine—in the synaptic cleft between neurons in the brain. Some medications affect the monoamine receptors directly.

Serotonin is hypothesized to regulate other neurotransmitter systems; decreased serotonin activity may allow these systems to act in unusual and erratic ways.[43] According to this "permissive hypothesis", depression arises when low serotonin levels promote low levels of norepinephrine, another monoamine neurotransmitter.[44] Some antidepressants enhance the levels of norepinephrine directly, whereas others raise the levels of dopamine, a third monoamine neurotransmitter. These observations gave rise to the monoamine hypothesis of depression. In its contemporary formulation, the monoamine hypothesis postulates that a deficiency of certain neurotransmitters is responsible for the corresponding features of depression: "Norepinephrine may be related to alertness and energy as well as anxiety, attention, and interest in life; [lack of] serotonin to anxiety, obsessions, and compulsions; and dopamine to attention, motivation, pleasure, and reward, as well as interest in life."[45] The proponents of this theory recommend the choice of an antidepressant with mechanism of action that impacts the most prominent symptoms. Anxious and irritable patients should be treated with SSRIs or norepinephrine reuptake inhibitors, and those experiencing a loss of energy and enjoyment of life with norepinephrine- and dopamine-enhancing drugs.[45]

However, since the 1990s, research has uncovered multiple limitations of the monoamine hypothesis, and its inadequacy has been criticized within the psychiatric community.[46] For one thing, serotonin system dysfunction cannot be the sole cause of depression; antidepressants usually bring serotonin levels up to normal very quickly, but it often takes at least two to four weeks before mood improves significantly. Intensive investigation has failed to find convincing evidence of a primary dysfunction of a specific monoamine system in patients with major depressive disorders. The antidepressants that do not act through the monoamine system, such as tianeptine and opipramol, have been known for a long time. There has also been inconsistency with regards to serum 5-HIAA levels, a metabolite of serotonin.[47] Experiments with pharmacological agents that cause depletion of monoamines have shown that this depletion does not cause depression in healthy people.[48][49] However depletion of tryptophan, tyrosine and phenylalanine does result in decreased mood in those with a predisposition to depression[50] Already limited, the

monoamine hypothesis has been further oversimplified when presented to the general public.[51]

## Drug and alcohol use

*See also: Substance-induced mood disorders*

Very high levels of substance abuse occur in the psychiatric population, especially alcohol, sedatives and cannabis. Depression and other mental health problems can have a substance induced cause; making a differential or dual diagnosis regarding whether mental ill-health is substance related or not or co-occurring is an important part of a psychiatric evaluation.[52] According to the DSM-IV, a diagnosis of mood disorder cannot be made if the cause is believed to be due to "the direct physiological effects of a substance"; when a syndrome resembling major depression is believed to be caused immediately by substance abuse or by an adverse drug reaction, it is referred to as, "substance-induced mood disturbance". Alcoholism or excessive alcohol consumption significantly increases the risk of developing major depression.[53][54] Like alcohol, the benzodiazepines are central nervous system depressants; this class of medication is commonly used to treat insomnia, anxiety, and muscular spasms. Similar to alcohol, benzodiazepines increase the risk of developing major depression. This increased risk of depression may be due in part to the adverse or toxic effects of sedative-hypnotic drugs including alcohol on neurochemistry,[54] such as decreased levels of serotonin and norepinephrine,[55] or activation of immune mediated inflammatory pathways in the brain.[56] Chronic use of benzodiazepines also can cause or worsen depression,[57] or depression may be part of a protracted withdrawal syndrome.[58][59] About a quarter of people recovering from alcoholism experience anxiety and depression, which can persist for up to 2 years.[60] Methamphetamine abuse is also commonly associated with depression.[61]

## Estrogens

The hormone estrogen has been implicated in depressive disorders due to the increase in risk of depressive episodes after puberty, the antenatal period, and reduced rates after menopause.[62] On the converse, the premenstrual and postpartum periods of low estrogen levels are also associated with increased risk.[62] Sudden withdrawal of, fluctuations in or periods of sustained low levels of estrogen have been linked to significant mood lowering. Clinical recovery from depression postpartum, perimenopause, and postmenopause was shown to be effective after levels of estrogen were stabilized or restored.[63][64]

## HPA Axis

There is some evidence that major depression may be caused in part by an overactive hypothalamic-pituitary-adrenal axis (HPA axis) that results in an effect similar to the neuro-endocrine response to stress. Investigations reveal increased levels of the hormone cortisol and enlarged pituitary and adrenal glands, suggesting disturbances of the endocrine system may play a role in some psychiatric disorders, including major depression. Oversecretion of corticotropin-releasing hormone from the hypothalamus is thought to drive this, and is implicated in the cognitive and arousal symptoms.[65]

## Genetics

Reviews and meta-analyses have contradicted one another with regard to genetic associations with depression.[66][67][68]

## Immune

Other research has explored potential roles of molecules necessary for overall cellular functioning: cytokines. The symptoms of major depressive disorder are nearly identical to those of sickness behavior, the response of the body when the immune system is fighting an infection. This raises the possibility that depression can result from a maladaptive manifestation of sickness behavior as a result of abnormalities in circulating cytokines.[69] The involvement of pro-inflammatory cytokines in depression is strongly suggested by a meta-analysis of the clinical literature showing higher blood concentrations of IL-6 and TNF-α in

depressed subjects compared to controls.[70] These immunological abnormalities may cause excessive prostaglandin E production and likely excessive COX-2 expression. Abnormalities in how indoleamine 2,3-dioxygenase enzyme activates as well as the metabolism of tryptophan-kynurenine may lead to excessive metabolism of tryptophan-kynurenine and lead to increased production of the neurotoxin quinolinic acid, contributing to major depression. N-Methyl-D-aspartic acid activation leading to excessive glutamatergic neurotransmission, may also contribute.[71] A number of factors that increase inflammation have been linked to depression including a poor diet, smoking, and obesity.[72]

### Trauma

Depression may be directly caused by damage to the cerebellum as is seen in cerebellar cognitive affective syndrome.[73][74][75]

## Social

Poverty and social isolation are associated with increased risk of mental health problems in general.[76] Child abuse (physical, emotional, sexual, or neglect) is also associated with increased risk of developing depressive disorders later in life.[77] Such a link has good face validity given that it is during the years of development that a child is learning how to become a social being. Abuse of the child by the caregiver is bound to distort the developing personality and create a much greater risk for depression and many other debilitating mental and emotional states. Disturbances in family functioning, such as parental (particularly maternal) depression, severe marital conflict or divorce, death of a parent, or other disturbances in parenting are additional risk factors.[76] In adulthood, stressful life events are strongly associated with the onset of major depressive episodes.[78] In this context, life events connected to social rejection appear to be particularly related to depression.[79][80] Evidence that a first episode of depression is more likely to be immediately preceded by stressful life events than are recurrent ones is consistent with the hypothesis that people may become increasingly sensitized to life stress over successive recurrences of depression.[81][82]

The relationship between stressful life events and social support has been a matter of some debate; the lack of social support may increase the likelihood that life stress will lead to depression, or the absence of social support may constitute a form of strain that leads to depression directly.[83] There is evidence that neighborhood social disorder, for example, due to crime or illicit drugs, is a risk factor, and that a high neighborhood socioeconomic status, with better amenities, is a protective factor.[84] Adverse conditions at work, particularly demanding jobs with little scope for decision-making, are associated with depression, although diversity and confounding factors make it difficult to confirm that the relationship is causal.[85]

Depression can be caused by prejudice. This can occur when people hold negative self-stereotypes about themselves. This "deprejudice" can be related to a group membership (e.g., Me-Gay-Bad) or not (Me-Bad). If someone has prejudicial beliefs about a stigmatized group and then becomes a member of that group, they may internalize their prejudice and develop depression. For example, a boy growing up in the United States may learn the negative stereotype that gay men are immoral. When he grows up and realizes he is gay, he may direct this prejudice inward on himself and become depressed. People may also show prejudice internalization through self-stereotyping because of negative childhood experiences such as verbal and physical abuse.[86]

## Evolutionary

*Main article: Evolutionary approaches to depression*

Depression is maladaptive and difficult to explain using evolutionary psychology; its heterogeneity also makes such explanations difficult. It may be however that some types of MDD may involve "exaggerated or distorted derivatives of human social behaviors which have survived over the eons because they conveyed enhanced survival", such as the behaviors relating to attachment and social rank.[87]

# Diagnosis

## Clinical assessment

*Further information: Rating scales for depression*

A diagnostic assessment may be conducted by a suitably trained general practitioner, or by a psychiatrist or psychologist,[19] who records the person's current circumstances, biographical history, current symptoms, and family history. The broad clinical aim is to formulate the relevant biological, psychological, and social factors that may be impacting on the individual's mood. The assessor may also discuss the person's current ways of regulating mood (healthy or otherwise) such as alcohol and drug use. The assessment also includes a mental state examination, which is an assessment of the person's current mood and thought content, in particular the presence of themes of hopelessness or pessimism, self-harm or suicide, and an absence of positive thoughts or plans.[19] Specialist mental health services are rare in rural areas, and thus diagnosis and management is left largely to primary-care clinicians.[88] This issue is even more marked in developing countries.[89] The mental health examination may include the use of a rating scale such as the Hamilton Rating Scale for Depression[90] or the Beck Depression Inventory[91] or the Suicide Behaviors Questionnaire-Revised.[92] The score on a rating scale alone is insufficient to diagnose depression to the satisfaction of the DSM or ICD, but it provides an indication of the severity of symptoms for a time period, so a person who scores above a given cut-off point can be more thoroughly evaluated for a depressive disorder diagnosis.[93] Several rating scales are used for this purpose.[93]

Primary-care physicians and other non-psychiatrist physicians have more difficulty with underrecognition and undertreatment of depression compared to psychiatric physicians, in part because of the physical symptoms that often accompany depression, in addition to the many potential patient, provider, and system barriers that the authors describe. A review found that non-psychiatrist physicians miss about two-thirds of cases, though this has improved somewhat in more recent studies.[94]

Before diagnosing a major depressive disorder, in general a doctor performs a medical examination and selected investigations to rule out other causes of symptoms. These include blood tests measuring TSH and thyroxine to exclude hypothyroidism; basic electrolytes and serum calcium to rule out a metabolic disturbance; and a full blood count including ESR to rule out a systemic infection or chronic disease.[95] Adverse affective reactions to medications or alcohol misuse are often ruled out, as well. Testosterone levels may be evaluated to diagnose hypogonadism, a cause of depression in men.[96] Vitamin D levels are often checked now, as low levels of vitamin D have been associated with greater risk for depression.[97]

Subjective cognitive complaints appear in older depressed people, but they can also be indicative of the onset of a dementing disorder, such as Alzheimer's disease.[98][99] Cognitive testing and brain imaging can help distinguish depression from dementia.[100] A CT scan can exclude brain pathology in those with psychotic, rapid-onset or otherwise unusual symptoms.[101] In general, investigations are not repeated for a subsequent episode unless there is a medical indication.

No biological tests confirm major depression.[102] Biomarkers of depression have been sought to provide an objective method of diagnosis. There are several potential biomarkers, including Brain-Derived Neurotrophic Factor and various functional MRI techniques. One study developed a decision tree model of interpreting a series of fMRI scans taken during various activities. In their subjects, the authors of that study were able to achieve a sensitivity of 80% and a specificity of 87%, corresponding to a negative predictive value of 98% and a positive predictive value of 32% (positive and negative likelihood ratios were 6.15, 0.23, respectively). However, much more research is needed before these tests could be used clinically.[103]

## DSM-IV-TR and ICD-10 criteria

The most widely used criteria for diagnosing depressive conditions are found in the American Psychiatric Association's revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR), and the World Health Organization's *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), which uses the name *depressive episode* for a single episode and *recurrent depressive disorder* for repeated episodes.[104] The latter system is typically used in European countries,[105]

while the former is used in the US and many other non-European nations, and the authors of both have worked towards conforming one with the other.[106]

Both DSM-IV-TR and ICD-10 mark out typical (main) depressive symptoms.[107] ICD-10 defines three typical depressive symptoms (depressed mood, anhedonia, and reduced energy), two of which should be present to determine depressive disorder diagnosis.[108][109] According to DSM-IV-TR, there are two main depressive symptoms—depressed mood and anhedonia. At least one of these must be present to make a diagnosis of major depressive episode.[110]

Major depressive disorder is classified as a mood disorder in DSM-IV-TR.[111] The diagnosis hinges on the presence of single or recurrent major depressive episodes.[21] Further qualifiers are used to classify both the episode itself and the course of the disorder. The category Depressive Disorder Not Otherwise Specified is diagnosed if the depressive episode's manifestation does not meet the criteria for a major depressive episode. The ICD-10 system does not use the term *major depressive disorder* but lists very similar criteria for the diagnosis of a depressive episode (mild, moderate or severe); the term *recurrent* may be added if there have been multiple episodes without mania.[104]

## Major depressive episode

*Main article: Major depressive episode*

A major depressive episode is characterized by the presence of a severely depressed mood that persists for at least two weeks.[21] Episodes may be isolated or recurrent and are categorized as mild (few symptoms in excess of minimum criteria), moderate, or severe (marked impact on social or occupational functioning). An episode with psychotic features—commonly referred to as *psychotic depression*—is automatically rated as severe. If the patient has had an episode of mania or markedly elevated mood, a diagnosis of bipolar disorder is made instead.[112] Depression without mania is sometimes referred to as *unipolar* because the mood remains at one emotional state or "pole".[113]

DSM-IV-TR excludes cases where the symptoms are a result of bereavement, although it is possible for normal bereavement to evolve into a depressive episode if the mood persists and the characteristic features of a major depressive episode develop.[114] The criteria have been criticized because they do not take into account any other aspects of the personal and social context in which depression can occur.[115] In addition, some studies have found little empirical support for the DSM-IV cut-off criteria, indicating they are a diagnostic convention imposed on a continuum of depressive symptoms of varying severity and duration:[116] Excluded are a range of related diagnoses, including dysthymia, which involves a chronic but milder mood disturbance;[117] recurrent brief depression, consisting of briefer depressive episodes;[118][119] minor depressive disorder, whereby only some symptoms of major depression are present;[120] and adjustment disorder with depressed mood, which denotes low mood resulting from a psychological response to an identifiable event or stressor.[121]

## Subtypes

The DSM-IV-TR recognizes five further subtypes of MDD, called *specifiers*, in addition to noting the length, severity and presence of psychotic features:

- **Melancholic depression** is characterized by a loss of pleasure in most or all activities, a failure of reactivity to pleasurable stimuli, a quality of depressed mood more pronounced than that of grief or loss, a worsening of symptoms in the morning hours, early-morning waking, psychomotor retardation, excessive weight loss (not to be confused with anorexia nervosa), or excessive guilt.[122]
- **Atypical depression** is characterized by mood reactivity (paradoxical anhedonia) and positivity, significant weight gain or increased appetite (comfort eating), excessive sleep or sleepiness (hypersomnia), a sensation of heaviness in limbs known as leaden paralysis, and significant social impairment as a consequence of hypersensitivity to perceived interpersonal rejection.[123]
- **Catatonic depression** is a rare and severe form of major depression involving disturbances of motor behavior and other symptoms. Here, the person is mute and almost stuporous, and either remains

immobile or exhibits purposeless or even bizarre movements. Catatonic symptoms also occur in schizophrenia or in manic episodes, or may be caused by neuroleptic malignant syndrome.[124]

- **Postpartum depression**, or **mental and behavioral disorders associated with the puerperium, not elsewhere classified**,[104] refers to the intense, sustained and sometimes disabling depression experienced by women after giving birth. Postpartum depression has an incidence rate of 10–15% among new mothers. The DSM-IV mandates that, in order to qualify as postpartum depression, onset occur within one month of delivery. It has been said that postpartum depression can last as long as three months.[125]
- **Seasonal affective disorder** (SAD) is a form of depression in which depressive episodes come on in the autumn or winter, and resolve in spring. The diagnosis is made if at least two episodes have occurred in colder months with none at other times, over a two-year period or longer.[126]

## Screening

In 2016 the United States Preventive Services Task Force (USPSTF) recommended screening in the adult populations with evidence that it increases the detection of people with depression and with proper treatment improves outcomes.[6] They recommend screening in those between the age of 12 to 18 as well.[7]

A Cochrane review from 2005 found screening programs do not significantly improve detection rates, treatment, or outcome.[8]

## Differential diagnoses

*Main article: Depression (differential diagnoses)*

To confer major depressive disorder as the most likely diagnosis, other potential diagnoses must be considered, including dysthymia, adjustment disorder with depressed mood, or bipolar disorder. Dysthymia is a chronic, milder mood disturbance in which a person reports a low mood almost daily over a span of at least two years. The symptoms are not as severe as those for major depression, although people with dysthymia are vulnerable to secondary episodes of major depression (sometimes referred to as *double depression*).[117] Adjustment disorder with depressed mood is a mood disturbance appearing as a psychological response to an identifiable event or stressor, in which the resulting emotional or behavioral symptoms are significant but do not meet the criteria for a major depressive episode.[121] Bipolar disorder, also known as *manic–depressive disorder*, is a condition in which depressive phases alternate with periods of mania or hypomania. Although depression is currently categorized as a separate disorder, there is ongoing debate because individuals diagnosed with major depression often experience some hypomanic symptoms, indicating a mood disorder continuum.[127]

Other disorders need to be ruled out before diagnosing major depressive disorder. They include depressions due to physical illness, medications, and substance abuse. Depression due to physical illness is diagnosed as a Mood disorder due to a general medical condition. This condition is determined based on history, laboratory findings, or physical examination. When the depression is caused by a medication, drug of abuse, or exposure to a toxin, it is then diagnosed as a specific mood disorder (previously called *Substance-induced mood disorder* in the DSM-IV-TR).[2]

# Prevention

Preventative efforts may result in decreases in rates of the condition of between 22 and 38%.[128] Eating large amounts of fish may also reduce the risk.[129]

Behavioral interventions, such as interpersonal therapy and cognitive-behavioral therapy, are effective at preventing new onset depression.[128][130][131] Because such interventions appear to be most effective when delivered to individuals or small groups, it has been suggested that they may be able to reach their large target audience most efficiently through the Internet.[132]

However, an earlier meta-analysis found preventive programs with a competence-enhancing component to be superior to behavior-oriented programs overall, and found behavioral programs to be particularly unhelpful for older people, for whom social support programs were uniquely beneficial. In addition, the programs that best prevented depression comprised more than eight sessions, each lasting between 60 and 90 minutes, were provided by a combination of lay and professional workers, had a high-quality research design, reported attrition rates, and had a well-defined intervention.[133]

The Netherlands mental health care system provides preventive interventions, such as the "Coping with Depression" course (CWD) for people with sub-threshold depression. The course is claimed to be the most successful of psychoeducational interventions for the treatment and prevention of depression (both for its adaptability to various populations and its results), with a risk reduction of 38% in major depression and an efficacy as a treatment comparing favorably to other psychotherapies.[130][134]

# Management

*Main article: Management of depression*

The three most common treatments for depression are psychotherapy, medication, and electroconvulsive therapy. Psychotherapy is the treatment of choice (over medication) for people under 18. The UK National Institute for Health and Care Excellence (NICE) 2004 guidelines indicate that antidepressants should not be used for the initial treatment of mild depression, because the risk-benefit ratio is poor. The guidelines recommend that antidepressants treatment in combination with psychosocial interventions should be considered for:

- People with a history of moderate or severe depression
- Those with mild depression that has been present for a long period
- As a second line treatment for mild depression that persists after other interventions
- As a first line treatment for moderate or severe depression.

The guidelines further note that antidepressant treatment should be continued for at least six months to reduce the risk of relapse, and that SSRIs are better tolerated than tricyclic antidepressants.[135]

American Psychiatric Association treatment guidelines recommend that initial treatment should be individually tailored based on factors including severity of symptoms, co-existing disorders, prior treatment experience, and patient preference. Options may include pharmacotherapy, psychotherapy, exercise, electroconvulsive therapy (ECT), transcranial magnetic stimulation (TMS) or light therapy. Antidepressant medication is recommended as an initial treatment choice in people with mild, moderate, or severe major depression, and should be given to all patients with severe depression unless ECT is planned.[136]

Treatment options are much more limited in developing countries, where access to mental health staff, medication, and psychotherapy is often difficult. Development of mental health services is minimal in many countries; depression is viewed as a phenomenon of the developed world despite evidence to the contrary, and not as an inherently life-threatening condition.[137] A 2014 Cochrane review found insufficient evidence to determine the effectiveness of psychological versus medical therapy in children.[138]

## Lifestyle

*Further information: Neurobiological effects of physical exercise § Major depressive disorder*

Physical exercise is recommended for management of mild depression,[139] and has a moderate effect on symptoms.[140] Exercise has also been found to be effective for (unipolar) major depression.[141] It is equivalent to the use of medications or psychological therapies in most people.[140] In the older people it does appear to decrease depression.[142] Exercise may be recommended to people who are willing, motivated, and physically healthy enough to participate in an exercise program as treatment.[141]

There is a small amount of evidence that skipping a night's sleep may improve depressive symptoms, with the effects usually showing up within a day. This effect is usually temporary. Besides sleepiness, this method can cause a side effect of mania or hypomania.[143]

In observational studies smoking cessation has benefits in depression as large as or larger than those of medications.[144]

## Counselling

Psychotherapy can be delivered, to individuals, groups, or families by mental health professionals. A 2015 review found that cognitive behavioral therapy appears to be similar to antidepressant medication in terms of effect.[145] A 2012 review found psychotherapy to be better than no treatment but not other treatments.[146] With more complex and chronic forms of depression, a combination of medication and psychotherapy may be used.[147][148] A 2014 Cochrane review found that work-directed interventions combined with clinical interventions helped to reduce sick days taken by people with depression.[149]

Psychotherapy has been shown to be effective in older people.[150][151] Successful psychotherapy appears to reduce the recurrence of depression even after it has been terminated or replaced by occasional booster sessions.

## Cognitive behavioral therapy

*See also: Behavioral theories of depression*

Cognitive behavioral therapy (CBT) currently has the most research evidence for the treatment of depression in children and adolescents, and CBT and interpersonal psychotherapy (IPT) are preferred therapies for adolescent depression.[152] In people under 18, according to the National Institute for Health and Clinical Excellence, medication should be offered only in conjunction with a psychological therapy, such as CBT, interpersonal therapy, or family therapy.[153] Cognitive behavioral therapy has also been shown to reduce the number of sick days taken by people with depression, when used in conjunction with primary care.[149]

The most-studied form of psychotherapy for depression is CBT, which teaches clients to challenge self-defeating, but enduring ways of thinking (cognitions) and change counter-productive behaviors. Research beginning in the mid-1990s suggested that CBT could perform as well or as better than antidepressants in patients with moderate to severe depression.[154][155] CBT may be effective in depressed adolescents,[156] although its effects on severe episodes are not definitively known.[157] Several variables predict success for cognitive behavioral therapy in adolescents: higher levels of rational thoughts, less hopelessness, fewer negative thoughts, and fewer cognitive distortions.[158] CBT is particularly beneficial in preventing relapse.[159][160]

Cognitive behavioral therapy and occupational programs (including modification of work activities and assistance) have been shown to be effective in reducing sick days taken by workers with depression.[161]

### Variants

Several variants of cognitive behavior therapy have been used in those with depression, the most notable being rational emotive behavior therapy,[162] and mindfulness-based cognitive therapy.[163] Mindfulness based stress reduction programs may reduce depression symptoms.[164][165] Mindfulness programs also appear to be a promising intervention in youth.[166]

## Psychoanalysis

Psychoanalysis is a school of thought, founded by Sigmund Freud, which emphasizes the resolution of unconscious mental conflicts.[167] Psychoanalytic techniques are used by some practitioners to treat clients presenting with major depression.[168] A more widely practiced, eclectic technique, called psychodynamic psychotherapy, is loosely based on psychoanalysis and has an additional social and interpersonal focus.[169] In a meta-analysis of three controlled trials of Short Psychodynamic Supportive Psychotherapy, this modification was found to be as effective as medication for mild to moderate depression.[170]

## Antidepressants

*Main article: Antidepressant*

Sertraline (Zoloft) is used primarily to treat major depression in adults.

Conflicting results have arisen from studies that look at the effectiveness of antidepressants in people with acute, mild to moderate depression. Stronger evidence supports the usefulness of antidepressants in the treatment of depression that is chronic (dysthymia) or severe.

While small benefits were found, researchers Irving Kirsch and Thomas Moore state they may be due to issues with the trials rather than a true effect of the medication.[171] In a later publication, Kirsch concluded that the overall effect of new-generation antidepressant medication is below recommended criteria for clinical significance.[10] Similar results were obtained in a meta analysis by Fornier.[9]

A review commissioned by the National Institute for Health and Care Excellence concluded that there is strong evidence that SSRIs have greater efficacy than placebo on achieving a 50% reduction in depression scores in moderate and severe major depression, and that there is some evidence for a similar effect in mild depression.[172] Similarly, a Cochrane systematic review of clinical trials of the generic antidepressant amitriptyline concluded that there is strong evidence that its efficacy is superior to placebo.[173]

In 2014 the U.S. FDA published a systematic review of all antidepressant maintenance trials submitted to the agency between 1985 and 2012. The authors concluded that maintenance treatment reduced the risk of relapse by 52% compared to placebo, and that this effect was primarily due to recurrent depression in the placebo group rather than a drug withdrawal effect.[9]

To find the most effective antidepressant medication with minimal side-effects, the dosages can be adjusted, and if necessary, combinations of different classes of antidepressants can be tried. Response rates to the first antidepressant administered range from 50–75%, and it can take at least six to eight weeks from the start of medication to remission.[174] Antidepressant medication treatment is usually continued for 16 to 20 weeks after remission, to minimize the chance of recurrence,[174] and even up to one year of continuation is recommended.[175] People with chronic depression may need to take medication indefinitely to avoid relapse.[19]

Selective serotonin reuptake inhibitors (SSRIs) are the primary medications prescribed, owing to their relatively mild side-effects, and because they are less toxic in overdose than other antidepressants.[176] People who do not respond to one SSRI can be switched to another antidepressant, and this results in improvement in almost 50% of cases.[177] Another option is to switch to the atypical antidepressant bupropion.[178] Venlafaxine, an antidepressant with a different mechanism of action, may be modestly more effective than SSRIs.[179] However, venlafaxine is not recommended in the UK as a first-line treatment because of evidence suggesting its risks may outweigh benefits,[180] and it is specifically discouraged in children and adolescents.[181][182]

For child and adolescent depression, fluoxetine is recommended if medication are used.[183] Fluoxetine; however, appears to have only slight benefit in children,[183][184] while other antidepressants have not been shown to be effective.[185] There is also insufficient evidence to determine effectiveness in those with depression complicated by dementia.[186] Any antidepressant can cause low serum sodium levels (also called hyponatremia);[187] nevertheless, it has been reported more often with SSRIs.[176] It is not uncommon for SSRIs to cause or worsen insomnia; the sedating antidepressant mirtazapine can be used in such cases.[188][189]

Irreversible monoamine oxidase inhibitors, an older class of antidepressants, have been plagued by potentially life-threatening dietary and drug interactions. They are still used only rarely, although newer and better-tolerated agents of this class have been developed.[190] The safety profile is different with reversible

monoamine oxidase inhibitors such as moclobemide where the risk of serious dietary interactions is negligible and dietary restrictions are less strict.[191]

For children, adolescents, and probably young adults between 18 and 24 years old, there is a higher risk of both suicidal ideations and suicidal behavior in those treated with SSRIs.[192][193] For adults, it is unclear whether SSRIs affect the risk of suicidality. One review found no connection;[194] another an increased risk;[195] and a third no risk in those 25–65 years old and a decrease risk in those more than 65.[196] A black box warning was introduced in the United States in 2007 on SSRI and other antidepressant medications due to increased risk of suicide in patients younger than 24 years old.[197] Similar precautionary notice revisions were implemented by the Japanese Ministry of Health.[198]

## Other medications

There is some evidence that fish oil supplements containing high levels of eicosapentaenoic acid (EPA) to docosahexaenoic acid (DHA) may be effective in major depression,[199] but other meta-analysis of the research conclude that positive effects may be due to publication bias.[200] There is some preliminary evidence that COX-2 inhibitors have a beneficial effect on major depression.[71] Lithium appears effective at lowering the risk of suicide in those with bipolar disorder and unipolar depression to nearly the same levels as the general population.[201] There is a narrow range of effective and safe dosages of lithium thus close monitoring may be needed.[202] Low-dose thyroid hormone may be added to existing antidepressants to treat persistent depression symptoms in people who have tried multiple courses of medication.[203]

## Electroconvulsive therapy

Electroconvulsive therapy (ECT) is a standard psychiatric treatment in which seizures are electrically induced in patients to provide relief from psychiatric illnesses.[204]:1880 ECT is used with informed consent[205] as a last line of intervention for major depressive disorder.[206]

A round of ECT is effective for about 50% of people with treatment-resistant major depressive disorder, whether it is unipolar or bipolar.[207] Follow-up treatment is still poorly studied, but about half of people who respond, relapse with twelve months.[208]

Aside from effects in the brain, the general physical risks of ECT are similar to those of brief general anesthesia.[209]:259 Immediately following treatment, the most common adverse effects are confusion and memory loss.[206][210] ECT is considered one of the least harmful treatment options available for severely depressed pregnant women.[211]

A usual course of ECT involves multiple administrations, typically given two or three times per week until the patient is no longer suffering symptoms ECT is administered under anesthetic with a muscle relaxant.[212] Electroconvulsive therapy can differ in its application in three ways: electrode placement, frequency of treatments, and the electrical waveform of the stimulus. These three forms of application have significant differences in both adverse side effects and symptom remission. After treatment, drug therapy is usually continued, and some patients receive maintenance ECT.[206]

ECT appears to work in the short term via an anticonvulsant effect mostly in the frontal lobes, and longer term via neurotrophic effects primarily in the medial temporal lobe.[213]

## Transcranial magnetic stimulation

Transcranial magnetic stimulation (TMS) or deep transcranial magnetic stimulation is a noninvasive method used to stimulate small regions of the brain.[214] TMS was approved by the FDA for treatment-resistant major depressive disorder in 2008[215] and as of 2014 evidence supports that it is probably effective.[216] The American Psychiatric Association[217] the Canadian Network for Mood and Anxiety Disorders,[218] and the Royal Australia and New Zealand College of Psychiatrists have endorsed rTMS for trMDD.[219]

### Other

Bright light therapy reduces depression symptom severity, with benefit was found for both seasonal affective disorder and for nonseasonal depression, and an effect similar to those for conventional antidepressants. For non-seasonal depression, adding light therapy to the standard antidepressant treatment was not effective.[220] For non-seasonal depression where light was used mostly in combination with antidepressants or wake therapy a moderate effect was found, with response better than control treatment in high-quality studies, in studies that applied morning light treatment, and with people who respond to total or partial sleep deprivation.[221] Both analyses noted poor quality, short duration, and small size of most of the reviewed studies.

## Prognosis

Major depressive episodes often resolve over time whether or not they are treated. Outpatients on a waiting list show a 10–15% reduction in symptoms within a few months, with approximately 20% no longer meeting the full criteria for a depressive disorder.[222] The median duration of an episode has been estimated to be 23 weeks, with the highest rate of recovery in the first three months.[223]

Studies have shown that 80% of those suffering from their first major depressive episode will suffer from at least 1 more during their life,[224] with a lifetime average of 4 episodes.[225] Other general population studies indicate that around half those who have an episode recover (whether treated or not) and remain well, while the other half will have at least one more, and around 15% of those experience chronic recurrence.[226] Studies recruiting from selective inpatient sources suggest lower recovery and higher chronicity, while studies of mostly outpatients show that nearly all recover, with a median episode duration of 11 months. Around 90% of those with severe or psychotic depression, most of whom also meet criteria for other mental disorders, experience recurrence.[227][228]

Recurrence is more likely if symptoms have not fully resolved with treatment. Current guidelines recommend continuing antidepressants for four to six months after remission to prevent relapse. Evidence from many randomized controlled trials indicates continuing antidepressant medications after recovery can reduce the chance of relapse by 70% (41% on placebo vs. 18% on antidepressant). The preventive effect probably lasts for at least the first 36 months of use.[229]

Those people experiencing repeated episodes of depression require ongoing treatment in order to prevent more severe, long-term depression. In some cases, people must take medications for long periods of time or for the rest of their lives.[230]

Cases when outcome is poor are associated with inappropriate treatment, severe initial symptoms that may include psychosis, early age of onset, more previous episodes, incomplete recovery after 1 year, pre-existing severe mental or medical disorder, and family dysfunction as well.[231]

Depressed individuals have a shorter life expectancy than those without depression, in part because depressed patients are at risk of dying by suicide.[232] However, they also have a higher rate of dying from other causes,[233] being more susceptible to medical conditions such as heart disease.[234] Up to 60% of people who die by suicide have a mood disorder such as major depression, and the risk is especially high if a person has a marked sense of hopelessness or has both depression and borderline personality disorder.[235] The lifetime risk of suicide associated with a diagnosis of major depression in the US is estimated at 3.4%, which averages two highly disparate figures of almost 7% for men and 1% for women[236] (although suicide attempts are more frequent in women).[237] The estimate is substantially lower than a previously accepted figure of 15%, which had been derived from older studies of hospitalized patients.[238]

Depression is often associated with unemployment and poverty.[239] Major depression is currently the leading cause of disease burden in North America and other high-income countries, and the fourth-leading cause worldwide. In the year 2030, it is predicted to be the second-leading cause of disease burden worldwide after HIV, according to the World Health Organization.[240] Delay or failure in seeking treatment

after relapse, and the failure of health professionals to provide treatment, are two barriers to reducing disability.[241]

# Epidemiology

*Main article: Epidemiology of depression*

Disability-adjusted life year for unipolar depressive disorders per 100,000 inhabitants in 2004.[242]

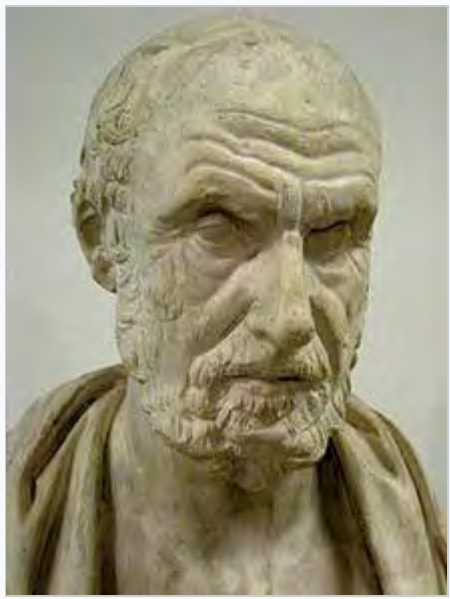
| | |
|---|---|
| no data | 1000–1075 |
| <700 | 1075–1150 |
| 700–775 | 1150–1225 |
| 775–850 | 1225–1300 |
| 850–925 | 1300–1375 |
| 925–1000 | 1375–1450 |
| | >1450 |

Major depressive disorder affects approximately 253 million people in 2013 (3.6% of the global population).[14] The percentage of people who are affected at one point in their life varies from 7% in Japan to 21% in France.[15] In most countries the number of people who have depression during their lives falls within an 8–18% range.[15] In North America, the probability of having a major depressive episode within a year-long period is 3–5% for males and 8–10% for females.[243][244] Major depression to be about twice as common in women as in men, although it is unclear why this is so, and whether factors unaccounted for are contributing to this.[245] The relative increase in occurrence is related to pubertal development rather than chronological age, reaches adult ratios between the ages of 15 and 18, and appears associated with psychosocial more than hormonal factors.[245] Depression is a major cause of disability worldwide.[246]

People are most likely to develop their first depressive episode between the ages of 30 and 40, and there is a second, smaller peak of incidence between ages 50 and 60.[247] The risk of major depression is increased with neurological conditions such as stroke, Parkinson's disease, or multiple sclerosis, and during the first year after childbirth.[248] It is also more common after cardiovascular illnesses, and is related more to a poor outcome than to a better one.[234][249] Studies conflict on the prevalence of depression in the elderly, but most data suggest there is a reduction in this age group.[250] Depressive disorders are more common to observe in urban than in rural population and the prevalence is in groups with stronger socioeconomic factors i.e. homelessness.[251]

# History

*Main article: History of depression*



The Ancient Greek physician Hippocrates described a syndrome of melancholia as a distinct disease with particular mental and physical symptoms; he characterized all "fears and despondencies, if they last a long time" as being symptomatic of the ailment.[252] It was a similar but far broader concept than today's depression; prominence was given to a clustering of the symptoms of sadness, dejection, and despondency, and often fear, anger, delusions and obsessions were included.[253]

The term *depression* itself was derived from the Latin verb *deprimere*, "to press down".[254] From the 14th century, "to depress" meant to subjugate or to bring down in spirits. It was used in 1665 in English author Richard Baker's *Chronicle* to refer to someone having "a great depression of spirit", and by English author Samuel Johnson in a similar sense in 1753.[255] The term also came into use in physiology and economics. An early usage referring to a psychiatric symptom was by French psychiatrist Louis Delasiauve in 1856, and by the 1860s it was

appearing in medical dictionaries to refer to a physiological and metaphorical lowering of emotional function.[256] Since Aristotle, melancholia had been associated with men of learning and intellectual brilliance, a hazard of contemplation and creativity. The newer concept abandoned these associations and through the 19th century, became more associated with women.[253]

Diagnoses of depression go back at least as far as Hippocrates

A historical caricature of a man with an approaching depression

Although *melancholia* remained the dominant diagnostic term, *depression* gained increasing currency in medical treatises and was a synonym by the end of the century; German psychiatrist Emil Kraepelin may have been the first to use it as the overarching term, referring to different kinds of melancholia as *depressive states*.[257]

Sigmund Freud likened the state of melancholia to mourning in his 1917 paper *Mourning and Melancholia*. He theorized that objective loss, such as the loss of a valued relationship through death or a romantic break-up, results in subjective loss as well; the depressed individual has identified with the object of affection through an unconscious, narcissistic process called the *libidinal cathexis* of the ego. Such loss results in severe melancholic symptoms more profound than mourning; not only is the outside world viewed negatively but the ego itself is compromised.[258] The patient's decline of self-perception is revealed in his belief of his own blame, inferiority, and unworthiness.[259] He also emphasized early life experiences as a predisposing factor.[253] Adolf Meyer put forward a mixed social and biological framework emphasizing *reactions* in the context of an individual's life, and argued that the term *depression* should be used instead of *melancholia*.[260] The first version of the DSM (DSM-I, 1952) contained *depressive reaction* and the DSM-II (1968) *depressive neurosis*, defined as an excessive reaction to internal conflict or an identifiable event, and also included a depressive type of manic-depressive psychosis within Major affective disorders.[261]

In the mid-20th century, researchers theorized that depression was caused by a chemical imbalance in neurotransmitters in the brain, a theory based on observations made in the 1950s of the effects of reserpine and isoniazid in altering monoamine neurotransmitter levels and affecting depressive symptoms.[262]

The term "unipolar" (along with the related term "bipolar") was coined by the neurologist and psychiatrist Karl Kleist, and subsequently used by his disciples Edda Neele and Karl Leonhard.[263]

The term *Major depressive disorder* was introduced by a group of US clinicians in the mid-1970s as part of proposals for diagnostic criteria based on patterns of symptoms (called the "Research Diagnostic Criteria", building on earlier Feighner Criteria),[264] and was incorporated into the DSM-III in 1980.[265] To maintain consistency the ICD-10 used the same criteria, with only minor alterations, but using the DSM diagnostic threshold to mark a *mild depressive episode*, adding higher threshold categories for moderate and severe episodes.[107][265] The ancient idea of *melancholia* still survives in the notion of a melancholic subtype.

The new definitions of depression were widely accepted, albeit with some conflicting findings and views. There have been some continued empirically based arguments for a return to the diagnosis of melancholia.[266][267] There has been some criticism of the expansion of coverage of the diagnosis, related to the development and promotion of antidepressants and the biological model since the late 1950s.[268]

## Society and culture

*See also: List of people with major depressive disorder*

## Terminology

The 16th American president Abraham Lincoln had "melancholy", a condition that now may be referred to as clinical depression.[269]

The term "depression" is used in a number of different ways. It is often used to mean this syndrome but may refer to other mood disorders or simply to a low mood. People's conceptualizations of depression vary widely, both within and among cultures. "Because of the lack of scientific certainty," one commentator has observed, "the debate over depression turns on questions of language. What we call it—'disease,' 'disorder,' 'state of mind'—affects how we view, diagnose, and treat it."[270] There are cultural differences in the extent to which serious depression is considered an illness requiring personal professional treatment, or is an indicator of something else, such as the need to address social or moral problems, the result of biological imbalances, or a reflection of individual differences in the understanding of distress that may reinforce feelings of powerlessness, and emotional struggle.[271][272]

The diagnosis is less common in some countries, such as China. It has been argued that the Chinese traditionally deny or somatize emotional depression (although since the early 1980s, the Chinese denial of depression may have modified).[273] Alternatively, it may be that Western cultures reframe and elevate some expressions of human distress to disorder status. Australian professor Gordon Parker and others have argued that the Western concept of depression "medicalizes" sadness or misery.[274][275] Similarly, Hungarian-American psychiatrist Thomas Szasz and others argue that depression is a metaphorical illness that is inappropriately regarded as an actual disease.[276] There has also been concern that the DSM, as well as the field of descriptive psychiatry that employs it, tends to reify abstract phenomena such as depression, which may in fact be social constructs.[277] American archetypal psychologist James Hillman writes that depression can be healthy for the soul, insofar as "it brings refuge, limitation, focus, gravity, weight, and humble powerlessness."[278] Hillman argues that therapeutic attempts to eliminate depression echo the Christian theme of resurrection, but have the unfortunate effect of demonizing a soulful state of being.

## Stigma

Historical figures were often reluctant to discuss or seek treatment for depression due to social stigma about the condition, or due to ignorance of diagnosis or treatments. Nevertheless, analysis or interpretation of letters, journals, artwork, writings, or statements of family and friends of some historical personalities has led to the presumption that they may have had some form of depression. People who may have had depression include English author Mary Shelley,[279] American-British writer Henry James,[280] and American president Abraham Lincoln.[281] Some well-known contemporary people with possible depression include Canadian songwriter Leonard Cohen[282] and American playwright and novelist Tennessee Williams.[283] Some pioneering psychologists, such as Americans William James[284][285] and John B. Watson,[286] dealt with their own depression.

There has been a continuing discussion of whether neurological disorders and mood disorders may be linked to creativity, a discussion that goes back to Aristotelian times.[287][288] British literature gives many examples of reflections on depression.[289] English philosopher John Stuart Mill experienced a several-months-long period of what he called "a dull state of nerves", when one is "unsusceptible to enjoyment or pleasurable excitement; one of those moods when what is pleasure at other times, becomes insipid or indifferent". He quoted English poet Samuel Taylor Coleridge's "Dejection" as a perfect description of his case: "A grief without a pang, void, dark and drear, / A drowsy, stifled, unimpassioned grief, / Which finds no natural outlet or relief / In word, or sigh, or tear."[290][291] English writer Samuel Johnson used the term

"the black dog" in the 1780s to describe his own depression,[292] and it was subsequently popularized by depression sufferer former British Prime Minister Sir Winston Churchill.[292]

Social stigma of major depression is widespread, and contact with mental health services reduces this only slightly. Public opinions on treatment differ markedly to those of health professionals; alternative treatments are held to be more helpful than pharmacological ones, which are viewed poorly.[293] In the UK, the Royal College of Psychiatrists and the Royal College of General Practitioners conducted a joint Five-year Defeat Depression campaign to educate and reduce stigma from 1992 to 1996;[294] a MORI study conducted afterwards showed a small positive change in public attitudes to depression and treatment.[295]

## Research

Trials are looking at the effects of botulinum toxins on depression. The idea is that the drug is used to make the person look less frowning and that this stops the negative facial feedback from the face.[296] In 2015 it turned out, however, that the partly positive effects that had been observed until then could have been placebo effects.[297]

MDD has been studied by taking MRI scans of patients with depression have revealed a number of differences in brain structure compared to those who are not depressed. Meta-analyses of neuroimaging studies in major depression reported that, compared to controls, depressed patients had increased volume of the lateral ventricles and adrenal gland and smaller volumes of the basal ganglia, thalamus, hippocampus, and frontal lobe (including the orbitofrontal cortex and gyrus rectus).[298][299] Hyperintensities have been associated with patients with a late age of onset, and have led to the development of the theory of vascular depression.[300]

## Elderly

*See also: Late life depression*

Depression is especially common among those over 65 years of age and increases in frequency with age beyond this age.[301] In addition the risk of depression increases in relation to the age and frailty of the individual.[301] Depression is one the most important factors which negatively impact quality of life in adults as well as the elderly.[301] Both symptoms and treatment among the elderly differ from those of the rest of the adult populations.[301]

As with many other diseases it is common among the elderly not to present classical depressive symptoms.[301] Diagnosis and treatment is further complicated in that the elderly are often simultaneously treated with a number of other drugs, and often have other concurrent diseases.[301] Treatment differs in that studies of SSRI-drugs have shown lesser and often inadequate effect among the elderly, while other drugs with more clear effects have adverse effects which can be especially difficult to handle among the elderly.[301] Duloxetine is an SNRI-drug with documented effect on recurring depression among the elderly, but has adverse effects in form of dizziness, dryness of the mouth, diarrhea, and constipation.[301]

Problem solving therapy was as of 2015 the only psychological therapy with proven effect, and can be likened to a simpler form of cognitive behavioral therapy.[301] However, elderly with depression are seldom offered any psychological treatment, and the evidence surrounding which other treatments are effective is incomplete.[301] Electroconvulsive therapy (ECT or electric-shock therapy) has been used as treatment of the elderly, and register-studies suggest it is effective although less so among the elderly than among the rest of the adult population.[301]

The risks involved with treatment of depression among the elderly as opposed to benefits is not entirely clear.[301] Awaiting more evidence on how depression-treatment among the elderly is best designed it is important to follow up treatment results, and to reconsider changing treatments if it does not help.[301]

# Obsessive–compulsive disorder

From Wikipedia, the free encyclopedia
(Redirected from Obsessive–compulsive disorder)

*"OCD" redirects here. For other uses, see OCD (disambiguation). Not to be confused with Obsessive–compulsive personality disorder.*

**Obsessive–compulsive disorder** (**OCD**) is a mental disorder where people feel the need to check things repeatedly, perform certain routines repeatedly (called "rituals"), or have certain thoughts repeatedly. People are unable to control either the thoughts or the activities for more than a short period of time. Common activities include hand washing, counting of things, and checking to see if a door is locked. Some may have difficulty throwing things out. These activities occur to such a degree that the person's daily life is negatively affected.[1] Often they take up more than an hour a day.[2] Most adults realize that the behaviors do not make sense.[1] The condition is associated with tics, anxiety disorder, and an increased risk of suicide.[2][3]

The cause is unknown.[1] There appear to be some genetic components with both identical twins more often affected than both non-identical twins. Risk factors include a history of child abuse or other stress inducing event. Some cases have been documented to occur following infections. The diagnosis is based on the symptoms and requires ruling out other drug related or medical causes.[2] Rating scales such as the Yale–Brown Obsessive Compulsive Scale can be used to assess the severity.[4] Other disorders with similar symptoms include anxiety disorder, major depressive disorder, eating disorders, tic disorders, and obsessive–compulsive personality disorder.[2]

Treatment involves counselling, such as cognitive behavioral therapy (CBT), and sometimes medication, typically selective serotonin reuptake inhibitors (SSRIs).[5][6] CBT for OCD involves increasing exposure to what causes the problems while not allowing the repetitive behavior to occur.[5] While clomipramine appears to work as well as SSRIs, it has greater side effects.[5] Atypical antipsychotics may be useful when used in addition to an SSRI in treatment-resistant cases but are also associated with an increased risk of side effects.[6][7] Without treatment, the condition often lasts decades.[2]

Obsessive–compulsive disorder affects about 2.3% of people at some point in their life.[8] Rates during a given year are about 1.2% and it occurs worldwide.[2] It is unusual for symptoms to begin after the age of thirty-five, and half of people develop problems before twenty.[1][2] Males and females are affected about equally.[1] In English the phrase *obsessive–compulsive* is often used in an informal manner unrelated to OCD to describe someone who is excessively meticulous, perfectionistic, absorbed, or otherwise fixated.[9]

# Signs and symptoms

## Obsessions

*Main article: Intrusive thought*

Obsessions are thoughts that recur and persist despite efforts to ignore or confront them.[10] People with OCD frequently perform tasks, or compulsions, to seek relief from obsession-related anxiety. Within and among individuals, the initial obsessions, or intrusive thoughts, vary in their clarity and vividness. A relatively vague obsession could involve a general sense of disarray or tension accompanied by a belief that life cannot proceed as normal while the imbalance remains. A more intense obsession could be a preoccupation with the thought or image of someone close to them dying[11][12] or intrusions related to "relationship rightness."[13] Other obsessions concern the possibility that someone or something other than oneself—such as God, the Devil, or disease—will harm either the person with OCD or the people or things that the person cares about. Other individuals with OCD may experience the sensation of invisible protrusions emanating from their bodies, or have the feeling that inanimate objects are ensouled.[14]

People with OCD may face intrusive thoughts, such as thoughts about the Devil (shown is a painted interpretation of Hell)

Some people with OCD experience sexual obsessions that may involve intrusive thoughts or images of "kissing, touching, fondling, oral sex, anal sex, intercourse, incest and rape" with "strangers, acquaintances, parents, children, family members, friends, coworkers, animals and religious figures", and can include "heterosexual or homosexual content" with persons of any age.[15] As with other intrusive, unpleasant thoughts or images, some disquieting sexual thoughts at times are normal, but people with OCD may attach extraordinary significance to the thoughts. For example, obsessive fears about sexual orientation can appear to the person with OCD, and even to those around them, as a crisis of sexual identity.[16][17] Furthermore, the doubt that accompanies OCD leads to uncertainty regarding whether one might act on the troubling thoughts, resulting in self-criticism or self-loathing.[15]

People with OCD understand that their notions do not correspond with reality; however, they feel that they must act as though their notions are correct. For example, an individual who engages in compulsive hoarding might be inclined to treat inorganic matter as if it had the sentience or rights of living organisms, while accepting that such behavior is irrational on a more intellectual level.

## Primarily obsessional

*Main article: Primarily Obsessional OCD*

OCD sometimes manifests without overt compulsions.[18] Nicknamed "Pure-O",[19] or referred to as Primarily Obsessional OCD, OCD without overt compulsions could, by one estimate, characterize as many as 50 percent to 60 percent of OCD cases.[20] Primarily obsessional OCD has been called one of the most distressing and challenging forms of OCD.[21] People with this form of OCD have distressing and unwanted thoughts emerging frequently, and these thoughts typically center on a fear that one may do something totally uncharacteristic of oneself, possibly something potentially fatal to oneself or others.[21] The thoughts may likely be of an aggressive or sexual nature.[21]

Rather than engaging in observable compulsions, the person with this subtype might perform more covert, mental rituals, or

might feel driven to avoid the situations in which particular thoughts seem likely to intrude.[19] As a result of this avoidance, people can struggle to fulfill both public and private roles, even if they place great value on these roles and even if they had fulfilled the roles successfully in the past.[19] Moreover, the individual's avoidance can confuse others who do not know its origin or intended purpose, as it did in the case of a man whose wife began to wonder why he would not hold their infant child.[19] The covert mental rituals can take up a great deal of a person's time during the day.

## Compulsions

*Main article: Compulsive behavior*

Skin-picking disorder

Some people with OCD perform compulsive rituals because they inexplicably feel they have to, others act compulsively so as to mitigate the anxiety that stems from particular obsessive thoughts. The person might feel that these actions somehow either will prevent a dreaded event from occurring, or will push the event from their thoughts. In any case, the individual's reasoning is so idiosyncratic or distorted that it results in significant distress for the individual with OCD or for those around them. Excessive skin picking, hair-pulling, nail biting, and other body-focused repetitive behavior disorders are all on the obsessive–compulsive spectrum.[2] Some individuals with OCD are aware that their behaviors are not rational, but feel compelled to follow through with them to fend off feelings of panic or dread.[2][22]

Some common compulsions include hand washing, cleaning, checking things (e.g., locks on doors), repeating actions (e.g., turning on and off switches), ordering items in a certain way, and requesting reassurance.[23] Compulsions are different than tics (such as touching, tapping, rubbing, or blinking)[24] and stereotyped movements (such as head banging, body rocking, or self-biting), which usually aren't as complex as compulsions and aren't precipitated by obsessions.[2] It can sometimes be difficult to tell the difference between compulsions and complex tics.[2] About 10% to 40% of individuals with OCD also have a lifetime tic disorder.[25]

People rely on compulsions as an escape from their obsessive thoughts; however, they are aware that the relief is only temporary, that the intrusive thoughts will soon return. Some people use compulsions to avoid situations that may trigger their obsessions. Although some people do certain things over and over again, they do not necessarily perform these actions compulsively. For example, bedtime routines, learning a new skill, and religious practices are not compulsions. Whether or not behaviors are compulsions or mere habit depends on the context in which the behaviors are performed. For example, arranging and ordering DVDs for eight hours a day would be expected of one who works in a video store, but would seem abnormal in other situations. In other words, habits tend to bring efficiency to one's life, while compulsions tend to disrupt it.[26]

In addition to the anxiety and fear that typically accompanies OCD, sufferers may spend hours performing such compulsions every day. In such situations, it can be hard for the person to fulfill their work, family, or social roles. In some cases, these behaviors can also cause adverse physical symptoms. For example, people who obsessively wash their hands with antibacterial soap and hot water can make their skin red and raw with dermatitis.[27]

People with OCD can use rationalizations to explain their behavior; however, these rationalizations do not apply to the overall behavior but to each instance individually. For example, a person compulsively checking the front door may argue that the time taken and stress caused by one more check of the front door is much less than the time and stress associated with being robbed, and thus checking is the better option. In practice, after that check, the person is *still* not sure and deems it is *still* better to perform one more check, and this reasoning can continue as long as necessary.

## Overvalued ideas

Some people with OCD exhibit what is known as *overvalued ideas*. In such cases, the person with OCD will truly be uncertain whether the fears that cause them to perform their compulsions are irrational or not. After some discussion, it is possible to convince the individual that their fears may be unfounded. It may be more difficult to do ERP therapy on such people because they may be unwilling to cooperate, at least initially. There are severe cases in which the person has an unshakeable belief in the context of OCD that is difficult to differentiate from psychotic disorders.[28]

## Cognitive performance

A 2013 meta-analysis confirmed people with OCD to have mild but wide-ranging cognitive deficits; significantly regarding spatial memory, to a lesser extent with verbal memory, fluency, executive function and processing speed, while auditory attention was not significantly affected.[29] People with OCD show impairment in formulating an organizational strategy for coding information, set-shifting, motor and cognitive inhibition.[30]

## Associated conditions

People with OCD may be diagnosed with other conditions, as well or instead of OCD, such as the aforementioned obsessive–compulsive personality disorder, major depressive disorder, bipolar disorder,[31] generalized anxiety disorder, anorexia

nervosa, social anxiety disorder, bulimia nervosa, Tourette syndrome, Asperger syndrome, attention deficit hyperactivity disorder, dermatillomania (compulsive skin picking), body dysmorphic disorder, and trichotillomania (hair pulling). In 2009 it was reported that depression among those with OCD is particularly alarming because their risk of suicide is high; more than 50 percent of people experience suicidal tendencies, and 15 percent have attempted suicide.[4] Individuals with OCD have also been found to be affected by delayed sleep phase syndrome at a substantially higher rate than the general public.[32] Moreover, severe OCD symptoms are consistently associated with greater sleep disturbance. Reduced total sleep time and sleep efficiency have been observed in people with OCD, with delayed sleep onset and offset and an increased prevalence of delayed sleep phase disorder.[33]

Behaviorally, there is some research demonstrating a link between drug addiction and the disorder as well. For example, there is a higher risk of drug addiction among those with any anxiety disorder (possibly as a way of coping with the heightened levels of anxiety), but drug addiction among people with OCD may serve as a type of compulsive behavior and not just as a coping mechanism. Depression is also extremely prevalent among people with OCD. One explanation for the high depression rate among OCD populations was posited by Mineka, Watson, and Clark (1998), who explained that people with OCD (or any other anxiety disorder) may feel depressed because of an "out of control" type of feeling.[34]

Someone exhibiting OCD signs does not necessarily have OCD. Behaviors that present as (or seem to be) obsessive or compulsive can also be found in a number of other conditions as well, including obsessive–compulsive *personality* disorder (OCPD), autism, disorders where perseveration is a possible feature (ADHD, PTSD, bodily disorders or habit problems),[35] or sub-clinically.

Some with OCD present with features typically associated with Tourette's syndrome, such as compulsions that may appear to resemble motor tics; this has been termed "tic-related OCD" or "Tourettic OCD".[36][37]

There is tentative evidence that OCD may be associated with above-average intelligence or at least a small increase in intelligence.[38][39]

# Causes

*Main article: Cause of obsessive-compulsive disorder*

The cause is unknown.[1] Both environmental and genetic factors are believed to play a role. Risk factors include a history of child abuse or other stress-inducing event.[2]

## Genetics

There appear to be some genetic components with identical twins more often affected than non-identical twins.[2] Further, individuals with OCD are more likely to have first-degree family members exhibiting the same disorders than do matched controls. In cases where OCD develops during childhood, there is a much stronger familial link in the disorder than cases in which OCD develops later in adulthood. In general, genetic factors account for 45–65% of the variability in OCD symptoms in children diagnosed with the disorder.[40] Recent evidence supports the possibility of a heritable predisposition for neurological development favoring OCD.[41]

A mutation has been found in the human serotonin transporter gene, hSERT, in unrelated families with OCD.[42]

Per evolutionary psychology moderate versions of compulsive behavior may have had evolutionary advantages. Examples would be moderate constant checking of hygiene, the hearth, or the environment for enemies. Similarly, hoarding may have had evolutionary advantages. In this view OCD may be the extreme statistical "tail" of such behaviors possibly due to a high amount of predisposing genes.[43]

## Infection

A controversial hypothesis[44] is that some cases of rapid onset of OCD in children and adolescents may be caused by a syndrome connected to Group A streptococcal infections, known as pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS).[44][45]

# Mechanisms

*Main article: Biology of obsessive–compulsive disorder*

Brain scans of people with OCD have shown that they have different patterns of brain activity than people without OCD and that different functioning of circuitry within a certain part of the brain, the striatum, may cause the disorder. Differences in other parts of the brain and neurotransmitter dysregulation, especially serotonin and dopamine, may also contribute to OCD.[46] Independent studies have consistently found unusual dopamine and serotonin activity in various regions of the brain in people with OCD. These can be defined as dopaminergic hypofunction in the prefrontal cortex (mesocortical dopamine pathway) and serotonergic hypofunction in the basal ganglia.[47][48][49] Glutamate dysregulation has also been the subject of

recent research,[50][51] although its role in the disorder's etiology is not yet clear. Glutamate is known to act as a cotransmitter with dopamine in dopamine pathways that project out of the ventral tegmental area.

People with OCD evince increased grey matter volumes in bilateral lenticular nuclei, extending to the caudate nuclei, with decreased grey matter volumes in bilateral dorsal medial frontal/anterior cingulate gyri.[52][53] These findings contrast with those in people with other anxiety disorders, who evince decreased (rather than increased) grey matter volumes in bilateral lenticular / caudate nuclei, while also decreased grey matter volumes in bilateral dorsal medial frontal/anterior cingulate gyri.[53] Orbitofrontal cortex overactivity is attenuated in people who have successfully responded to SSRI medication, a result believed to be caused by increased stimulation of serotonin receptors 5-HT2A and 5-HT2C.[54] The striatum, linked to planning and the initiation of appropriate actions, has also been implicated; mice genetically engineered with a striatal abnormality exhibit OCD-like behavior, grooming themselves three times as frequently as ordinary mice.[55]

A meta analysis of functional neuroimaging in OCD reported the only consistent findings have been in the orbital gyrus and head of the caudate nucleus.[56]

# Diagnosis

Formal diagnosis may be performed by a psychologist, psychiatrist, clinical social worker, or other licensed mental health professional. To be diagnosed with OCD, a person must have obsessions, compulsions, or both, according to the Diagnostic and Statistical Manual of Mental Disorders (DSM). The Quick Reference to the 2000 edition of the DSM states that several features characterize clinically significant obsessions and compulsions. Such obsessions, the DSM says, are recurrent and persistent thoughts, impulses, or images that are experienced as intrusive and that cause marked anxiety or distress. These thoughts, impulses, or images are of a degree or type that lies outside the normal range of worries about conventional problems.[57] A person may attempt to ignore or suppress such obsessions, or to neutralize them with some other thought or action, and will tend to recognize the obsessions as idiosyncratic or irrational.

Compulsions become clinically significant when a person feels driven to perform them in response to an obsession, or according to rules that must be applied rigidly, and when the person consequently feels or causes significant distress. Therefore, while many people who do not suffer from OCD may perform actions often associated with OCD (such as ordering items in a pantry by height), the distinction with clinically significant OCD lies in the fact that the person who suffers from OCD *must* perform these actions, otherwise they will experience significant psychological distress. These behaviors or mental acts are aimed at preventing or reducing distress or preventing some dreaded event or situation; however, these activities are not logically or practically connected to the issue, or they are excessive. In addition, at some point during the course of the disorder, the individual must realize that their obsessions or compulsions are unreasonable or excessive.

Moreover, the obsessions or compulsions must be time-consuming (taking up more than one hour per day) or cause impairment in social, occupational, or scholastic functioning.[57] It is helpful to quantify the severity of symptoms and impairment before and during treatment for OCD. In addition to the peron's estimate of the time spent each day harboring obsessive-compulsive thoughts or behaviors, concrete tools can be used to gauge the people's condition. This may be done with rating scales, such as the Yale–Brown Obsessive Compulsive Scale (Y-BOCS). With measurements like these, psychiatric consultation can be more appropriately determined because it has been standardized.[4]

OCD is sometimes placed in a group of disorders called the obsessive–compulsive spectrum.[58]

## Differential diagnosis

OCD is often confused with the separate condition obsessive–compulsive personality disorder (OCPD). OCD is egodystonic, meaning that the disorder is incompatible with the sufferer's self-concept.[59][60] Because ego dystonic disorders go against a person's self-concept, they tend to cause much distress. OCPD, on the other hand, is egosyntonic—marked by the person's acceptance that the characteristics and behaviours displayed as a result are compatible with their self-image, or are otherwise appropriate, correct or reasonable.

As a result, people with OCD are often aware that their behavior is not rational, are unhappy about their obsessions but nevertheless feel compelled by them.[61] By contrast people with OCPD are not aware of anything abnormal; they will readily explain why their actions are rational, it is usually impossible to convince them otherwise, and they tend to derive pleasure from their obsessions or compulsions.[61]

# Management

A form of psychotherapy called "cognitive behavioral therapy" (CBT) and psychotropic medications are first-line treatments for OCD.[1][62] Other forms of psychotherapy, such as psychodynamic and psychoanalysis may help in managing some aspects of the disorder, but in 2007 the American Psychiatric Association (APA) noted a lack of controlled studies showing their effectiveness "in dealing with the core symptoms of OCD".[63] The fact that many individuals do not seek treatment may be due in part to stigma associated with OCD.[*citation needed*]

## Therapy

The specific technique used in CBT is called exposure and response prevention (ERP) which involves teaching the person to deliberately come into contact with the situations that trigger the obsessive thoughts and fears ("exposure"), without carrying out the usual compulsive acts associated with the obsession ("response prevention"), thus gradually learning to tolerate the discomfort and anxiety associated with not performing the ritualistic behavior. At first, for example, someone might touch something only very mildly "contaminated" (such as a tissue that has been touched by another tissue that has been touched by the end of a toothpick that has touched a book that came from a "contaminated" location, such as a school.) That is the "exposure". The "ritual prevention" is not washing. Another example might be leaving the house and checking the lock only once (exposure) without going back and checking again (ritual prevention). The person fairly quickly habituates to the anxiety-producing situation and discovers that their anxiety level drops considerably; they can then progress to touching something more "contaminated" or not checking the lock at all—again, without performing the ritual behavior of washing or checking.[64]

One exposure and ritual prevention activity would be to check the lock only once, and then leave.

ERP has a strong evidence base, and it is considered the most effective treatment for OCD.[64] However, this claim was doubted by some researchers in 2000 who criticized the quality of many studies.[65]

It has generally been accepted that psychotherapy, in combination with psychiatric medication, is more effective than either option alone. However, more recent studies have shown no difference in outcomes for those treated with the combination of medicine and CBT versus CBT alone.[66]

## Medication

The medications most frequently used are the selective serotonin reuptake inhibitors (SSRIs).[5] Clomipramine, a medication belonging to the class of tricyclic antidepressants appears to work as well as SSRIs but has a higher rate of side effects.[5]

A blister pack of clomipramine under the brand name "Anafranil".

SSRIs are a second line treatment of adult obsessive compulsive disorder (OCD) with mild functional impairment and as first line treatment for those with moderate or severe impairment. In children, SSRIs can be considered as a second line therapy in those with moderate-to-severe impairment, with close monitoring for psychiatric adverse effects.[62] SSRIs are efficacious in the treatment of OCD; people treated with SSRIs are about twice as likely to respond to treatment as those treated with placebo.[67][68] Efficacy has been demonstrated both in short-term (6–24 weeks) treatment trials and in discontinuation trials with durations of 28–52 weeks.[69][70][71]

In 2006, the National Institute of Clinical and Health Excellence (NICE) guidelines recommended anti-psychotics for OCD that does not improve with SSRI treatment.[6] For OCD the evidence for the atypical antipsychotic drugs risperidone and quetiapine is tentative with insufficient evidence for olanzapine.[72] A 2014 review article found two studies that indicated that aripiprazole was "effective in the short-term" and found that "[t]here was a small effect-size for risperidone or anti-psychotics in general in the short-term"; however, the study authors found "no evidence for the effectiveness of quetiapine or olanzapine in comparison to placebo."[6] While quetiapine may be useful when used in addition to an SSRI in treatment-resistant OCD, these drugs are often poorly tolerated, and have metabolic side effects that limit their use. None of the atypical antipsychotics appear to be useful when used alone.[7]

A guideline by the APA suggested that dextroamphetamine may be considered by itself after more well supported treatments have been tried.[73]

## Procedures

Electroconvulsive therapy (ECT) has been found to have effectiveness in some severe and refractory cases.[74]

Surgery may be used as a last resort in people who do not improve with other treatments. In this procedure, a surgical lesion is made in an area of the brain (the cingulate cortex). In one study, 30% of participants benefited significantly from this procedure.[75] Deep-brain stimulation and vagus nerve stimulation are possible surgical options that do not require destruction of brain tissue. In the US, the Food and Drug Administration approved deep-brain stimulation for the treatment of OCD under a humanitarian device exemption requiring that the procedure be performed only in a hospital with specialist qualifications to do so.[76]

In the US, psychosurgery for OCD is a treatment of last resort and will not be performed until the person has failed several attempts at medication (at the full dosage) with augmentation, and many months of intensive cognitive–behavioral therapy

with exposure and ritual/response prevention.[77] Likewise, in the United Kingdom, psychosurgery cannot be performed unless a course of treatment from a suitably qualified cognitive–behavioral therapist has been carried out.

### Children

Therapeutic treatment may be effective in reducing ritual behaviors of OCD for children and adolescents.[78] Similar to the treatment of adults with OCD, CBT stands as an effective and validated first line of treatment of OCD in children.[79] Family involvement, in the form of behavioral observations and reports, is a key component to the success of such treatments.[80] Parental interventions also provide positive reinforcement for a child who exhibits appropriate behaviors as alternatives to compulsive responses. In a recent meta-analysis of evidenced-based treatment of OCD in children, family-focused individual CBT was labeled as "probably efficacious", establishing it as one of the leading psychosocial treatments for youth with OCD.[79] After one or two years of therapy, in which a child learns the nature of his or her obsession and acquires strategies for coping, that child may acquire a larger circle of friends, exhibit less shyness, and become less self-critical.[81]

Although the causes of OCD in younger age groups range from brain abnormalities to psychological preoccupations, life stress such as bullying and traumatic familial deaths may also contribute to childhood cases of OCD, and acknowledging these stressors can play a role in treating the disorder.[82]

## Epidemiology

Obsessive–compulsive disorder affects about 2.3% of people at some point in their life.[8] Rates during a given year are about 1.2% and it occurs worldwide.[2] It is unusual for symptoms to begin after the age of thirty five and half of people develop problems before twenty.[1][2] Males and females are affected about equally.[1]

Age-standardized disability-adjusted life year estimated rates for obsessive-compulsive disorder per 100,000 inhabitants in 2004.

## Prognosis

Psychological interventions such as behavioral therapy and cognitive-behavioral therapy as well as medication can lead to a reduction of OCD symptoms for a number of people. However, symptoms may persist at moderate levels even following adequate treatment courses, and completely symptom-free periods are uncommon.[83]

## History

From the 14th to the 16th century in Europe, it was believed that people who experienced blasphemous, sexual, or other obsessive thoughts were possessed by the Devil.[59] Based on this reasoning, treatment involved banishing the "evil" from the "possessed" person through exorcism.[84][85] In the early 1910s, Sigmund Freud attributed obsessive–compulsive behavior to unconscious conflicts that manifest as symptoms.[84] Freud describes the clinical history of a typical case of "touching phobia" as starting in early childhood, when the person has a strong desire to touch an item. In response, the person develops an "external prohibition" against this type of touching. However, this "prohibition does not succeed in abolishing" the desire to touch; all it can do is repress the desire and "force it into the unconscious".[86]

## Society and culture

### Notable cases

Some notable historical and contemporary figures known to have had OCD are listed below.

- The American aviator and filmmaker Howard Hughes is known to have had OCD.[87] Friends of Hughes have also mentioned his obsession with minor flaws in clothing.[88] This was conveyed in the *The Aviator* (2004), a film biography of Hughes.[89]
- British poet, essayist, and lexicographer Samuel Johnson is an example of an historical figure with a retrospective diagnosis of OCD. He had elaborate rituals for crossing the thresholds of doorways, and repeatedly walked up and down staircases counting the steps.[90]

### Art, entertainment, and media

Movies and television shows often portray idealized representations of disorders such as OCD. These depictions may lead to increased public awareness, understanding, and sympathy for such

disorders.[91]

- In the film *As Good as it Gets* (1997), actor Jack Nicholson portrays a man "with Obsessive Compulsive Disorder (OCD)".[92] "Throughout the film, [he] engages in ritualistic behaviors (i.e., compulsions) that disrupt his interpersonal and professional life", a "cinematic representation of psychopathology [that] accurately depicts the functional interference and distress associated with OCD".[92]
- The film *Matchstick Men* (2003), directed by Ridley Scott, portrays a con-man named Roy (Nicolas Cage) who has obsessive-compulsive disorder. The film "opens with Roy, at home, suffering with his numerous obsessive compulsive symptoms, which take the form of a need for order and cleanliness and a compulsion to open and close doors three times, whilst counting aloud, before he can walk through them."[93]
- In the USA Network American comedy-drama detective mystery television series *Monk* (2002–2009), the titular Adrian Monk fears both human contact and dirt.[94][95]

This ribbon represents Trichotillomania and other body focused repetitive behaviors. Concept for the ribbon was started by Jenne Schrader. Colors were voted on by the Trichotillomania Facebook community, and made official by Trichotillomania Learning Center in August 2013

## Research

The naturally occurring sugar inositol has been suggested as a treatment for OCD.[96]

Nutrition deficiencies may also contribute to OCD and other mental disorders. Vitamin and mineral supplements may aid in such disorders and provide nutrients necessary for proper mental functioning.[97]

μ-Opioids, such as hydrocodone and tramadol, may improve OCD symptoms.[98] Administration of opiate treatment may be contraindicated in individuals concurrently taking CYP2D6 inhibitors such as fluoxetine and paroxetine.[99]

Much current research is devoted to the therapeutic potential of the agents that affect the release of the neurotransmitter glutamate or the binding to its receptors. These include riluzole,[51] memantine, gabapentin, N-acetylcysteine, topiramate and lamotrigine.[*citation needed*]

# Phobia

From Wikipedia, the free encyclopedia

*This article is about the clinical psychology. For other uses, see Phobia (disambiguation).*

A **phobia** is a type of anxiety disorder, defined by a persistent fear of an object or situation.[1] The phobia typically results in a rapid onset of fear and is present for more than six months. The affected person will go to great lengths to avoid the situation or object, typically to a degree greater than the actual danger posed. If the feared object or situation cannot be avoided, the affected person will have significant distress. With blood or injury phobia, fainting may occur.[1] Agoraphobia is often associated with panic attacks.[2] Usually a person has phobias to a number of objects or situations.[1]

Phobias can be divided into specific phobias, social phobia, and agoraphobia.[1][3] Types of specific phobias include to certain animals, natural environment situations, blood or injury, and specific situations.[1] The most common are fear of spiders, fear of snakes, and fear of heights.[4] Occasionally they are triggered by a negative experience with the object or situation. Social phobia is when the situation is feared as the person is worried about others judging them. Agoraphobia is when fear of a situation occurs because it is felt that escape would not be possible.[1]

Specific phobias should be treated with exposure therapy where the person is introduced to the situation or object in question until the fear resolves. Medications are not useful in this type of phobia.[3] Social phobia and agoraphobia are often treated with some combination of counselling and medication.[5][6] Medications used include antidepressants, benzodiazepines, or beta-blockers.[5]

Specific phobias affect about 6-8% of people in the Western world and 2-4% of people in Asian, Africa, and Latin America in a given year.[1] Social phobia affects about 7% of people in the United States and 0.5-2.5% of people in the rest of the world. Agoraphobia affects about 1.7% of people.[2] Women are affected about twice as often as men. Typically onset is around the age of 10 to 17. Rates become lower as people get older.[1][2] People with phobias are at a higher risk of suicide.[1]

Video explanation

# Classification [edit]

Most phobias are classified into three categories and, according to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-V), such phobias are considered to be sub-types of anxiety disorder. The categories are:

1. Specific phobias: Fear of particular objects or social situations that immediately results in anxiety and can sometimes lead to panic attacks. Specific phobia may be further subdivided into five categories: animal type, natural environment type, situational type, blood-injection-injury type, and other.[7]
2. Agoraphobia: a generalized fear of leaving home or a small familiar 'safe' area, and of possible panic attacks that might follow. It may also be caused by various specific phobias such as fear of open spaces, social embarrassment (social agoraphobia), fear of contamination (fear of germs, possibly complicated by obsessive-compulsive disorder) or PTSD (post traumatic stress disorder) related to a trauma that occurred out of doors.
3. Social phobia, also known as social anxiety disorder, is when the situation is feared as the person is worried about others judging them.[1]

Phobias vary in severity among individuals. Some individuals can simply avoid the subject of their fear and suffer relatively mild anxiety over that fear. Others suffer full-fledged panic attacks with all the associated disabling symptoms. Most individuals understand that they are suffering from an irrational fear, but are powerless to override their panic reaction. These individuals often report dizziness, loss of bladder or bowel control, tachypnea, feelings of pain, and shortness of breath.[8]

## Specific phobias [edit]

A specific phobia is a marked and persistent fear of an object or situation which brings about an excessive or unreasonable fear when in the presence of, or anticipating, a specific object; the specific phobias may also include concerns with losing control, panicking, and fainting which is the direct result of an encounter with the phobia.[9] Specific phobias are defined in relation to objects or situations whereas social phobias emphasize social fear and the evaluations that might accompany them.

The DSM breaks specific phobias into five subtypes: animal, natural environment, blood-injection-injury, situational, and other.[10] In children, phobias involving animals, natural environment (darkness), and blood-injection-injury usually develop between the ages of 7 and 9, and these are reflective of normal

development. Additionally, specific phobias are most prevalent in children between ages 10 and 13.[11]

## Social phobia [edit]

*See also: Social anxiety disorder*

Unlike specific phobias, social phobias include fear of public situations and scrutiny which leads to embarrassment or humiliation in the diagnostic criteria.

# Causes [edit]

## Environmental [edit]

Rachman proposed three pathways to acquiring fear conditioning: classical conditioning, vicarious acquisition and informational/instructional acquisition:[12]

Much of the progress in understanding the acquisition of fear responses in phobias can be attributed to classical conditioning (Pavlovian model).[13] When an aversive stimulus and a neutral one are paired together, for instance when an electric shock is given in a specific room, the subject can start to fear not only the shock but the room as well. In behavioral terms, this is described as a conditioned stimulus (CS) *(the room)* that is paired with an aversive unconditioned stimulus (UCS) *(the shock)*, which leads to a conditioned response (CR) *(fear for the room)* (CS+UCS=CR).[13] For instance, in case of the fear of heights (acrophobia), the CS is heights such as a balcony on the top floors of a high rise building. The UCS originates from an aversive or traumatizing event in the person's life, such as almost falling down from a great height. The original fear of almost falling down is associated with being on a high place, leading to a fear of heights. In other words, the CS *(heights)* associated with the aversive UCS *(almost falling down)* leads to the CR *(fear)*. This direct conditioning model, though very influential in the theory of fear acquisition, is not the only way to acquire a phobia.

Vicarious fear acquisition is learning to fear something, not by a subject's own experience of fear, but by watching others reacting fearfully (observational learning). For instance, when a child sees a parent reacting fearfully to an animal, the child can become afraid of the animal as well.[14] Through observational learning, humans are able to learn to fear potentially dangerous objects;a reaction which also been observed in non-human primates.[15] In a study focusing on non-human primates, results showed that the primates learned to fear snakes at a fast rate after observing parents' fearful reactions.[15] An increase of fearful behaviors was observed as the non-human primates continued to observe their parents' fearful reaction.[15] Even though observational learning has been proven to be effective in creating reactions of fear and phobias, it has also been shown that by physically experiencing an event, chances increase of fearful and phobic behaviors.[15] In some cases physically experiencing an event, may increase the fear and phobia more so than observing a fearful reaction of another human or non-human primate.

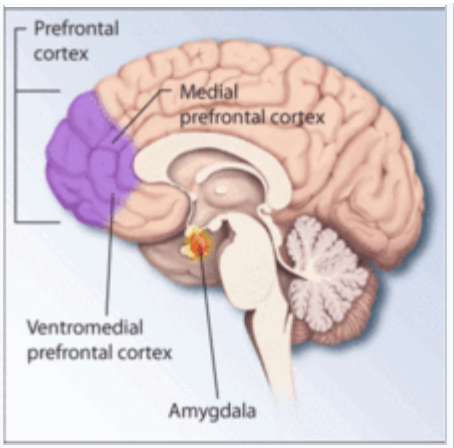
Informational/instructional fear acquisition is learning to fear something by getting information. For instance, fearing electrical wire after having heard that touching it will result in an electric shock.[16]

A conditioned fear response to an object or situation is not always a phobia. To meet the criteria for a phobia there must also be symptoms of impairment and avoidance. Impairment is defined as being unable to complete routine tasks whether occupational, academic or social. In acrophobia an impairment of occupation could result from not taking a job solely because of its location at the top floor of a building, or socially not participating in a social event at a theme park. The avoidance aspect is defined as behavior that results in the omission of an aversive event that would otherwise occur with the goal of the preventing anxiety.[17]

# Mechanism [edit]

Beneath the lateral fissure in the cerebral cortex, the insula, or insular

cortex, of the brain has been identified as part of the limbic system, along with cingulated gyrus, hippocampus, corpus callosum, and other nearby cortices. This system has been found to play a role in emotion processing[19] and the insula, in particular, may contribute through its role in maintaining autonomic functions.[20] Studies by Critchley et al. indicate the insula as being involved in the experience of emotion by detecting and interpreting threatening stimuli.[21] Similar studies involved in monitoring the activity of the insula show a correlation between increased insular activation and anxiety.[19]



Regions of the brain associated with phobias[18]

In the frontal lobes, other cortices involved with phobia and fear are the anterior cingulate cortex and the medial prefrontal cortex. In the processing of emotional stimuli, studies on phobic reactions to facial expressions have indicated these areas to be involved in processing and responding to negative stimuli.[22] The ventromedial prefrontal cortex has been said to influence the amygdala by monitoring its reaction to emotional stimuli or even fearful memories.[19] Most specifically, the medial prefrontal cortex is active during extinction of fear and is responsible for long term extinction. Stimulation of this area decreases conditioned fear responses and so its role may be in inhibiting the amygdala and its reaction to fearful stimuli.[23]

The hippocampus is a horseshoe shaped structure that plays an important part in the brain's limbic system because of its role in forming memories and connecting them with emotions and the senses. When dealing with fear, the hippocampus receives impulses from the amygdala that allows it to connect the fear with a certain sense, such as a smell or sound.

## Amygdala [edit]

The amygdala is an almond shaped mass of nuclei that is located deep in the brain's medial temporal lobe. It processes the events associated with fear and is being linked to social phobia and other anxiety disorders. The amygdala's ability to respond to fearful stimuli occurs through the process of fear conditioning. Similar to classical conditioning, the amygdala learns to associate a conditioned stimulus with a negative or avoidant stimulus, creating a conditioned fear response that is often seen in phobic individuals. In this way the amygdala is responsible for not only recognizing certain stimuli or cues as dangerous, but plays a role in the storage of threatening stimuli to memory. The basolateral nuclei (or basolateral amygdala) and the hippocampus interact with the amygdala in the storage of memory, which suggests why memories are often remembered more vividly if they have emotional significance.[24]

In addition to memory, the amygdala also triggers the secretion of hormones that affect fear and aggression. When the fear or aggression response is initiated, the amygdala releases hormones into the body to put the human body into an "alert" state, which prepares the individual to move, run, fight, etc.[25] This defensive "alert" state and response is generally referred to in psychology as the fight-or-flight response.[*citation needed*]

Inside the brain, however, this stress response can be observed in the hypothalamic-pituitary-adrenal axis (HPA).This circuit incorporates the process of receiving stimuli, interpreting it, and releasing certain hormones into the blood stream. The parvocellular neurosecretary neurons of the hypothalamus release corticotropin-releasing hormone(CRH) which is sent to the anterior pituitary. Here the pituitary releases adrenocorticotropic hormone (ACTH) which ultimately stimulates the release of cortisol. In relation to anxiety, the amygdala is responsible for activating this circuit, while the hippocampus is responsible for suppressing it. Glucocorticoid receptors in the hippocampus monitor the amount of cortisol in the system and through negative feedback can tell the hypothalamus to stop releasing CRH.[20]

Studies on mice engineered to have high concentrations of CRH showed higher levels of anxiety, while those engineered to have no or low amounts of CRH receptors were less anxious. In phobic patients, therefore, high amounts of cortisol may be present, or alternatively, there may be low levels of glucocorticoid receptors or even serotonin (5-HT).[20]

### Disruption by damage [edit]

For the areas in the brain involved in emotion—most specifically fear— the processing and response to emotional stimuli can be significantly altered when one of these regions becomes lesioned or damaged. Damage to the cortical areas involved in the limbic system such as the cingulate cortex or frontal lobes have resulted in extreme changes in emotion.[20] Other types of damage include Klüver–Bucy syndrome and Urbach–Wiethe disease. In Klüver–Bucy syndrome, a temporal lobectomy, or removal of the temporal lobes results in changes involving fear and aggression. Specifically, the removal of these lobes results in decreased fear, confirming its role in fear recognition and response. Bilateral damage to the medial temporal lobes, which is known as Urbach–Wiethe disease exhibits similar symptoms of decreased fear and aggression, but also an inability to recognize emotional expressions, especially angry or fearful faces.[20]

The amygdala's role in learned fear includes interactions with other brain regions in the neural circuit of fear. While lesions in the amygdala can inhibit its ability to recognize fearful stimuli, other areas such as the ventromedial prefrontal cortex and the basolateral nuclei of the amygdala can affect the region's ability to not only become conditioned to fearful stimuli, but to eventually extinguish them. The basolateral nuclei, through receiving stimulus info, undergo synaptic changes which allow the amygdala to develop a conditioned response to fearful stimuli. Lesions in this area, therefore, have been shown to disrupt the acquisition of learned responses to fear.[20] Likewise, lesions in the ventromedial prefrontal cortex (the area responsible for monitoring the amygdala) have been shown to not only slow down the speed of extinguishing a learned fear response, but also how effective or strong the extinction is. This suggests there is a pathway or circuit among the amygdala and nearby cortical areas that process emotional stimuli and influence emotional expression, all of which can be disrupted when an area becomes damaged.[19]

## Diagnosis [edit]

The terms *distress* and *impairment* as defined by the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV-TR) should also take into account the context of the person's environment if attempting a diagnosis. The DSM-IV-TR states that if a phobic stimulus, whether it be an object or a social situation, is absent entirely in an environment — a diagnosis cannot be made. An example of this situation would be an individual who has a fear of mice but lives in an area devoid of mice. Even though the concept of mice causes marked distress and impairment within the individual, because the individual does not encounter mice in the environment no actual distress or impairment is ever experienced. Proximity and the degree to which escape from the phobic stimulus is impossible should also be considered. As the person approaches a phobic stimulus, anxiety levels increase (e.g. as one gets closer to a snake, fear increases in ophidiophobia), and the degree to which escape of the phobic stimulus is limited has the effect of varying the intensity of fear in instances such as riding an elevator (e.g. anxiety increases at the midway point between floors and decreases when the floor is reached and the doors open).[26]

## Treatments [edit]

There are various methods used to treat phobias. These methods include: systematic desensitization, progressive relaxation, virtual reality, modeling, medications, and hypnotherapy.

### Therapy [edit]

Cognitive behavioral therapy (CBT) can be beneficial. Cognitive behavioral therapy allows the patient to challenge dysfunctional thoughts or beliefs by being mindful of their own feelings with the aim that the patient will realize their fear is irrational. CBT may be conducted in a group setting. Gradual desensitisation treatment and CBT are often successful, provided the patient is willing to endure some discomfort.[27][28] In one clinical trial, 90% of patients were observed to no longer have a phobic reaction after successful CBT treatment.[28][29][30][31]

CBT is also an effective treatment for phobias in children and adolescents, and it has been adapted to be

appropriate for use with this age. One example of a CBT program targeted towards children is the Coping Cat. This treatment program can be used with children between the ages of 7 and 13 to treat social phobia. This program works to decrease negative thinking, increase problem solving, and to provide a functional coping outlook in the child.[32] Another CBT program was developed by Ann Marie Albano to treat social phobia in adolescents. This program has five stages: Psychoeducation, Skill Building, Problem Solving, Exposure, and Generalization and Maintenance. Psycho education focuses on identifying and understanding symptoms. Skill Building focuses on learning cognitive restructuring, social skills, and problem solving skills. Problem Solving focuses on identifying problems and using a proactive approach to solving them. Exposure involves exposing the adolescent to social situations in a hierarchical approach. Finally, Generalization and Maintenance involves practicing the skills learned.[33]

Eye movement desensitization and reprocessing (EMDR) has been demonstrated in peer-reviewed clinical trials to be effective in treating some phobias. Mainly used to treat post-traumatic stress disorder, EMDR has been demonstrated as effective in easing phobia symptoms following a specific trauma, such as a fear of dogs following a dog bite.[34]

Another method psychologists and psychiatrists use to treat patients with extreme phobias is prolonged exposure. Prolonged exposure is used in psychotherapy when the person with the phobia is exposed to the object of their fear over a long period of time. This technique is only tested[*clarification needed*] when a person has overcome avoidance of or escape from the phobic object or situation. People with slight distress from their phobias usually do not need prolonged exposure to their fear.[35]

## Systematic desensitization [edit]

A method used in the treatment of a phobia is systematic desensitization, a process in which the patients seeking help slowly become accustomed to their phobia, and ultimately overcome it. Traditional systematic desensitization involves a person being exposed to the object they are afraid of over time, so that the fear and discomfort do not become overwhelming. This controlled exposure to the anxiety provoking stimulus is key to the effectiveness of exposure therapy in the treatment of specific phobia's. One form of systematic desensitization involves, humor. It has been shown that humor is an excellent alternative to the traditional systematic desensitization, when it does not efficiently rid someone of a phobia.[36] Humor systematic desensitization involves a series of treatment activities that consist of activities that elicit humor with the feared object.[36] Previously learned progressive muscle relaxation procedures can be used as the activities become more difficult in a person's own hierarchy level. Progressive muscle relaxation helps patients relax their muscles before and during exposures to the phobic object.

Participant modeling has been proven to be effective for children and adolescents. Participant modeling consists of a therapist modeling how the patients should respond to their fears.[37] This encourages the patients to practice this behavior and reinforces their efforts. Similar to systematic desensitization, patients are gradually introduced to the phobic objects. The main difference between participant modeling and systematic desensitization, involves observations and modeling. Participant modeling encompasses a therapist modeling positive behavior(s), observing the positive behavior(s), and gradual exposure to the phobic object.[37]

Virtual reality therapy is a type of therapy that helps patients imagine scenes with the phobic object, like systematic desensitization therapy. Using virtual reality, virtual reality therapy generates scenes that may not have been possible in the physical world. There are several advantages that virtual reality therapy has over systematic desensitization therapy: patients have the ability to control the scenes produced, patients can endure more phobic scenes (i.e. they may not be able to experience/handle these harsh scenes in real life), it is more realistic than simply imagining a scene, it occurs in a private room, and is very efficient.[38]

## Medications [edit]

Medications can help regulate the apprehension and fear that comes from thinking about or being exposed to a particular fearful object or situation. Antidepressant medications such as SSRIs or MAOIs may be helpful in some cases of phobia. SSRIs (antidepressants) act with serotonin, a neurotransmitter in the brain. Since serotonin impacts mood, patients may be prescribed an antidepressant. Another type of medication

used for treating patients with phobias are sedatives. Benzodiazepines are sedatives, which can help patients relax by reducing the amount of anxiety they feel.[39] Benzodiazepines may be useful in acute treatment of severe symptoms, but the risk-benefit ratio is against their long-term use in phobic disorders.[40] Though once believed to be highly addictive, these prescriptions have been recently shown as addictive if used with negative behaviors (i.e. alcohol abuse) .[39] Despite this recent positive finding, benzodiazepines should be used with caution. Beta blockers are another medication that can be used as a treatment for phobias. Beta blockers stop the stimulating effects of adrenaline in a person's body. These effects include: sweating, increased heart rate, elevated blood pressure, tremors, and the feeling of a pounding heart.[39] By taking beta blockers before a phobic event, these symptoms are decreased, causing the event to be less frightening.

### Hypnotherapy [edit]

Hypnotherapy can be used alone and in conjunction with systematic desensitization to treatment phobias.[41] Hypnotherapy can help people with phobias, resolve their issue, by uncovering the underlying cause of the phobia. The cause of phobias may be from a past event that the patient does not remember. When a traumatic event has occurred and the person who experienced it does not remember the event, the term is called repression. Repression is a mechanism our mind uses to keep the memory of the trauma out of our conscious mind until we are ready to deal with it. Hypnotherapy may also eliminate the conditioned responses that occur during different situations: the phobic object is within eyesight of the patient, the patient is placed in a phobic situation, or the patient is attempting to complete a phobic task. Patients are first placed into a hypnotic trance (i.e. an extremely relaxed state).[42] The unconscious can be retrieved during the hypnotic trance. This state allows for patients to be open to suggestion, which helps bring about a desired change.[42] Addressing old memories consciously helps individuals understand the event and see the event in a way which is no longer threatening.

## Epidemiology [edit]

Phobias are a common form of anxiety disorders and distributions are heterogeneous by age and gender. An American study by the National Institute of Mental Health (NIMH) found that between 8.7 percent and 18.1 percent of Americans suffer from phobias,[43] making it the most common mental illness among women in all age groups and the second most common illness among men older than 25. Between 4 percent and 10 percent of all children experience specific phobias during their lives,[11] and social phobias occur in one percent to three percent of children and adolescents.[*citation needed*]

A Swedish study found that females have a higher incidence than males (26.5 percent for females and 12.4 percent for males).[44] Among adults, 21.2 percent of women and 10.9 percent of men have a single specific phobia, while multiple phobias occur in 5.4 percent of females and 1.5 percent of males.[44] Women are nearly four times as likely as men to have a fear of animals (12.1 percent in women and 3.3 percent in men) — a higher dimorphic than with all specific or generalized phobias or social phobias.[44] Social phobias are more common in girls than in boys,[45] while situational phobia occurs in 17.4 percent of women and 8.5 percent of men.[44]

## Society and culture [edit]

### Terminology [edit]

*Main article: List of phobias*

The word *phobia* comes from the Greek: φόβος (*phóbos*), meaning "aversion", "fear", or "morbid fear". In popular culture, it is common for specific phobias to be given a name based on a Greek word for the object of the fear, plus the suffix *-phobia*. Creating these terms is something of a word game. Few of these terms are found in medical literature.[46] In ancient Greek mythology Phobos was the twin brother of Deimos

(terror).

The word *phobia* may also refer to conditions other than true phobias. For example, the term *hydrophobia* is an old name for rabies, since an aversion to water is one of that disease's symptoms. A specific phobia to water is called aquaphobia instead. A hydrophobe is a chemical compound which repels water. Similarly, the term *photophobia* usually refers to a physical complaint (aversion to light due to inflamed eyes or excessively dilated pupils), rather than an irrational fear of light.

## Non medical use [edit]

A number of terms with the suffix -phobia are used non-clinically. Examples include:

- Chemophobia – Negative attitudes and mistrust towards chemistry and synthetic chemicals.
- Xenophobia – Fear or dislike of strangers or the unknown, sometimes used to describe nationalistic political beliefs and movements.
- Homophobia – Negative attitudes and feelings toward homosexuality or people who are identified or perceived as being lesbian, gay, bisexual or transgender (LGBT).

Such terms are not phobias. They are derogatory terms for negative attitudes towards certain categories of people or other things, used in an invalid analogy with the medical usage of the term. These terms were coined with the purpose of shedding a negative light on the people within these opposing groups, by suggesting that everyone within has an irrational fear towards the objects of the terms. Usually these kinds of "phobias" are described as fear, dislike, disapproval, prejudice, hatred, discrimination, or hostility towards the object of the "phobia".[47]

"Fears are common in children and adolescents. However, for some youth, these fears persist and develop into specific phobias. A specific phobia is an intense, enduring fear of an identifiable object or situation that may lead to panic symptoms, distress, and avoidance (e.g., fears of dogs, snakes, storms, heights, costumed characters, the dark, and similar objects or situations). Moreover, phobias can affect a youngster's quality of life by interfering with school, family, friends, and free-time. It is estimated that 5% to 10% of youth will develop a phobia before reaching the age of 16."

# Posttraumatic stress disorder

From Wikipedia, the free encyclopedia

(Redirected from Post traumatic stress disorder)

*"PTSD" redirects here. For the album by Pharoahe Monch, see PTSD (album).*

**Posttraumatic stress disorder** (**PTSD**)[note 1] is a mental disorder that can develop after a person is exposed to a traumatic event, such as sexual assault, warfare, traffic collisions, or other threats on a person's life.[1] Symptoms may include disturbing thoughts, feelings, or dreams related to the events, mental or physical distress to trauma-related cues, attempts to avoid trauma-related cues, alterations in how a person thinks and feels, and increased arousal. These symptoms last for more than a month after the event. Young children are less likely to show distress but instead may express their memories through play.[1] Those with PTSD are at a higher risk of suicide.[2]

Most people who have experienced a traumatic event will not develop PTSD.[2] People who experience interpersonal trauma (for example rape or child abuse) are more likely to develop PTSD, as compared to people who experience non-assault based trauma such as accidents and natural disasters.[3] About half of people develop PTSD following rape.[2] Children are less likely than adults to develop PTSD after trauma, especially if they are under ten years of age.[4] Diagnosis is based on the presence of specific symptoms following a traumatic event.[2]

Prevention may be possible when therapy is targeted at those with early symptoms but is not effective when carried out among all people following trauma.[2] The main treatments for people with PTSD are counselling and medication.[5] A number of different types of therapy may be useful.[6] This may occur one-on-one or in a group.[5] Antidepressants of the selective serotonin reuptake inhibitor type are the first-line medications for PTSD and result in benefit in about half of people.[7] These benefits are less than those seen with therapy.[2] It is unclear if using medications and therapy together has greater benefit.[2][8] Other medications do not have enough evidence to support their use and in the case of benzodiazepines may worsen outcomes.[9][10]

In the United States about 3.5% of adults have PTSD in a given year, and 9% of people develop it at some point in their life.[1] In much of the rest of the world, rates during a given year are between 0.5% and 1%.[1] Higher rates may occur in regions of armed conflict.[2] It is more common in women than men.[5]

[edit on Wikidata]

Symptoms of trauma-related mental disorders have been documented since at least the time of the ancient Greeks.[11] During the World Wars study increased and it was known under various terms including "shell shock" and "combat neurosis".[12] The term "posttraumatic stress disorder" came into use in the 1970s in large part due to the diagnoses of US military veterans of the Vietnam War.[13] It was officially recognized by the American Psychiatric Association in 1980 in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III).[14]

Video explanation

# Classification

PTSD was classified as an anxiety disorder in the DSM-IV, but has since been reclassified as a "trauma- and stressor-related disorder" in the DSM-5. The characteristic symptoms are not present before exposure to the traumatic event. In the typical case, the individual with PTSD persistently avoids trauma-related thoughts and emotions, and discussion of the traumatic event, and may even have amnesia of the event. However, the event is commonly relived by the individual through intrusive, recurrent recollections, flashbacks, and nightmares.[15] While it is common to have symptoms after any traumatic event, these must persist to a sufficient degree (i.e., causing dysfunction in life or clinical levels of distress) for longer than one month after the trauma to be classified as PTSD (clinically significant dysfunction or distress for less than one month after the trauma may be acute stress disorder).[1][16][17][18]

# Risk factors

Persons considered at risk include, for example, combat military personnel, victims of natural disasters, concentration camp survivors, and victims of violent crime. Individuals frequently experience "survivor's guilt" for remaining alive while others died. Causes of the symptoms of PTSD are the experiencing or witnessing of a stressor event involving death, serious injury or such threat to the self or others in a situation in which the individual felt intense fear, horror, or powerlessness.[20] Persons employed in occupations that expose them to violence (such as soldiers) or disasters (such as emergency service workers) are also at risk.[20] Other occupations that are at higher risk, including police officers, firefighters, ambulance personnel, health care professionals, train drivers, divers, journalists, and sailors, in addition to people who work at banks, post offices or in stores.[21] The size of the hippocampus is inversely related to post-traumatic stress disorder and treatment success; the smaller the higher risk of PTSD.[22]

*No quieren (They do not want to)* by Francisco Goya (1746–1828) depicts an elderly woman wielding a knife in defense of a girl being assaulted by a soldier.[19]

## Trauma

*See also: Psychological resilience*

PTSD is believed to be caused by the experience of a wide range of traumatic events and, in particular if the trauma is extreme, can occur in persons with no predisposing conditions.[23][24] Most people will experience at least one traumatizing event in their lifetime.[25] Men are more likely to experience a traumatic event, but women are more likely to experience the kind of high-impact traumatic event that can lead to PTSD, such as interpersonal violence and sexual assault.[4]

Posttraumatic stress reactions have not been studied as well in children and adolescents as adults.[4] The rate of PTSD may be lower in children than adults, but in the absence of therapy, symptoms may continue for decades.[4] One estimate suggests that the proportion of children and adolescents having PTSD in a non-wartorn population in a developed country may be 1% compared to 1.5% to 3% of adults, and much lower below the age of 10 years.[4] On average, 16% of children exposed to a traumatic event develop PTSD, varying according to type of exposure and gender.[26]

Predictor models have consistently found that childhood trauma, chronic adversity, and familial stressors increase risk for PTSD as well as risk for biological markers of risk for PTSD after a traumatic event in adulthood.[27][28][29] Experiencing bullying as a child or an adult has been correlated with the development of PTSD.[30] Peritraumatic dissociation in children is a predictive indicator of the development of PTSD later in life.[31] This effect of childhood trauma, which is not well-understood, may be a marker for both traumatic experiences and attachment problems.[32][33] Proximity to, duration of, and severity of the trauma make an impact, and interpersonal traumas cause more problems than impersonal ones.[34]

Quasi-experimental studies have demonstrated a relationship between intrusive thoughts and intentional control responses such that suppression increases the frequency of unwanted intrusive thoughts. These results suggest that suppression of intrusive thoughts may be important in the development and maintenance of PTSD.[35]

## Foster care

Adults who were in foster care as children have a higher rate of PTSD.[*medical citation needed*]

## Domestic violence

An individual that has been exposed to domestic violence is predisposed to the development of PTSD.

However, being exposed to a traumatic experience does not automatically indicate that an individual will develop PTSD.[16] There is a strong association between the development of PTSD in mothers that experienced domestic violence during the perinatal period of their pregnancy.[36]

## Military experience

Early intervention appears to be a critical preventive measure.[37] Studies have shown that soldiers prepared for the potential of a traumatic experience are more prepared to deal with the stress of a traumatic experience and therefore less likely to develop PTSD.[16]

A U.S. Long-Range Patrol team leader in Vietnam, 1968.

Among American troops in Vietnam a greater portion of women experienced high levels of war-zone stress compared to theater men—39.9 percent versus 23.5 percent. The key to this fact is that the vast majority (6,250 or 83.3%) of the women who served in the war zone were nurses who dealt almost daily with death. Black veterans had nearly 2.5 fold the risk of developing war zone-related PTSD as compared to white/other veterans. Hispanics had more than three times the risk. But the most revealing fact, theater veterans injured or wounded in combat had nearly four times the risk of developing PTSD compared to those not injured/wounded according to two key studies—the August 2014 *National Vietnam Veterans Longitudinal Study* (NVVLS). Paired with the late 1980s *National Vietnam Veterans Readjustment Study* (NVVRS).[38]

The long-term medical consequence of PTSD among male veterans who served in the Vietnam War was that they were almost twice as likely to die in the quarter of a century between the two key studies than those who did not have PTSD. PTSD can have numerous clinical and occupational effects. It was also found those with PTSD were more likely to die of chronic conditions such as cancer, nervous system disorders, and musculoskeletal problems. The etiology of this relationship is not certain other than lingering stress from combat such as nightmares, intrusive memories, and hyper-vigilance are aggravating factors contributing to psychological and physiological illnesses.[38]

The racial similarity between Hispanic and Vietnamese soldiers, and the discrimination Hispanic soldiers faced from their own military, made it difficult for Hispanic soldiers to dehumanize their enemy. Hispanic veterans who reported experiencing racial discrimination during their service displayed more symptoms of PTSD than Hispanic veterans who did not.[39]

PTSD is under-diagnosed in female veterans.[40] Sexual assault in the military is a leading cause for female soldiers developing PTSD; a female soldier who is sexually assaulted while serving in the military is nine times more likely to develop PTSD than a female soldier who is not assaulted. A soldier's assailant may be her colleague or superior officer, making it difficult for her to both report the crime and to avoid interacting with her assailant again.[41] Until the Tailhook scandal drew attention to the problem, the role that sexual assault in the military plays in female veterans developing PTSD went largely unstudied.[42]

Protective effects include social support, which also helps with recovery if PTSD develops.[43][44] For more aggravating factors to recovery once home, see social alienation among returning war veterans.

## Genetics

*Main article: Genetics of posttraumatic stress disorder*

There is evidence that susceptibility to PTSD is hereditary. Approximately 30% of the variance in PTSD is caused from genetics alone. For twin pairs exposed to combat in Vietnam, having a monozygotic (identical) twin with PTSD was associated with an increased risk of the co-twin's having PTSD compared to twins that were dizygotic (non-identical twins).[45] There is evidence that those with a genetically smaller

hippocampus are more likely to develop PTSD following a traumatic event. Research has also found that PTSD shares many genetic influences common to other psychiatric disorders. Panic and generalized anxiety disorders and PTSD share 60% of the same genetic variance. Alcohol, nicotine, and drug dependence share greater than 40% genetic similarities.[31]

Several biological indicators have been identified that are related to later PTSD development. Heightened startle responses and a smaller hippocampal volume have been identified as biomarkers for the risk of developing PTSD.[22] Additionally, one study found that soldiers whose leukocytes had greater numbers of glucocorticoid receptors were more prone to developing PTSD after experiencing trauma.[46]

### Drug and substance abuse

Drug abuse and alcohol abuse commonly co-occur with PTSD.[47] Recovery from posttraumatic stress disorder or other anxiety disorders may be hindered, or the condition worsened, by medication or substance use; resolving these problems can bring about improvement in an individual's mental health status and anxiety levels.[48][49]

## Pathophysiology

### Neuroendocrinology

PTSD symptoms may result when a traumatic event causes an over-reactive adrenaline response, which creates deep neurological patterns in the brain. These patterns can persist long after the event that triggered the fear, making an individual hyper-responsive to future fearful situations.[16][50] During traumatic experiences the high levels of stress hormones secreted suppress hypothalamic activity that may be a major factor toward the development of PTSD.[51]

PTSD causes biochemical changes in the brain and body, that differ from other psychiatric disorders such as major depression. Individuals diagnosed with PTSD respond more strongly to a dexamethasone suppression test than individuals diagnosed with clinical depression.[52][53]

Most people with PTSD show a low secretion of cortisol and high secretion of catecholamines in urine,[54] with a norepinephrine/cortisol ratio consequently higher than comparable non-diagnosed individuals.[55] This is in contrast to the normative fight-or-flight response, in which both catecholamine and cortisol levels are elevated after exposure to a stressor.[56]

Brain catecholamine levels are high,[57] and corticotropin-releasing factor (CRF) concentrations are high.[58][59] Together, these findings suggest abnormality in the hypothalamic-pituitary-adrenal (HPA) axis.

The maintenance of fear has been shown to include the HPA axis, the locus coeruleus-noradrenergic systems, and the connections between the limbic system and frontal cortex. The HPA axis that coordinates the hormonal response to stress,[60] which activates the LC-noradrenergic system, is implicated in the over-consolidation of memories that occurs in the aftermath of trauma.[61] This over-consolidation increases the likelihood of one's developing PTSD. The amygdala is responsible for threat detection and the conditioned and unconditioned fear responses that are carried out as a response to a threat.[31]

The HPA axis is responsible for coordinating the hormonal response to stress.[31] Given the strong cortisol suppression to dexamethasone in PTSD, HPA axis abnormalities are likely predicated on strong negative feedback inhibition of cortisol, itself likely due to an increased sensitivity of glucocorticoid receptors.[62] PTSD has been hypothesized to be a maladaptive learning pathway to fear response through a hypersensitive, hyperreactive, and hyperresponsive HPA axis.[63]

Low cortisol levels may predispose individuals to PTSD: Following war trauma, Swedish soldiers serving in Bosnia and Herzegovina with low pre-service salivary cortisol levels had a higher risk of reacting with PTSD symptoms, following war trauma, than soldiers with normal pre-service levels.[64] Because cortisol is normally important in restoring homeostasis after the stress response, it is thought that trauma survivors

with low cortisol experience a poorly contained—that is, longer and more distressing—response, setting the stage for PTSD.

It is thought that the locus coeruleus-noradrenergic system mediates the over-consolidation of fear memory. High levels of cortisol reduce noradrenergic activity, and because people with PTSD tend to have reduced levels of cortisol, it has been proposed that individuals with PTSD cannot regulate the increased noradrenergic response to traumatic stress.[65] Intrusive memories and conditioned fear responses are thought to be a result of the response to associated triggers. Neuropeptide Y has been reported to reduce the release of norepinephrine and has been demonstrated to have anxiolytic properties in animal models. Studies have shown people with PTSD demonstrate reduced levels of NPY, possibly indicating their increased anxiety levels.[31]

Other studies indicate that people that suffer from PTSD have chronically low levels of serotonin, which contributes to the commonly associated behavioral symptoms such as anxiety, ruminations, irritability, aggression, suicidality, and impulsivity.[66] Serotonin also contributes to the stabilization of glucocorticoid production.

Dopamine levels in a person with PTSD can help contribute to the symptoms associated. Low levels of dopamine can contribute to anhedonia, apathy, impaired attention, and motor deficits. Increased levels of dopamine can cause psychosis, agitation, and restlessness.[66]

Hyperresponsiveness in the norepinephrine system can be caused by continued exposure to high stress. Overactivation of norepinephrine receptors in the prefrontal cortex can be connected to the flashbacks and nightmares frequently experienced by those with PTSD. A decrease in other norepinephrine functions (awareness of the current environment) prevents the memory mechanisms in the brain from processing that the experience, and emotions the person is experiencing during a flashback are not associated with the current environment.[66]

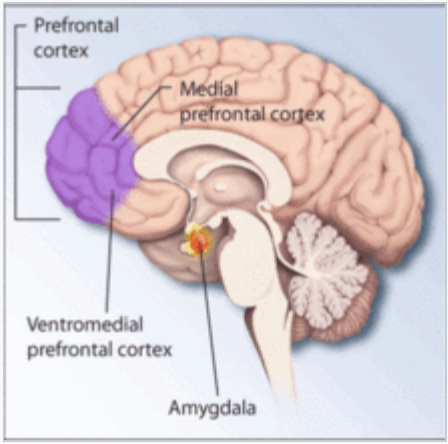
There is considerable controversy within the medical community regarding the neurobiology of PTSD. A 2012 review showed no clear relationship between cortisol levels and PTSD. The majority of reports indicate people with PTSD have elevated levels of corticotropin-releasing hormone, lower basal cortisol levels, and enhanced negative feedback suppression of the HPA axis by dexamethasone.[31][67]

## Neuroanatomy

The three brain areas with changed function are the prefrontal cortex, amygdala, and hippocampus. Much of this research stems from PTSD victims from the Vietnam War.

For example, a prospective study using the Vietnam Head Injury Study showed that damage to the prefrontal cortex may be protective against later development of PTSD.[69] PTSD patients have decreased brain activity in the dorsal and rostral anterior cingulate cortices and the ventromedial prefrontal cortex, areas linked to the experience and regulation of emotion.[70]

The amygdala is strongly involved in forming emotional memories, especially fear-related memories. Neuroimaging studies in humans have revealed aspects of PTSD morphology and function.[71] During high stress, the hippocampus, which is associated with placing memories in the correct context of space and time and memory recall, is suppressed. According to one theory this suppression may be the cause of the flashbacks that can affect people with PTSD. When someone with PTSD undergoes stimuli similar to the traumatic event, the body perceives the event as occurring again because the memory was never properly recorded in the person's memory.[31][72][*unreliable medical source?*]



Regions of the brain associated with stress and posttraumatic stress disorder[68]

The amygdalocentric model of PTSD proposes that the amygdala is very much aroused and insufficiently controlled by the medial prefrontal cortex and the hippocampus, in particular during extinction.[73] This is

consistent with an interpretation of PTSD as a syndrome of deficient extinction ability.[73][74]

A 2011 study found that fear extinction-induced IGF2/IGFBP7 signalling promotes the survival of hippocampal neurons in 2-3 week old newborn mice. This suggests that enhancing IGF2 signalling and adult neurogenesis might be suitable to treat diseases linked to excessive fear memory such as PTSD.[75] Further animal and clinical research into the amygdala and fear conditioning may suggest additional treatments for the condition.

The basolateral nucleus (BLA) of the amygdala is responsible for the comparison and development of associations between unconditioned and conditioned responses to stimuli, which results in the fear conditioning present in PTSD. The BLA activates the central nucleus (CeA) of the amygdala, which elaborates the fear response, (including behavioral response to threat and elevated startle response). Descending inhibitory inputs from the medial prefrontal cortex (mPFC) regulate the transmission from the BLA to the CeA, which is hypothesized to play a role in the extinction of conditioned fear responses.[31]

In a 2007 study Vietnam War combat veterans with PTSD showed a 20% reduction in the volume of their hippocampus compared with veterans having suffered no such symptoms.[76] This finding was not replicated in chronic PTSD patients traumatized at an air show plane crash in 1988 (Ramstein, Germany).[77] A 2016 study strengthened theory that a smaller hippocampus increases the risk for post-traumatic stress disorder, and a larger hippocampus increases the likelihood efficacious treatment.[78]

# Diagnosis

PTSD can be particularly difficult to diagnose, because numerous factors can lead to over-reporting (e.g., disability) and under-reporting (e.g., avoidance) symptoms, dysfunction and distress.

## Screening and assessment

A number of screening instruments are used for screening adults for PTSD, as well as youth, such as the UCLA PTSD Index for DSM-IV.[79] The Primary Care PTSD Screen,[80][81] PTSD Checklist,[82][83][84] GAD-7,[85] Child PTSD Symptom Scale,[86] and M3 Checklist[87] are other screening tools.[25][88]

The U.S. Department of Veterans Affairs' Evidence-based Synthesis Program published an exhaustive systematic review of studies about PTSD screening instruments, fully reviewing 15 of the highest quality studies. There were a total of 12 PTSD screening tools reviewed, 7 that screen for only PTSD and 5 that "screen for the psychiatric disorders commonly encountered and treated by primary care providers". The authors divided these into brief, intermediate, and multiple condition screens.[25] The brief screens (SIPS, ADD, and PDI-4A) were least useful due to poor discrimination. Of the intermediate screens (Breslau, M3,[87] PC-PTSD,[81] and SPAN), their performances were "comparable." The most used screen, the PCL (or PTSD Checklist),[84] was the longest one (17 items) and had the most variability in cut points across various clinical populations. While the 5 multidimensional screens—those that screened for multiple psychiatric conditions—performed less well than the PTSD-only screens, "this might be preferable, as 'false positives' on [multidimensional] screens may reflect psychiatric symptomatology requiring further evaluation." Of these multidimensional screens, "the M-3 performed better than the GAD-7 at identifying probable cases of PTSD." The M3 uses a "two-staged screening approach" that also assesses for depression, bipolar, and anxiety disorders. The study concludes with recommendations for future research.[25]

The American Academy of Child and Adolescent Psychiatry has a practice guideline for the assessment and treatment of PTSD in children and adolescents.[89] The American Psychiatric Association has a more general practice guideline for the assessment and management of acute stress disorder and PTSD.[90]

A revised form of the *Impact of Events* scale (IES-R) gives a total score ranging from 0 to 88.[91] A score of 24 or more confers a clinical concern for PTSD, and a score of 33 is suggested to represent the best cutoff for a probable diagnosis of PTSD.[92]

## Diagnostic and statistical manual

Since the introduction of DSM-IV, the number of possible events that might be used to diagnose PTSD has increased; one study suggests that the increase is around 50%.[93] Various scales to measure the severity and frequency of PTSD symptoms exist.[94][95] Standardized screening tools such as Trauma Screening Questionnaire[96] and PTSD Symptom Scale[97] can be used to detect possible symptoms of posttraumatic stress disorder and suggest the need for a formal diagnostic assessment.

In the May 2013 DSM-5, PTSD was classified as a trauma- and stress-related disorder.[1]

## International classification of diseases

The diagnostic criteria for PTSD, stipulated in the International Statistical Classification of Diseases and Related Health Problems 10 (ICD-10), may be summarized as:[98]

- Exposure to a stressful event or situation (either short or long lasting) of exceptionally threatening or catastrophic nature, which is likely to cause pervasive distress in almost anyone.
- Persistent remembering, or "reliving" the stressor by intrusive flashbacks, vivid memories, recurring dreams, or by experiencing distress when exposed to circumstances resembling or associated with the stressor.
- Actual or preferred avoidance of circumstances resembling or associated with the stressor (not present before exposure to the stressor).
- Either (1) or (2):
  1. Inability to recall, either partially or completely, some important aspects of the period of exposure to the stressor
  2. Persistent symptoms of increased psychological sensitivity and arousal (not present before exposure to the stressor) shown by any two of the following:
- difficulty in falling or staying asleep
- irritability or outbursts of anger
- difficulty in concentrating
- hyper-vigilance
- exaggerated startle response.

The International Statistical Classification of Diseases and Related Health Problems 10 diagnostic guidelines state:[98] In general, this disorder should not be diagnosed unless there is evidence that it arose within 6 months of a traumatic event of exceptional severity. A "probable" diagnosis might still be possible if the delay between the event and the onset was longer than 6 months, provided that the clinical manifestations are typical and no alternative identification of the disorder (e.g., as an anxiety or obsessive-compulsive disorder or depressive episode) is plausible. In addition to evidence of trauma, there must be a repetitive, intrusive recollection or re-enactment of the event in memories, daytime imagery, or dreams. Conspicuous emotional detachment, numbing of feeling, and avoidance of stimuli that might arouse recollection of the trauma are often present but are not essential for the diagnosis. The autonomic disturbances, mood disorder, and behavioural abnormalities all contribute to the diagnosis but are not of prime importance. The late chronic sequelae of devastating stress, i.e. those manifest decades after the stressful experience, should be classified under F62.0.

## Differential diagnosis

A diagnosis of PTSD requires that the person has been exposed to an extreme stressor such as one that is life-threatening. Any stressor can result in a diagnosis of adjustment disorder and it is an appropriate diagnosis for a stressor and a symptom pattern that does not meet the criteria for PTSD, for example a partner being fired, or a spouse leaving. If any of the symptom pattern is present before the stressor, another diagnosis is required, such as brief psychotic disorder or major depressive disorder. Other differential diagnoses are schizophrenia or other disorders with psychotic features such as Psychotic disorders due to a general medical condition. Drug-induced psychotic disorders can be considered if substance abuse is involved.[15]

The symptom pattern for acute stress disorder must occur and be resolved within four weeks of the trauma. If it lasts longer, and the symptom pattern fits that characteristic of PTSD, the diagnosis may be changed.[15]

Obsessive compulsive disorder may be diagnosed for intrusive thoughts that are recurring but not related to a specific traumatic event.[15]

# Prevention

*See also: Traumatic memories*

Modest benefits have been seen from early access to cognitive behavioral therapy.[99] Critical incident stress management has been suggested as a means of preventing PTSD, but subsequent studies suggest the likelihood of its producing negative outcomes.[100][101] A review "...did not find any evidence to support the use of an intervention offered to everyone", and that "...multiple session interventions may result in worse outcome than no intervention for some individuals."[102] The World Health Organization recommends against the use of benzodiazepines and antidepressants in those having experienced trauma.[103] Some evidence supports the use of hydrocortisone for prevention in adults, however there is limited or no evidence supporting propranolol, escitalopram, temazepam, or gabapentin.[104]

## Psychological debriefing

Trauma-exposed individuals often receive treatment called *psychological debriefing* in an effort to prevent PTSD.[99] Several meta-analyses; however, find that psychological debriefing is unhelpful and is potentially harmful.[99][105][106] This is true for both single-session debriefing and multiple session interventions.[102] The American Psychological Association judges the status of psychological debriefing as *No Research Support/Treatment is Potentially Harmful*.[107]

Psychological debriefing was in the past, however, the most often used preventive measure, partly because of the relative ease with which this treatment can be given to individuals directly following an event. It consists of interviews that are meant to allow individuals to directly confront the event and share their feelings with the counselor and to help structure their memories of the event. This treatment has since been found to be potentially harmful.[99]

## Risk-targeted interventions

*For one such method, see trauma risk management.*

Risk-targeted interventions are those that attempt to mitigate specific formative information or events. It can target modeling normal behaviors, instruction on a task, or giving information on the event.[108][109]

# Management

*Further information: Treatments for combat-related PTSD*

Systematic reviews have found that combination therapy (psychological and pharmacotherapy) is no more effective than psychological therapy alone.[110]

## Psychotherapy

Many forms of psychotherapy have been found to be efficacious for trauma-related problems such as PTSD. Basic counseling practices common to many treatments for PTSD include education about the condition, and provision of safety and support.[16][97]

help veterans with PTSD

The psychotherapy programs with the strongest demonstrated efficacy include cognitive behavioral programs, variants of exposure therapy[*citation needed*], stress inoculation training (SIT), variants of cognitive therapy (CT), eye movement desensitization and reprocessing (EMDR),[111] mindfulness-based meditation[112] and many combinations of these procedures.[113] EMDR and trauma-focused cognitive behavioral therapy (TFCBT) were recommended as first-line treatments for trauma victims in a 2007 review; however, "the evidence base [for EMDR] was not as strong as that for TFCBT ... Furthermore, there was limited evidence that TFCBT and EMDR were superior to supportive/non-directive treatments, hence it is highly unlikely that their effectiveness is due to non-specific factors such as attention."[114] A meta-analytic comparison of EMDR and cognitive behavioral therapy found both protocols indistinguishable in terms of effectiveness in treating PTSD; however, "the contribution of the eye movement component in EMDR to treatment outcome" is unclear.[115]

Furthermore, the availability of school-based therapy is particularly important for children with PTSD. Children with PTSD are far more likely to pursue treatment at school (because of its proximity and ease) than at a free clinic.[116]

## Cognitive behavioral therapy

Cognitive behavioral therapy (CBT) seeks to change the way a trauma victim feels and acts by changing the patterns of thinking or behavior, or both, responsible for negative emotions. CBT has been proven to be an effective treatment for PTSD and is currently considered the standard of care for PTSD by the United States Department of Defense.[117][118] In CBT, individuals learn to identify thoughts that make them feel afraid or upset and replace them with less distressing thoughts. The goal is to understand how certain thoughts about events cause PTSD-related stress.

Recent research on contextually based third-generation behavior therapies suggests that they may produce results comparable to some of the better validated therapies.[119] Many of these therapy methods have a significant element of exposure[120] and have demonstrated success in treating the primary problems of PTSD and co-occurring depressive symptoms.[121]

Exposure therapy is a type of cognitive behavioral therapy[122] that involves assisting trauma survivors to re-experience distressing trauma-related memories and reminders in order to facilitate habituation and successful emotional processing of the trauma memory. Most exposure therapy programs include both imaginal confrontation with the traumatic memories and real-life exposure to trauma reminders; this therapy modality is well supported by clinical evidence[*citation needed*]. The success of exposure-based therapies has raised the question of whether exposure is a necessary ingredient in the treatment of PTSD.[123] Some organizations[*which?*] have endorsed the need for exposure.[124][125] The US Department of Veterans Affairs has been actively training mental health treatment staff in prolonged exposure therapy[126] and Cognitive Processing Therapy[127] in an effort to better treat US veterans with PTSD.

## Eye movement desensitization and reprocessing

*Main article: Eye movement desensitization and reprocessing*

Eye movement desensitization and reprocessing (EMDR) is a form of psychotherapy developed and studied by Francine Shapiro.[128] She had noticed that, when she was thinking about disturbing memories herself, her eyes were moving rapidly. When she brought her eye movements under control while thinking, the thoughts were less distressing.[128]

In 2002, Shapiro and Maxfield published a theory of why this might work, called adaptive information processing.[129] This theory proposes that eye movement can be used to facilitate emotional processing of memories, changing the person's memory to attend to more adaptive information.[130] The therapist initiates voluntary rapid eye movements while the person focuses on memories, feelings or thoughts about a particular trauma.[4][131] The therapists uses hand movements to get the person to move their eyes backward and forward, but hand-tapping or tones can also be used.[4] EMDR closely resembles cognitive

behavior therapy as it combines exposure (re-visiting the traumatic event), working on cognitive processes and relaxation/self-monitoring.[4] However, exposure by way of being asked to think about the experience rather than talk about it has been highlighted as one of the more important distinguishing elements of EMDR.[132]

There have been multiple small controlled trials of four to eight weeks of EMDR in adults[133] as well as children and adolescents.[131] EMDR reduced PTSD symptoms enough in the short term that one in two adults no longer met the criteria for PTSD, but the number of people involved in these trials was small.[133] There was not enough evidence to know whether or not EMDR could eliminate PTSD.[133] There was some evidence that EMDR might prevent depression.[133] There were no studies comparing EMDR to other psychological treatments or to medication.[133] Adverse effects were largely unstudied.[133] The benefits were greater for women with a history of sexual assault compared with people who had experienced other types of traumatizing events (such as accidents, physical assaults and war). There is a small amount of evidence that EMDR may improve re-experiencing symptoms in children and adolescents, but EMDR has not been shown to improve other PTSD symptoms, anxiety, or depression.[131]

The eye movement component of the therapy may not be critical for benefit.[4][130] As there has been no major, high quality randomized trial of EMDR with eye movements versus EMDR without eye movements, the controversy over effectiveness is likely to continue.[132] Authors of a meta-analysis published in 2013 stated, "We found that people treated with eye movement therapy had greater improvement in their symptoms of post-traumatic stress disorder than people given therapy without eye movements….Secondly we found that that in laboratory studies the evidence concludes that thinking of upsetting memories and simultaneously doing a task that facilitates eye movements reduces the vividness and distress associated with the upsetting memories."[111]

## Interpersonal psychotherapy

Other approaches, in particular involving social supports,[43][44] may also be important. An open trial of interpersonal psychotherapy[134] reported high rates of remission from PTSD symptoms without using exposure.[135] A current, NIMH-funded trial in New York City is now (and into 2013) comparing interpersonal psychotherapy, prolonged exposure therapy, and relaxation therapy.[136][*full citation needed*][137][138]

## Medication

While many medications do not have enough evidence to support their use, three (fluoxetine, paroxetine, and venlafaxine) have been shown to have a small benefit over placebo.[10] This study concluded that "the drugs included were well tolerated overall." With many medications, residual PTSD symptoms following treatment is the rule rather than the exception.[139]

## Antidepressants

Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) may have some benefit for PTSD symptoms.[10][140] Tricyclic antidepressants are equally effective but are less well tolerated.[141] Evidence provides support for a small or modest improvement with sertraline, fluoxetine, paroxetine, and venlafaxine.[10][142] Thus, these four medications are considered to be first-line medications for PTSD.[140][143]

## Benzodiazepines

Benzodiazepines are not recommended for the treatment of PTSD due to a lack of evidence of benefit and risk of worsening PTSD symptoms.[144] Some authors believe that the use of benzodiazepines is contraindicated for acute stress, as this group of drugs promotes dissociation and ulterior revivals.[145] Nevertheless, some use benzodiazepines with caution for short-term anxiety and insomnia.[146][147][148]

While benzodiazepines can alleviate acute anxiety, there is no consistent evidence that they can stop the development of PTSD and may actually increase the risk of developing PTSD 2-5 times.[9] Additionally, benzodiazepines may reduce the effectiveness of psychotherapeutic interventions, and there is some evidence that benzodiazepines may actually contribute to the development and chronification of PTSD. For those who already have PTSD, benzodiazepines may worsen and prolong the course of illness, by worsening psychotherapy outcomes, and causing or exacerbating aggression, depression (including suicidality), and substance use.[9] Drawbacks include the risk of developing a benzodiazepine dependence, tolerance (i.e., short-term benefits wearing off with time), and withdrawal syndrome; additionally, individuals with PTSD (even those without a history of alcohol or drug misuse) are at an increased risk of abusing benzodiazepines.[143][149] Due to a number of other treatments with greater efficacy for PTSD and less risks (e.g., prolonged exposure, cognitive processing therapy, eye movement desensitization and reprocessing, cognitive restructuring therapy, trauma-focused cognitive behavioral therapy, brief eclectic psychotherapy, narrative therapy, stress inoculation training, serotonergic antidepressants, adrenergic inhibitors, antipsychotics, and even anticonvulsants), benzodiazepines should be considered relatively contraindicated until all other treatment options are exhausted.[6][150] For those who argue that benzodiazepines should be used sooner in the most severe cases, the adverse risk of disinhibition (associated with suicidality, aggression and crimes) and clinical risks of delaying or inhibiting definitive efficacious treatments, make other alternative treatments preferable (e.g., inpatient, residential, partial hospitalization, intensive outpatient, dialectic behavior therapy; and other fast-acting sedating medications such as trazodone, mirtazapine, amitripytline, doxepin, prazosin, propranolol, guanfacine, clonidine, quetiapine, olanzapine, valproate, gabapentin).[7][150][151]

### Glucocorticoids

Glucocorticoids may be useful for short-term therapy to protect against neurodegeneration caused by the extended stress response that characterizes PTSD, but long-term use may actually promote neurodegeneration.[152]

### Cannabinoids

There is tentative evidence that medical cannabis may be effective at reducing PTSD symptoms, but, as of as of 2015, there is insufficient evidence to confirm its effectiveness for this condition.[153][154] Despite the uncertain evidence, use of cannabis or derived products is widespread among US veterans with PTSD.[155]

The cannabinoid nabilone is sometimes used off-label for nightmares in PTSD. Although some short-term benefit was shown, adverse effects are common and it has not been adequately studied to determine efficacy.[156] Additionally, there are other treatments with stronger efficacy and less risks (e.g., psychotherapy, serotonergic antidepressants, adrenergic inhibitors). The use of medical marijuana for PTSD is controversial, with only a handful of states permitting its use for that purpose.[157]

## Other

### Exercise, sport and physical activity

Physical activity can influence people's psychological wellbeing[158] and physical health.[159] The U.S. National Center for PTSD recommends moderate exercise as a way to distract from disturbing emotions, build self-esteem and increase feelings of being in control again. They recommend a discussion with a doctor before starting an exercise program.[160]

### Play therapy for children

Play is thought to help children link their inner thoughts with their outer world, connecting real experiences with abstract thought.[161] Repetitive play can also be one of the ways a child relives traumatic events, and that can be a symptom of traumatization in a child or young person.[162] Although it is commonly used, there have not been enough studies comparing outcomes in groups of children receiving and not receiving

play therapy, so the effects of play therapy are not yet understood.[4][161]

### Military programs

Many veterans of the wars in Iraq and Afghanistan have faced significant physical, emotional, and relational disruptions. In response, the United States Marine Corps has instituted programs to assist them in re-adjusting to civilian life, especially in their relationships with spouses and loved ones, to help them communicate better and understand what the other has gone through.[163] Walter Reed Army Institute of Research (WRAIR) developed the Battlemind program to assist service members avoid or ameliorate PTSD and related problems.

## Epidemiology

There is debate over the rates of PTSD found in populations, but, despite changes in diagnosis and the criteria used to define PTSD between 1997 and 2007, epidemiological rates have not changed significantly.[165]

The United Nations' World Health Organization publishes estimates of PTSD impact for each of its member states; the latest data available are for 2004. Considering only the 25 most populated countries ranked by overall age-standardized Disability-Adjusted Life Year (DALY) rate, the top half of the ranked list is dominated by Asian/Pacific countries, the US, and Egypt.[166] Ranking the countries by the male-only or female-only rates produces much the same result, but with less meaningfulness, as the score range in the single-sex rankings is much-reduced (4 for women, 3 for men, as compared with 14 for the overall score range), suggesting that the differences between female and male rates, within each country, is what drives the distinctions between the countries.[167][168]

## United States

The National Comorbidity Survey Replication has estimated that the lifetime prevalence of PTSD among adult Americans is 6.8%, with women (9.7%) more than twice as likely as men[66] (3.6%) to have PTSD at some point in their lives.[169] More than 60% of men and more than 60% of women experience at least one traumatic event in their life. The most frequently reported traumatic events by men are rape, combat, and childhood neglect or physical abuse. Women most frequently report instances of rape, sexual molestation, physical attack, being threatened with a weapon and childhood physical abuse.[66] 88% of men and 79% of women with lifetime PTSD have at least one comorbid psychiatric disorder. Major depressive disorder, 48% of men and 49% of women, and lifetime alcohol abuse or dependence, 51.9% of men and 27.9% of women, are the most common comorbid disorders.[170]

The United States Department of Veterans Affairs estimates that 830,000 Vietnam War veterans suffered symptoms of PTSD.[171] The *National Vietnam Veterans' Readjustment Study* (NVVRS) found 15.2% of male and 8.5% of female Vietnam veterans to suffer from current PTSD at the time of the study. Life-Time prevalence of PTSD was 30.9% for males and 26.9% for females. In a reanalysis of the NVVRS data, along with analysis of the data from the Matsunaga Vietnam Veterans Project, Schnurr, Lunney, Sengupta, and Waelde found that, contrary to the initial analysis of the NVVRS data, a large majority of Vietnam veterans suffered from PTSD symptoms (but not the disorder itself). Four out of five reported recent symptoms when interviewed 20–25 years after Vietnam.[172]

A 2011 study from Georgia State University and San Diego State University found that rates of PTSD diagnosis increased significantly when troops were stationed in combat zones, had tours of longer than a year, experienced combat, or were injured. Military personnel serving in combat zones were 12.1

percentage points more likely to receive a PTSD diagnosis than their active-duty counterparts in non-combat zones. Those serving more than 12 months in a combat zone were 14.3 percentage points more likely to be diagnosed with PTSD than those having served less than one year. Experiencing an enemy firefight was associated a 18.3 percentage point increase in the probability of PTSD, while being wounded or injured in combat was associated a 23.9 percentage point increase in the likelihood of a PTSD diagnosis. For the 2.16 million U.S. troops deployed in combat zones between 2001 and 2010, the total estimated two-year costs of treatment for combat-related PTSD are between $1.54 billion and $2.69 billion.[173]

As of 2013, rates of PTSD have been estimated at up to 20% for veterans returning from Iraq and Afghanistan.[25] As of 2013 13% of veterans returning from Iraq were unemployed.[174]

# Veterans

## United States

*Further information: Benefits for US Veterans with PTSD*

## United Kingdom

In the UK, there are various charities and service organisations dedicated to aiding veterans in readjusting to civilian life. The Royal British Legion and the more recently established Help for Heroes are two of Britain's more high-profile veterans' organisations which have actively advocated for veterans over the years. There has been some controversy that the NHS has not done enough in tackling mental health issues and is instead "dumping" veterans on charities such as Combat Stress.[175][176]

## Canada

Veterans Affairs Canada offers a new program that includes rehabilitation, financial benefits, job placement, health benefits program, disability awards, peer support[177][178][179] and family support.[180]

Vietnam Veterans Memorial, Washington, D.C.

# History

The 1952 edition of the DSM-I includes a diagnosis of "gross stress reaction", which has similarities to the modern definition and understanding of PTSD.[181] Gross stress reaction is defined as a "normal personality [utilizing] established patterns of reaction to deal with overwhelming fear" as a response to "conditions of great stress".[182] The diagnosis includes language which relates the condition to combat as well as to "civilian catastrophe".[182]

Early in 1978, the term was used in a working group finding presented to the Committee of Reactive Disorders.[183] The condition was added to the DSM-III, which was being developed in the 1980s, as posttraumatic stress disorder.[181][183] In the DSM-IV, the spelling "posttraumatic stress disorder" is used, while in the ICD-10, the spelling is "post-traumatic stress disorder".[184]

The addition of the term to the DSM-III was greatly influenced by the experiences and conditions of US military veterans of the Vietnam War.[185] Due to its association with the war in Vietnam, PTSD has become synonymous with many historical war-time diagnoses such as railway spine, stress syndrome, nostalgia, soldier's heart, shell shock, battle fatigue, combat stress reaction, or traumatic war neurosis.[186][187] Some of these terms date back to the 19th century, which is indicative of the universal nature of the condition. In a similar vein, psychiatrist Jonathan Shay has proposed that Lady Percy's soliloquy in the William Shakespeare play *Henry IV, Part 1* (act 2, scene 3, lines 40–62[188]), written around 1597, represents an

unusually accurate description of the symptom constellation of PTSD.[189]

Statue, *Three Servicemen*, Vietnam Veterans Memorial

The correlations between combat and PTSD are undeniable; according to Stéphane Audoin-Rouzeau and Annette Becker, "One-tenth of mobilized American men were hospitalized for mental disturbances between 1942 and 1945, and, after thirty-five days of uninterrupted combat, 98% of them manifested psychiatric disturbances in varying degrees."[190] In fact, much of the available published research regarding PTSD is based on studies done on veterans of the war in Vietnam. A study based on personal letters from soldiers of the 18th-century Prussian Army concludes that combatants may have had PTSD.[191]

The researchers from the Grady Trauma Project highlight the tendency people have to focus on the combat side of PTSD: "less public awareness has focused on civilian PTSD, which results from trauma exposure that is not combat related... " and "much of the research on civilian PTSD has focused on the sequelae of a single, disastrous event, such as the Oklahoma City bombing, September 11th attacks, and Hurricane Katrina".[192] Disparity in the focus of PTSD research affects the already popular perception of the exclusive interconnectedness of combat and PTSD. This is misleading when it comes to understanding the implications and extent of PTSD as a neurological disorder. Dating back to the definition of Gross stress reaction in the DSM-I, civilian experience of catastrophic or high stress events is included as a cause of PTSD in medical literature. The 2014 National Comorbidity Survey reports that "the traumas most commonly associated with PTSD are combat exposure and witnessing among men and rape and sexual molestation among women."[193] Because of the initial overt focus on PTSD as a combat related disorder when it was first fleshed out in the years following the war in Vietnam, in 1975 Ann Wolbert Burgess and Lynda Lytle Holmstrom defined Rape trauma syndrome, RTS, in order to draw attention to the striking similarities between the experiences of soldiers returning from war and of rape victims.[194] This paved the way for a more comprehensive understanding of causes of PTSD.

The DSM-IV classified PTSD under anxiety disorders, but the DSM-5 created a new category called "Trauma- and Stressor-Related Disorders," in which PTSD is now classified.[1]

## Terminology

The Diagnostic and Statistical Manual of Mental Disorders does not hyphenate 'post' and 'traumatic', thus, the DSM-5 lists the disorder as *posttraumatic stress disorder*. However, many scientific journal articles and other scholarly publications do hyphenate the name of the disorder, *viz.*, post-traumatic stress disorder.[195] Dictionaries also differ with regard to the preferred spelling of the disorder with the *Collins English Dictionary - Complete and Unabridged* using the hyphenated spelling, and the *American Heritage Dictionary of the English Language, Fifth Edition* and the *Random House Kernerman Webster's College Dictionary* giving the non-hyphenated spelling.[196]

## Research

Most knowledge regarding PTSD comes from studies in high-income countries.[197]

To recapitulate some of the neurological and neurobehavioral symptoms experienced by the veteran population of recent conflicts in Iraq and Afghanistan, researchers at the Roskamp Institute and the James A Haley Veteran's Hospital (Tampa) have developed an animal model to study the consequences of mild traumatic brain injury (mTBI) and PTSD.[198] In the laboratory, the researchers exposed mice to a repeated session of unpredictable stressor (i.e. predator odor while restrained), and physical trauma in the form of inescapable foot-shock, and this was also combined with a mTBI. In this study, PTSD animals demonstrated recall of traumatic memories, anxiety, and an impaired social behavior, while animals subject to both mTBI

and PTSD had a pattern of disinhibitory-like behavior. mTBI abrogated both contextual fear and impairments in social behavior seen in PTSD animals. In comparison with other animal studies,[198][199] examination of neuroendocrine and neuroimmune responses in plasma revealed a trend toward increase in corticosterone in PTSD and combination groups.

### Psychotherapy adjuncts

MDMA was used for psychedelic therapy for a variety of indications before its criminalization in the US in 1985. In response to its criminalization, the Multidisciplinary Association for Psychedelic Studies was founded as a nonprofit drug-development organization to develop MDMA into a legal prescription drug for use as an adjunct in psychotherapy.[200] The drug is hypothesized to facilitate psychotherapy by reducing fear, thereby allowing patients to reprocess and accept their traumatic memories without becoming emotionally overwhelmed. In this treatment, patients participate in an extended psychotherapy session during the acute activity of the drug, and then spend the night at the treatment facility. In the sessions with the drug, therapists are not directive and support the patients in exploring their inner experiences. Patients participate in standard psychotherapy sessions before the drug-assisted sessions, as well as after the drug-assisted psychotherapy to help them integrate their experiences with the drug.[201] Preliminary results suggest MDMA-assisted psychotherapy might be effective for individuals who have not responded favorably to other treatments. Future research employing larger sample sizes and an appropriate placebo condition, i.e., one in which subjects cannot discern if they are in the experimental or control condition, will increase confidence in the results of initial research.[202][203]

Clinical research is also investigating using D-cycloserine, hydrocortisone, and propranolol as adjuncts to more conventional exposure therapy.[203]

# Schizophrenia

From Wikipedia, the free encyclopedia

*For other uses, see Schizophrenia (disambiguation).*

**Schizophrenia** is a mental disorder characterized by abnormal social behavior and failure to understand what is real.[2] Common symptoms include false beliefs, unclear or confused thinking, hearing voices that others do not, reduced social engagement and emotional expression, and a lack of motivation.[2][3] People with schizophrenia often have additional mental health problems such as anxiety disorders, major depressive illness, or substance use disorders.[4] Symptoms typically come on gradually, begin in young adulthood, and last a long time.[3][5]

The causes of schizophrenia include environmental and genetic factors.[6] Possible environmental factors include being raised in a city, cannabis use, certain infections, parental age, and poor nutrition during pregnancy.[6][7] Genetic factors include a variety of common and rare genetic variants.[8] Diagnosis is based on observed behavior, the person's reported experiences, and reports of others familiar with the person.[5] During diagnosis a person's culture must also be taken into account.[5] As of 2013 there is no objective test.[5] Schizophrenia does not imply a "split personality" or "multiple personality disorder" — conditions with which it is often confused in public perception.[9]

The mainstay of treatment is antipsychotic medication, along with counselling, job training, and social rehabilitation.[2][6] It is unclear whether typical or atypical antipsychotics are better.[10] In those who do not improve with other antipsychotics clozapine may be tried.[6] In more serious situations—where there is risk to self or others—involuntary hospitalization may be necessary, although hospital stays are now shorter and less frequent than they once

[edit on Wikidata]

About 0.3–0.7% of people are affected by schizophrenia during their lifetimes.[12] In 2013 there were estimated to be 23.6 million cases globally.[13] Males are more often affected than females.[2] About 20% of people do well, and a few recover completely.[5] Social problems, such as long-term unemployment, poverty, and homelessness are common.[5][14] The average life expectancy of people with the disorder is ten to twenty-five years less than for the general population.[15] This is the result of increased physical health problems and a higher suicide rate (about 5%).[12][16] In 2013 an estimated 16,000 people worldwide died from behavior related to, or caused by, schizophrenia.[17]

# Symptoms

*See also: Basic symptoms of schizophrenia*

Individuals with schizophrenia may experience hallucinations (most reported are hearing voices), delusions (often bizarre or persecutory in nature), and disorganized thinking and speech. The last may range from loss of train of thought, to sentences only loosely connected in meaning, to speech that is not understandable known as word salad. Social withdrawal, sloppiness of dress and hygiene, and loss of motivation and judgment are all common in schizophrenia.[18] Distortions of self-experience such as feeling as if one's thoughts or feelings are not really one's own to believing thoughts are being inserted into one's mind, sometimes termed passivity phenomena, are also common.[19] There is often an observable pattern of emotional difficulty, for example lack of [20]

*My Eyes at the Moment of the Apparitions* by German artist

responsiveness. Impairment in social cognition is associated with schizophrenia,[21] as are symptoms of paranoia. Social isolation commonly occurs.[22] Difficulties in working and long-term memory, attention, executive functioning, and speed of processing also commonly occur.[12] In one uncommon subtype, the person may be largely mute, remain motionless in bizarre postures, or exhibit purposeless agitation, all signs of catatonia.[23] About 30 to 50 percent of people with schizophrenia fail to accept that they have an illness or comply with their recommended treatment.[24] Treatment may have some effect on insight.[25] People with schizophrenia often find facial emotion perception to be difficult.[26]

People with schizophrenia may have a high rate of irritable bowel syndrome but they often do not mention it unless specifically asked.[27]

## Positive and negative

Schizophrenia is often described in terms of positive and negative (or deficit) symptoms.[28] *Positive symptoms* are those that most individuals do not normally experience, but are present in people with schizophrenia. They can include delusions, disordered thoughts and speech, and tactile, auditory, visual, olfactory and gustatory hallucinations, typically regarded as manifestations of psychosis.[29] Hallucinations are also typically related to the content of the delusional theme.[30] Positive symptoms generally respond well to medication.[30]

*Negative symptoms* are deficits of normal emotional responses or of other thought processes, and are less responsive to medication.[18] They commonly include flat expressions or little emotion, poverty of speech, inability to experience pleasure, lack of desire to form relationships, and lack of motivation. Negative symptoms appear to contribute more to poor quality of life, functional ability, and the burden on others than positive symptoms do.[31] People with greater negative symptoms often have a history of poor adjustment before the onset of illness, and response to medication is often limited.[18][32]

## Cognitive dysfunction

Deficits in cognitive abilities are widely recognized as a core feature of schizophrenia.[33][34][35] The extent of the cognitive deficits an individual experiences is a predictor of how functional an individual will be, the quality of occupational performance, and how successful the individual will be in maintaining treatment.[36] The presence and degree of cognitive dysfunction in individuals with schizophrenia has been reported to be a better indicator of functionality than the presentation of positive or negative symptoms.[33] The deficits impacting the cognitive function are found in a large number of areas: working memory, long-term memory,[37][38] verbal declarative memory,[39] semantic processing,[40] episodic memory,[36] attention, learning (particularly verbal learning).[37] Deficits in verbal memory are the most pronounced in individuals with schizophrenia, and are not accounted for by deficit in attention. Verbal memory impairment has been linked to a decreased ability in individuals with schizophrenia to semantically encode (process information relating to meaning), which is cited as a cause for another known deficit in long-term memory.[37] When given a list of words, healthy individuals remember positive words more frequently (known as the Pollyanna principle); however, individuals with schizophrenia tend to remember all words equally regardless of their connotations, suggesting that the experience of anhedonia impairs the semantic encoding of the words.[37] These deficits have been found in individuals before the onset of the illness to some extent.[33][35][41] First-degree family members of individuals with schizophrenia and other high-risk individuals also show a degree of deficit in cognitive abilities, and specifically in working memory.[41] A review of the literature on cognitive deficits in individuals with schizophrenia shows that the deficits may be present in early adolescence, or as early as childhood.[33] The deficits which an individual with schizophrenia presents tend to remain the same over time in most patients, or follow an identifiable course based upon environmental variables.[33][37]

Although the evidence that cognitive deficits remain stable over time is reliable and abundant,[36][37] much of the research in this domain focuses on methods to improve attention and working memory.[37][38] Efforts to improve learning ability in individuals with schizophrenia using a high- versus low-reward condition and an instruction-absent or instruction-present condition revealed that increasing reward leads to poorer performance while providing instruction leads to improved performance, highlighting that some treatments may exist to increase cognitive performance.[37] Training individuals with schizophrenia to alter their thinking, attention, and language behaviors by verbalizing tasks, engaging in cognitive rehearsal, giving self-instructions, giving coping statements to the self to handle failure, and providing self-reinforcement for success, significantly improves performance on recall tasks.[37] This type of training, known as self-instructional (SI) training, produced benefits such as lower number of nonsense verbalizations and improved recall while distracted.[37]

### Onset

*See also: Schizophrenia in children*

Late adolescence and early adulthood are peak periods for the onset of schizophrenia,[12] critical years in a young adult's social and vocational development.[42] In 40% of men and 23% of women diagnosed with schizophrenia, the condition manifested itself before the age of 19.[43] To minimize the developmental disruption associated with schizophrenia, much work has recently been done to identify and treat the prodromal (pre-onset) phase of the illness, which has been detected up to 30 months before the onset of symptoms.[42] Those who go on to develop schizophrenia may experience transient or self-limiting psychotic symptoms[44] and the non-specific symptoms of social withdrawal, irritability, dysphoria,[45] and clumsiness[46] during the prodromal phase.

## Causes

*Main article: Causes of schizophrenia*

A combination of genetic and environmental factors play a role in the development of schizophrenia.[9][12] People with a family history of schizophrenia who have a transient psychosis have a 20–40% chance of being diagnosed one year later.[47]

### Genetic

Estimates of heritability vary because of the difficulty in separating genetic and environmental influences;[48] averages of 0.80 have been given.[49] The greatest single risk factor for developing schizophrenia is having a first-degree relative with the disease (risk is 6.5%); more than 40% of monozygotic twins of those with schizophrenia are also affected.[9] If one parent is affected the risk is about 13% and if both are affected the risk is nearly 50%.[49]

Many genes are believed to be involved in schizophrenia, each of small effect and unknown transmission and expression.[8][9] Many possible candidates have been proposed, including specific copy number variations, *NOTCH4*, and histone protein loci.[50] A number of genome-wide associations such as zinc finger protein 804A have also been linked.[51] There appears to be overlap in the genetics of schizophrenia and bipolar disorder.[52] Evidence is emerging that the genetic architecture of schizophrenia involved both common and rare risk variation.[53]

Assuming a hereditary basis, one question from evolutionary psychology is why genes that *increase* the likelihood of psychosis evolved, assuming the condition would have been maladaptive from an evolutionary point of view. One idea is that genes are involved in the evolution of language and human nature, but to date such ideas remain little more than hypothetical in nature.[54][55]

### Environment

Environmental factors associated with the development of schizophrenia include the living environment, drug use, and prenatal stressors.[12]

Parenting style seems to have no major effect, although people with supportive parents do better than those with critical or hostile parents.[9] Childhood trauma, death of a parent, and being bullied or abused increase the risk of psychosis.[56] Living in an urban environment during childhood or as an adult has consistently been found to increase the risk of schizophrenia by a factor of two,[9][12] even after taking into account drug use, ethnic group, and size of social group.[57] Other factors that play an important role include social isolation and immigration related to social adversity, racial discrimination, family dysfunction, unemployment, and poor housing conditions.[9][58]

It has been hypothesized that in some people, development of schizophrenia is related to intestinal tract dysfunction such as seen with non-celiac gluten sensitivity or abnormalities in the intestinal flora.[59] A subgroup of persons with schizophrenia present an immune response to gluten different from that found in people with celiac, with elevated levels of certain serum biomarkers of gluten sensitivity such as anti-gliadin IgG or anti-gliadin IgA antibodies.[60]

### Substance use

About half of those with schizophrenia use drugs or alcohol excessively.[61] Amphetamine, cocaine, and to a lesser extent alcohol, can result in a transient stimulant psychosis or alcohol-related psychosis that presents very similarly to schizophrenia.[9][62] Although it is not generally believed to be a cause of the illness, people with schizophrenia use nicotine at much higher rates than the general population.[63]

Alcohol abuse can occasionally cause the development of a chronic, substance-induced psychotic disorder via a kindling mechanism.[64] Alcohol use is not associated with an earlier onset of psychosis.[65]

Cannabis can be a contributory factor in schizophrenia,[7][66][67] potentially causing the disease in those who are already at risk.[67] The increased risk may require the presence of certain genes within an individual[67] or may be related to preexisting psychopathology.[7] Early exposure is strongly associated with an increased risk.[7] The size of the increased risk is not clear,[68] but appears to be in the range of two to three times greater for psychosis.[66] Higher dosage and greater frequency of use are indicators of increased risk of chronic psychoses.[66]

Other drugs may be used only as coping mechanisms by individuals who have schizophrenia, to deal with depression, anxiety, boredom, and loneliness.[61][69]

### Developmental factors

Factors such as hypoxia and infection, or stress and malnutrition in the mother during fetal development, may result in a slight increase in the risk of schizophrenia later in life.[12] People diagnosed with schizophrenia are more likely to have been born in winter or spring (at least in the northern hemisphere), which may be a result of increased rates of viral exposures in utero.[9] The increased risk is about five to eight percent.[70] Other infections during pregnancy or around the time of birth that may increase the risk include *Toxoplasma gondi* and *Chlamydia*.[71]

## Mechanisms

*Main article: Mechanisms of schizophrenia*

A number of attempts have been made to explain the link between altered brain function and schizophrenia.[12] One of the most common is the dopamine hypothesis, which attributes psychosis to the mind's faulty interpretation of the misfiring of dopaminergic neurons.[12]

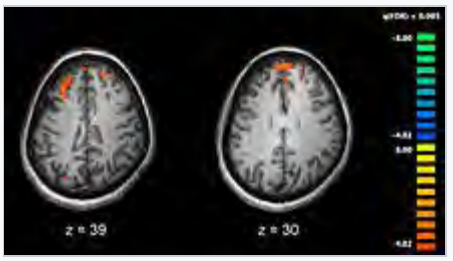
## Psychological

Many psychological mechanisms have been implicated in the development and maintenance of schizophrenia. Cognitive biases have been identified in those with the diagnosis or those at risk, especially when under stress or in confusing situations.[72] Some cognitive features may reflect global neurocognitive deficits such as memory loss, while others may be related to particular issues and experiences.[73][74]

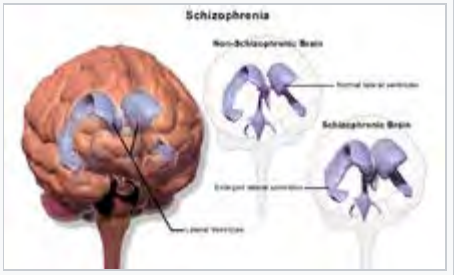
Despite a demonstrated appearance of blunted affect, recent findings indicate that many individuals diagnosed with schizophrenia are emotionally responsive, particularly to stressful or negative stimuli, and that such sensitivity may cause vulnerability to symptoms or to the disorder.[75][76] Some evidence suggests that the content of delusional beliefs and psychotic experiences can reflect emotional causes of the disorder, and that how a person interprets such experiences can influence symptomatology.[77][78][79] The use of "safety behaviors" (acts such as gestures or the use of words in specific contexts) to avoid or neutralize imagined threats may actually contribute to the chronicity of delusions.[80] Further evidence for the role of psychological mechanisms comes from the effects of psychotherapies on symptoms of schizophrenia.[81]

## Neurological

Schizophrenia is associated with subtle differences in brain structures, found in forty to fifty percent of cases, and in brain chemistry during acute psychotic states.[12] Studies using neuropsychological tests and brain imaging technologies such as fMRI and PET to examine functional differences in brain activity have shown that differences seem to occur most commonly in the frontal lobes, hippocampus and temporal lobes.[83] Reductions in brain volume, smaller than those found in Alzheimer's disease, have been reported in areas of the frontal cortex and temporal lobes. It is uncertain whether these volumetric changes are progressive or exist prior to the onset of the disease.[46] These differences have been linked to the neurocognitive deficits often associated with schizophrenia.[84] Because neural circuits are altered, it has alternatively been suggested that schizophrenia should be thought of as a collection of neurodevelopmental disorders.[85] There has been debate on whether treatment with antipsychotics can itself cause reduction of brain volume.[86]



Functional magnetic resonance imaging (fMRI) showing two levels of the brain; areas in orange were more active in healthy controls than in medicated people with schizophrenia.



People with schizophrenia who are medication compliant have an association with enlarged lateral ventricles in the brain.[82]

Particular attention has been paid to the function of dopamine in the mesolimbic pathway of the brain. This focus largely resulted from the accidental finding that phenothiazine drugs, which block dopamine function, could reduce psychotic symptoms. It is also supported by the fact that amphetamines, which trigger the release of dopamine, may exacerbate the psychotic symptoms in schizophrenia.[87] The influential dopamine hypothesis of schizophrenia proposed that excessive activation of $D_2$ receptors was the cause of (the positive symptoms of) schizophrenia. Although postulated for about 20 years based on the $D_2$ blockade effect common to all antipsychotics, it was not until the mid-1990s that PET and SPET imaging studies provided supporting evidence. The dopamine hypothesis is now thought to be simplistic, partly because newer antipsychotic medication (atypical antipsychotic medication) can be just as effective as older medication (typical antipsychotic medication), but also affects serotonin function and may have slightly less of a dopamine blocking effect.[88]

Interest has also focused on the neurotransmitter glutamate and the reduced function of the NMDA glutamate receptor in schizophrenia, largely because of the abnormally low levels of glutamate receptors [89]

found in the postmortem brains of those diagnosed with schizophrenia, and the discovery that glutamate-blocking drugs such as phencyclidine and ketamine can mimic the symptoms and cognitive problems associated with the condition.[90] Reduced glutamate function is linked to poor performance on tests requiring frontal lobe and hippocampal function, and glutamate can affect dopamine function, both of which have been implicated in schizophrenia; this has suggested an important mediating (and possibly causal) role of glutamate pathways in the condition.[91] But positive symptoms fail to respond to glutamatergic medication.[92]

# Diagnosis

*Main article: Diagnosis of schizophrenia*

Schizophrenia is diagnosed based on criteria in either the American Psychiatric Association's fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM 5), or the World Health Organization's International Statistical Classification of Diseases and Related Health Problems (ICD-10). These criteria use the self-reported experiences of the person and reported abnormalities in behavior, followed by a clinical assessment by a mental health professional. Symptoms associated with schizophrenia occur along a continuum in the population and must reach a certain severity before a diagnosis is made.[9] As of 2013 there is no objective test.[5]

## Criteria

In 2013, the American Psychiatric Association released the fifth edition of the DSM (DSM-5). To be diagnosed with schizophrenia, two diagnostic criteria have to be met over much of the time of a period of at least one month, with a significant impact on social or occupational functioning for at least six months. The person had to be suffering from delusions, hallucinations, or disorganized speech. A second symptom could be negative symptoms, or severely disorganized or catatonic behaviour.[93] The definition of schizophrenia remained essentially the same as that specified by the 2000 version of DSM (DSM-IV-TR), but DSM-5 makes a number of changes.

- Subtype classifications – such as catatonic and paranoid schizophrenia – are removed. These were retained in previous revisions largely for reasons of tradition, but had subsequently proved to be of little worth.[94]
- Catatonia is no longer so strongly associated with schizophrenia.[95]
- In describing a person's schizophrenia, it is recommended that a better distinction be made between the current state of the condition and its historical progress, to achieve a clearer overall characterization.[94]
- Special treatment of Schneider's first-rank symptoms is no longer recommended.[94]
- Schizoaffective disorder is better defined to demarcate it more cleanly from schizophrenia.[94]
- An assessment covering eight domains of psychopathology – such as whether hallucination or mania is experienced – is recommended to help clinical decision-making.[96]

The ICD-10 criteria are typically used in European countries, while the DSM criteria are used in the United States and to varying degrees around the world, and are prevailing in research studies. The ICD-10 criteria put more emphasis on Schneiderian first-rank symptoms. In practice, agreement between the two systems is high.[97] The current proposal for the ICD-11 criteria for schizophrenia recommends adding self-disorder as a symptom.[19]
